The viscous behavior of soft material in the microsecond range is illustrated by the magnetization processes in amorphous material under a constant magnetization voltage ($dB/dt = \text{const}$) [3]. Dynamic magnetization curves measured on metallic glass ribbon are shown by the solid lines in Fig. 1. They correspond to a B swing from negative remanence to positive saturation.

As can be seen in Fig. 1, the higher the dB/dt the greater is the shift of the dynamic curve to the right. It was found expedient to reproduce experimental curves in Fig. 1 by means of the Thin Sheet Model (TSM) [4].

It is remarkable that the excess field term in the TSM is valid for a wide majority of soft materials and is also observed at much lower dB/dt than those shown in Fig. 1. An example is grain-oriented (GO) electrical steel, for which the TSM works quite accurately even at lowest measurable frequencies.

The calculated loops in Fig. 2(a) have been obtained through the TSM whose parameters have been chosen so as to reach the best coincidence of the calculated and modeled loops under sinusoidal induction ($f=100$ Hz, $B_m=1.7$ T). The same excellent coincidence of the TSM-modeled and experimental dynamic loops has been obtained for thin non-oriented steels [4] and in our preliminary studies of the soft magnetic powder composites [5].

The transients calculated using the TSM for sinusoidal field with amplitude close to the coercive force of the GO steel above are shown by dashed lines in Fig. 2(b). Similar to that found from the measured loops, a decrease of the calculated total loss with increasing magnetizing frequency is observed in the current-driven regime with a fixed peak magnetic field (it can be seen in Fig. 2(b) that the area of the loop at 500 Hz is substantially less than that at 5 Hz). This is explained by the fact that at shorter period, the induction has no time to rise due to the eddy currents and magnetic

viscosity. This leads to decreasing hysteresis loss which is the prevailing loss factor in the regime considered.

Among other problems, the TSM technique allows one to reproduce the constant field regime commonly used in studying magnetic viscosity. In the full paper we compare their representation by the TSM and by the well-known exponential and logarithmic laws [2]. In contrast to the vague frequency properties of the equations in [2], the viscous-type TSM is characterized by definite frequency dependence of the energy loss per cycle that makes it suitable for many technological applications.

Size effects influence on hysteresis and relaxation for a Random Anisotropy Ising System.

C. Enachescu, A. Stancu

Department of Physics, Alexandru Ioan Cuza University, Iasi, Romania

The problem of the correlation between the particle size and the kinetic behavior in magnetic media is of increasing importance due to the technological use of nanoparticulate media in various applications [1]. Ising type models proved to be an efficient tool to describe the effect of surface magnetic moments and the rate dependent properties of these systems. They have been used previously mainly to characterize thermal effects [2] and recently to calculate First-order reversal curves (FORC) distributions for nanoparticulate media [3]. In this paper we propose to analyze the size influence on the hysteresis properties, relaxation curves and other kinetic effects using a Random Anisotropy Ising Model (RAIM).

We consider that in the RAIM every molecule has a spin $s=\pm 1$ and an anisotropy field H_k , Gaussian distributed. The energy barriers have the expressions

$$E_b = \mu H_k / 2(1 \pm H/H_k)^2 \text{ for } s=\pm 1 \text{ and } H > /< \pm H_k. \text{ Otherwise they are 0.}$$

We refer here to spherical shape systems, with diameter varying from 7 molecules (total 123 molecules, 73.1% on surface) to 31 molecules (total 14127 molecules, 15.9% on surface). The anisotropy field is oriented on the z axis direction. To compute local interaction field for a molecule, we consider its interactions with all the other molecules in the system. The interactions are positive and decrease proportionally with the cube of the distance between molecules. At every step, we compute the energy barriers and then decide, using Monte Carlo Metropolis method, if the moment will commute.

Our investigation has been carried on two directions: first we computed hysteresis cycles for different systems and field scanning rates and secondly we calculated relaxation curves at different fields and for different system sizes.

The results presented in figs. 1-2 show that: (i) clusters of positive and negative magnetized molecules are formed; they are dependent on interaction strength (ii) the coercivity diminishes for a decreasing size of the system and for longer waiting times. A stabilization is observed for a sphere diameter of 31 molecules, that correspond to a percentage of 15,9% molecules on surface, close to the observed ones [1].

In fig. 3 up we present relaxation curves for different particle sizes, in constant external field. We noticed that, for increasing sphere diameter, the relaxation time is increasing. More, even if the hysteresis cycles for spheres with diameter of 27 and 31 molecules are quite similar, the relaxation time for the second system is about 3 times higher. In fig. 3 down, we represent on a logarithmic scale the relaxation time (the moment when the system passes through 0 is considered) in function of the system size for different external fields. One may notice that, for small sphere size, there is almost an exponential dependence between diameter and relaxation times, but as the system size grows the relaxation time increases dramatically.

In conclusion we notice that the RAIM model proved to be tractable to describe the behavior of isolated single-particle and can provide useful information. In the full paper we also discuss the correlations evolution during magnetization process and the influence of the system compactness on hysteresis and relaxation.

Correction of permeability of a soft ferromagnet measured by using vibrating sample magnetometer.

M. Chan, C. Ong, Y. Wong

Department of Applied Physics and Materials Research Center, The Hong Kong Polytechnic University, Hong Kong, China

Vibrating sample magnetometer (VSM) is a high-sensitivity system for probing the magnetic properties of a small specimen. The magnetic induction B_{int} and magnetic field H_{int} inside a specimen in an applied magnetic field H_{app} are related with:

$$B_{\text{int}} = \mu_0 \mu_r H_{\text{int}} = \mu_0 (H_{\text{int}} + M) \quad (1)$$

where μ_r , μ_0 and M are the relative permeability, permeability of vacuum and magnetization. Determination of μ_r is particularly important for practical use. B_{int} and H_{app} are detected with a pick-up coil and a sensor outside the specimen, but H_{int} is not directly measurable. For a magnetic sample, a demagnetization field $H_d = DM$ exists inside the specimen with D being the demagnetization factor. H_d weakens the magnetic field inside the specimen to $H_{\text{app}} - DM$. An apparent relationship defining the measured permeability μ_m is expressed as:

$$B_{\text{int}} = \mu_0 \mu_m H_{\text{app}} \quad (2)$$

Combining (1) and (2), one obtains [1]:

$$\mu_m / \mu_r = 1/(1+D\mu_r) \quad (3)$$

When $\mu_r \gg 1$ and D has a moderate value, the measured μ_m value is much smaller than the true value μ_r . One method to make correction is to calculate D values for various sample shapes, and the apply Eq. (3) to calculate μ_r from the measured μ_m [2]. However, this method may generate great error. Hence, we propose the following method, with the aid of finite element analysis (FEA), to give an estimate of μ_r based on VSM measurements. The method is applied to permalloy to check the validity.

1. A commercial FEA package is used to set up a model (Fig. 1) containing a block-shaped specimen in a magnetic field. The width x and thickness y of the block are equal and perpendicular to the applied field. Its length z is parallel to the field.

2. μ_r is set at $\mu_{r,1}=10$, $\mu_{r,2}=500$ and $\mu_{r,3}=3000$ respectively. For each $\mu_{r,i}$ ($i=1, 2, 3$), the ratio z/x is varied over a range from 1 to 1000 (labeled by an index j). For each combination, a magnetic field H_{app} is applied (outside the specimen) to build up a magnetic induction field inside the specimen. The average magnitude of the induction field $\langle B_{\text{int}} \rangle_{i,j}$ is derived. A representative permeability, denoted as $\mu_{m,i,j}^*$, is defined with the formula:

$$\langle B_{\text{int}} \rangle_{i,j} = \mu_0 \mu_{m,i,j}^* H_{\text{app}} \quad (4)$$

3. For each of the three $\mu_{r,i}$ ($i=1, 2, 3$), the calculated values $\mu_{m,i,j}^*$ are plotted in Fig. 2 against z/x , and are fitted to a function $\mu_{m,i,j}^* = A_{2,i} + (A_{1,i} - A_{2,i}) / (1 + ((z/x)/r_{0,i})^P)$. The fitting parameters for each $\mu_{r,i}$ ($i=1, 2, 3$) are shown in Table 1.

4. VSM measurements are performed to get $B_{\text{int}} - H_{\text{app}}$ loops for several block-shaped samples specified with various z/x ratios between 1 and 1000 (labeled by k). For each sample, the slope of the curve at $B_{\text{int}} \approx 0$ is derived and plotted in Fig. 2, which gives an experimental permeability $\mu_{\text{exp},k}^*$. The best fit to the data of $\mu_{\text{exp},k}^*$ is obtained with a set of fitting parameters A_1^* , A_2^* , r_0^* and P^* . Each parameter is combined with those of the same kind listed in Table 1 to create an estimate of μ_r by applying interpolation technique, which is denoted as $\mu_{r,q}^*$ ($q=1, \dots, 4$). A final estimated value of μ_r is set as $\langle \mu_r^* \rangle = \sum_{q=1}^4 \mu_{r,q}^* / 4$.

The applicability of the method to permalloy is checked and discussed. The method is further extended to cover the other sample shapes, such as hollow cylinder.

The temperature dependence of magnetostatic interactions in nanowires systems.

A. Diaconu, I. Dumitru, A. Stancu

Department of Solid State and Theoretical Physics, "Alexandru Ioan Cuza" University, Iasi, Romania

Magnetic nanowires have potential applications in many areas of advanced nanotechnology, including patterned magnetic media, nanosensors magnetic devices and materials for microwave applications [1]. Using the electrodeposition technique the Fe, Co and Ni wires with diameters ranging from 4 to 200 nm, and lengths of up to few microns can be produced easily.

Starting from the magnetic properties of the individual wires, the paper evaluates the temperature effects on the magnetostatic interaction field between wires and on the magnetic properties of wires ensemble. The systems used in our simulations are Co nanowires arrays with different geometries: square and hexagonal lattice.

The hysteresis loop of the nanowires system was calculated using an Ising type model, in which the wires magnetization vector has two preferred directions along nanowires axis. The nanowires, considered as single domain, exhibit a magnetic anisotropy with an easy magnetization along the axis of the wire. The values of the uniaxial anisotropy field are normally distributed. Each wire is divided into a number of magnetic dipoles which have the magnetizations parallel with the wires magnetization direction. The magnetostatic interactions are calculated along the symmetry axis of each wire as a sum of the fields created by all the magnetic dipoles. The value interaction field depends on the wire magnetizations and, consequently, on the magnetization of the system. The demagnetizing field along wires axis, for different wires length and diameters, was evaluated using a procedure based on the equivalent magnetic charges on the wires ends [2]. A standard Metropolis-Monte-Carlo numerical procedure was used to evaluate which wire is reversing the magnetic moment.

Each nanowire the 2D array has a normalized magnetic moment which can take the values as function of moment orientation: up (+1) or down (-1). Considering the nanowire arrays as an assemble of uniaxial single domain particles and the angle between this direction and applied field is zero, the height of the energy barriers corresponding to the magnetic moment vector rotation from in to out of the static field direction is given by the classical Stoner-Wohlfarth expression: $\Delta E_{\pm} = KV/k_B T [1 \pm H/H_k]^2$ where H_k is the uniaxial anisotropy field, K is the anisotropy constant, V is the wire volume and H is the effective field acting on a wire, k_B is the Boltzmann constant and T is the system temperature. The magnetic dipole switches from up to down state with the probability given by $p = \exp[-\Delta E_{\pm}/k_B T]$, where ΔE_{\pm} are the heights of the energy barriers defined before. The net magnetization of the system is the sum of the magnetization of constituent wires.

In simulation we considered a sufficient number of wires for a given wire network in order as the magnetic interaction field to be independent of the number of wires.

It was drawn the hysteresis loops for a set of geometric parameters: diameter and length of wires and lattice constant for two temperatures 5K and 200K (Fig.1). As it is expected, the interactions have an essential role in defining the shape of the hysteresis loop of the nanowire system.

The magnetostatic interactions between wires as function of the array lattice constant were analyzed using the FORC (First Order Reversal Curve) diagram [3,4]. For each considered case the determined FORC diagrams (ex: Fig 2) are function of the geometric wires parameters like wires diameters and lengths was drawn. The distribution of the interaction field was also determined as function of temperature and geometric parameters.

A magnetostriction model with stress dependence for real-time control applications.

D. Davino¹, A. Giustiniani², C. Visone¹

1. Engineering Department, University of Sannio, Benevento, Italy; 2. DIIE, University of Salerno, Salerno, Italy

This paper proposes a magnetostriction model with a dependence on the applied stress, aimed to real-time control system applications.

Devices employing magnetostrictive materials suffer an hysteretic behavior, as all ferromagnetic materials based devices do [1]. As a consequence, one should expect a decrease of the control system performances when making use of them. With the aim to overcome such a drawback, several solutions have been proposed to compensate hysteresis in a feedback control system, [2],[3]. Unfortunately, the magnetostrictive behavior depends on the stress experienced by the active material [1]. In real *dynamic* conditions the device could experience time-varying forces that can significantly change the actuator behavior. Therefore, the models would require a generalization to take into account the effects of variable stress. In past years, some papers have been proposed to model magnetic and magnetostrictive materials under variable stress [4, 5], but they hardly arrived at an easy identification procedure and implementation of the algorithm.

In this paper we propose a phenomenological magnetostrictive model defined by the following:

$$s(t) = G\{f[i(t), T(t)-T_0]\},$$

where $s(t)$ is the displacement, $G\{\cdot\}$ is a classical Preisach Model [1], $i(t)$ is the input current and $T(t)$ is the applied load. The function f defines an *effective current* for the operator $G\{\cdot\}$ [6] while T_0 represents a compressive prestress applied to the active material that can be used as *working point* for the effective current.

Concerning the application of the model, the operator $G\{\cdot\}$ and its inverse $G^{-1}\{\cdot\}$ (which exists under some hypothesis [7]) can be easily identified by applying the constant prestress T_0 , because the condition $f[i(t), 0] = i(t)$ applies. Then, a standard procedure for the identification of the Preisach model can be used, as the classical one found in [5] or the neuro-fuzzy based one proposed by the authors in [3].

The effective current function is formally defined by the equation $f[i, T-T_0] = G^{-1}\{s\}$ but, since the inverse operator $G^{-1}\{\cdot\}$ depends on the current past history, a working hypothesis must be done: the reconstruction of the function is performed by taking the current values i at constant loads T over an assigned hysteresis branch, as the upper curve of the limit cycle.

This model has been applied to the magnetostrictive measurements of a real actuator loaded by a compression-tests machine. In fig.1 are shown some measured cycles with respect to the positive input current. The operator $G\{\cdot\}$ has been identified at 200N load and then the *effective current* f has been reconstructed at several constant loads, as shown in fig.2.

Finally, fig.3 presents the time signals of the measured displacements at 80 and 140N compared to the direct model $s(t) = G\{f[i(t), T(t)-T_0]\}$ and to a classical Preisach model without stress correction ($s(t) = G\{i(t)\}$). The error reduction is quite evident for a 140N load and is still acceptable when a 80N load is applied.

An Improved Engineering Model of Vector Magnetic Properties of Grain-oriented Electrical Steels.

Y. Zhang¹, Y. Eum², C. Koh², D. Xie¹

1. School of Electrical Engineering, Shenyang University of Technology, Shenyang, Liaoning 110023, China; 2. School of Electrical & Computer Engineering, Chungbuk National University, Cheongju, Chungbuk 361-763, South Korea

Grain-oriented electrical steels are widely used as industrial materials in transformers. It is necessary to develop the effective expression of the vector magnetic properties in order to analyze field performance and loss characteristics of three phase transformers accurately. The objective of this paper is to give an improved expression of the vector magnetic hysteresis model based on Fourier series expansions of measured \mathbf{B} and \mathbf{H} waveforms in the viewpoint of engineering application. The accuracy of the improved model is checked by comparing with experimental data, and the effectiveness of the suggested modeling algorithm, when combined with finite element analysis, is verified with the single-phase transformer core model.

An expression of 2D vector magnetic property of grain-oriented silicon steels proposed in [1] can be defined as follows:

$$H_k = v_{kr} B_k + v_{ki} \partial B_k / \partial \tau \quad (k=x, y) \quad (1)$$

where the magnetic reluctivity coefficients v_{kr} and v_{ki} can be expressed by means of Fourier series expansion of the measured magnetic field intensity waveforms.

In this paper, it is revealed that the hysteresis model considering only the first and third harmonics is not accurate enough to describe the vector magnetic property, especially when the material is highly saturated. On the other hand, with the increasing of the number of harmonic terms under consideration, the expressions of v_{kr} and v_{ki} in (1) become more complicated with the quartic function of $(B_k, \partial B_k / \partial \tau)$, which will result in the divergence of finite element analysis when combined with the vector magnetic property. The accuracy of the model and the computational cost when combined with finite element analysis, therefore, conflict with each other. In this paper, a new expression of v_{kr} and v_{ki} satisfying above two requirements is proposed as follows:

$$v_{kr} = C_{0kr}^{kr} + C_{1kr}^{kr} \cos^2 \tau + C_{2kr}^{kr} \cos^4 \tau + C_{3kr}^{kr} \sin^2 \tau + C_{4kr}^{kr} \sin^4 \tau \quad (2-a)$$

$$v_{ki} = C_{0ki}^{ki} + C_{1ki}^{ki} \cos^2 \tau + C_{2ki}^{ki} \cos^4 \tau + C_{3ki}^{ki} \sin^2 \tau + C_{4ki}^{ki} \sin^4 \tau \quad (k=x, y) \quad (2-b)$$

where τ is in a range from 0 to 2π , and the parameters C can be obtained from the measured H-waveforms under different B-waveform conditions.

The proposed expression of vector magnetic property is verified with experimental data. In this paper, the B-spline interpolation algorithm is utilized to smooth the measured data. Fig.1 shows B-splined surfaces of magnetic reluctivity v_{xr} and v_{yi} , under the sinusoidal magnetic flux density of $B_{max}=0.9T$, as a function of τ and the inclination angle θ of the applied magnetic flux density. Fig.2 shows the comparison of H-waveforms between the results computed from (1) and (2) and measured data. It is shown that the measurement data and computed results are in good agreement.

Finally, the suggested algorithm is applied to the finite element analysis for a single-phase transformer core model, of which the width and height are 400mm and 180mm, respectively, with a rectangular hole of 220mm×40mm. In this paper, the hybrid finite element and material modeling equations are derived in detail and the convergency of the nonlinear analysis is discussed. Fig.3 shows the flux distribution when the average magnetic flux density is $B_{avg}=0.5T$. The calculation results show that, compared with conventional magnetic property modeling algorithm, the suggested algorithm gives more effective and reliable field performance analysis of electromagnetic devices.

Magnetic behaviour of assemblies of nanoparticles with core/shell morphology: Interparticle interaction effects.

M. Vasilakaki¹, K. N. Trohidou¹, J. A. Blackman²

1. Institute of Materials Science, NCSR "Demokritos", Athens, Greece; 2. Department of Physics, Reading University, Reading, United Kingdom

We have studied the hysteresis behaviour of assemblies of composite magnetic nanoparticles with ferromagnetic (FM) core and antiferromagnetic (AFM) shell morphology, using the Monte Carlo simulation technique. The system has been modelled by considering random assemblies and ordered arrays of nanoparticles on a hexagonal lattice. We consider both dipolar and exchange interparticle interactions between the nanoparticles. The core/shell interface leads to an exchange bias effect and the high-density of the assembly produces strong interparticle interactions [1,2]. We have introduced a model that takes into account explicitly the dynamics of the FM/AFM interface region. In this model, each composite nanoparticle consists of four different regions: the FM core, the FM interface, the AFM interface and the shell.

In the present work we study the magnetic behavior of an assembly of composite nanoparticles that results from the interplay between the intrinsic properties (single particle anisotropy and the exchange coupling between the atomic spins of each nanoparticle) and the extrinsic properties (dipolar and the exchange interparticle interactions). Our results demonstrate the dependence of the exchange bias and the coercive field on the dipolar strength ($g = \mu^2/d^3$).

In figure 1 we present results for the coercive (H_c) and exchange bias field (H_E) as a function of interparticle spacing (d_0) for the ordered arrays of nanoparticles with core radius $R_c = 5a$ and shell thickness $t_{sh} = 4a$, both the core and the shell thicknesses are expressed in lattice spacings a . The results are presented for magnetically hard ($\alpha = 6.5$, upper part) and magnetically soft ($\alpha = 1$, lower part) materials, where the dimensionless parameter α is defined as the ratio of the magnetization density squared over the core anisotropy strength, $\alpha = \mu^2/K_c$. In both cases we observe a decrease of the coercive field with increasing the nanoparticle density, which we attribute to the broadening of the energy barrier distribution and the appearance of low-energy barriers in the system. The reduction of H_c is more pronounced in strongly dipolar materials and large nanoparticles. On the other hand the exchange bias shows a weak increase with increasing nanoparticle density. We attribute this behaviour to the distinct role of dipolar interparticle interactions during the magnetization reversal process in the left and right branch of the hysteresis loop, which are characterized by different energy barriers due to the unidirectional interface anisotropy. The same behaviour is also observed in randomly placed assemblies of nanoparticles as it is presented in figure 2, where we have plotted the H_c and H_E as a function of particle density for an assembly of randomly placed nanoparticles of core radius $R_c = 5a$ and shell thickness $t_{sh} = 4a$. The decrease of H_E in this case is in agreement with the behavior observed on Co/Mn samples [3].

Compensation of Hysteresis and Time- dependent Error for Magnetostrictive Actuators.

H. Choi, Y. Park

Mechatronics Engineering, Chungnam National University, Daejeon, South Korea

Smart actuators, such as piezoelectric and magnetostrictive actuators are widely accepted for fine positioning control. They, however, inherently possess hysteresis, which hinders the wide applications of them [1]. In addition, magnetostrictive actuator exhibits hysteretic nonlinearity and time-dependent error. This paper proposes two stage compensation scheme to control the magnetostrictive actuator precisely: First, hysteresis compensation, and second, time-dependent error compensation.

Fig. 1 (a) is hysteresis data according to time. Fig. 1 (b) is an enlarged view of a certain time range. It is clear that the shapes of wave are distorted.

The Preisach model is modified and used to compensate hysteresis [2].

Fig. 2 (a) is hysteresis-compensated data according to time. Fig. 2 (b) is an enlarged view of a certain time range. It is obvious that the shapes of wave are corrected. Nevertheless, the data in Fig. 2 (a) reveals some errors according to time. It is called time-dependent error and needs to be compensated.

Fig. 3 shows the time-dependent error data obtained from Fig. 2 (a). The error can be approximated by using the following equations.

$$E = at + b \quad (t \leq 150)$$

$$E = cxe^{(-t/d)} - k/t \quad (t > 150)$$

Using a regression, the coefficients in the equations can be obtained, i.e., $a=-0.012$, $b=4.5$, $c=5$, $d=500$, $k=150$. Fig 3 (b) is comparisons between error data & approximation data.

Fig. 4 shows simulation result with the compensation of hysteresis and time-dependent error. Maximum error without compensation of time-depnt error equation is $4.5\mu\text{m}$, but Maximum error with combined compensation is $0.4\mu\text{m}$. It can be concluded that compensation of both hysteresis and time-dependent error is needed for precise control of magnetostrictive actuator.

1. Department of Physics, Alexandru Ioan Cuza University, Iasi, Romania; 2. Department of Electrical and Computer Engineering, Florida State University and Florida A&M University, Tallahassee, FL

In recent years, one can observe a strong interest in the development of more efficient vector hysteresis models which can describe correctly the magnetization processes in ferromagnetic materials taking into account the vector nature of both applied field and magnetic moment. The intense studies concentrated on scalar hysteresis models have provided a number of models with reliable identification techniques which can explain a wide range of typical scalar measurements specific to most of the magnetometers commonly available in the laboratories. The scalar Preisach-type models complemented with the identification based on a set of First-order reversal curves (FORC) is a typical example of a scalar hysteresis model [1] which can provide accurate results in a large variety of cases.

However, the development of vector models was not as successful, due to the difficult implementation of the variants proposed by different authors (e.g. [2], [3]), and to the lack of clear and tractable identification techniques.

In a previous paper [4] we have presented a complete implementation of a vector Preisach-Mayergoyz model with an identification algorithm based on a set of scalar FORCs, measured systematically for different angles between the global easy axis of the magnetic system and the applied field direction. We also developed a new vectorial model with a remarkable numerical efficiency related to the fact that can be easily implemented on parallel computer environments [5]. Essentially, this model, referred to as the Preisach-LLG model, uses the concept of vectorial pseudoparticle for which the equilibrium state in a given applied field is calculated with the well known Landau-Lifshitz-Gilbert algorithm. A statistically stable vectorial distribution of interaction fields is taken into account which makes possible the de-coupling of the differential equations describing the magnetic behavior of each pseudo-particle.

In this paper we are evaluating the possibility to use a set of FORCs measured on the rotational hysteresis as a testing method for the vector hysteresis models performances. The rotational hysteresis loop can be experimentally obtained in the following sequence of fields. First, one saturates the sample on one direction, and then the field is decreased to a certain value. The field is maintained at a constant value and it is rotated 360°. For a number of values of the rotation angle the projection of the total magnetic moment on the field direction is measured. When the field is rotated back 360° towards the initial direction the magnetic moment is not following the same path and a hysteresis loop is obtained. The surface of this hysteresis loop can be covered systematically with first-order reversal curves, in a similar manner as it is done for any typical ferromagnetic hysteresis loop. From these FORC-type data, using the second order mixed derivative [6] one can obtain a FORC distribution which is representative for the sample and which is sensitive to various physical characteristic parameters and which is describing the vectorial switching properties of the material.

Fig. 1 presents the rotational hysteresis curve obtained on a commercial magnetic tape sample as well as the first-order reversal curves - with θ_r one denotes the values of the angle for which the reversal of the rotation direction takes place. The FORC diagram presented on the right hand side is the color map representation of the above mentioned FORC distribution. Fig. 2 shows the results of the simulation of the experimental procedure with Preisach-LLG model.

In the full paper we shall discuss the ability of the vectorial models to describe various rotational FORC diagrams. The models with the optimum set of parameters obtained from the identification procedure will be tested on the rotational hysteresis FORC diagram and the differences will be discussed.

A micromagnetic model will give the dependence of the rotational FORC diagram on the dispersion of the anisotropy field, easy axis orientation and inter-particle interaction distributions.

Identification of the parameters of reduced vector Preisach model by neural networks.

M. Trapanese

Dipartimento di Ingegneria Elettrica, Elettronica e delle Telecomunicazioni, University of Palermo, Palermo, Italy

All Preisach models describe hysteresis loop by a superposition of the magnetization values of Preisach particles, the hysterons, which are mathematical functions that can have two values. The switching from one value to the other is triggered when the external field reaches specific values. In its classical formulation [1], Preisach model does not take into account the intrinsic vectorial nature of magnetization of any material. However, several Vector Preisach Models (VPM) have been proposed: one approach considers the superposition of an infinite number of scalar models pointing along all possible directions [2]; another one is based on the energy minimization of uniformly magnetized particles placed on a vectorial field [3]. In this paper the Reduced Vector Preisach Models (RVPM) is considered [4]. All Preisach Models are identified through the careful choice of their parameters. In the case of RVPM seven parameters must be identified for each axis: the saturation magnetization; the squareness; the average critical field; the zero field susceptibility; the standard deviation of the interaction field; the standard deviation of the critical field; and the moving parameter.

Several procedures have been developed in order to identify Preisach parameters; some of them implies the solution of set of differential equations and the experimental knowledge of several parameters, while others use artificial intelligence techniques. Almost all of these papers refer to CPM, which is a scalar model, but some authors have also examined the problem of the identification in the vector Preisach model. However, the use of neural networks to the identification problem for RVPM has not been very extensively examined.

This paper presents a methodology for identifying RVPM parameters by using neural networks. The neural network used is a multilayer perceptron trained with the Levenberg-Marquadt training algorithm. The network is trained by some hysteresis data, which are generated by using Reduced Vector Preisach Model with pre-assigned parameters.

The trained network is able to yield the parameters that must be used in order to reproduce, by using RVPM, the hysteresis loop that has been submitted.

The identification procedure can be divided into two steps: A) network training; B) output of the results.

The neural network, that has been chosen, is a three layer neural network: in the proposed approach, the first layer consists of linear neurons, the second layer of neurons with hyperbolic tangent sigmoid function, and the output layer of linear neurons. The input is made up of a vector describing a hysteresis curve. The first layer makes a linear reduction from the high dimension input space to a slightly lower dimension space. The output of the first layer is therefore the feature vector that sums up the most relevant characteristics of the input space and is strictly connected to the relevant properties of the hysteresis loop: remanence, coercive field, and slopes in correspondence of some points of the loop. The output layer is made up of neurons that are the free parameters of the RVPM that permits to reproduce the hysteresis curve that best matches the inputs.

The Levenberg-Marquadt algorithm has been used for the training phase.

In order to verify the ability of the trained neural network to obtain the right parameters of the submitted curves three tests were performed: in the first one the same vectors used for the training were submitted to the network, in the second one vectors that did not belong to the training set were

submitted to the network, and in the third one an experimental hysteresis curve obtained in non static condition was used. In all cases, the abscissa field is equal to the ones used in the training phase. In the first test set the error made by the network in this case was always lower than 0.1% for all the parameters for every vector.

The second test set consisted of several vectors obtained by using RVPM with parameters not used in the training phase whose values were inside the intervals of the training parameters. RVPM was able to reconstruct the submitted curves. The errors on parameters are reported in table 1.

Finally, in the third experiment the network showed the ability to reconstruct an experimental curve.

Analysis of Permanent Magnet Demagnetization Accounting for Minor BH-curves.

Y. Zhilichev

Magnequench International, Inc, Durham, NC

When sizing permanent magnets in electric motors, generators and magnetically biased inductors they are designed to withstand the demagnetization fields. It is well known that an operating point of the magnet (or its portion) may slip below the knee of a demagnetization curve at high temperatures and under heavy overloads. Then the magnet operates on a recoil line that is different from the major bh-curve. The paper describes a calculation algorithm that allows us to account for the minor bh-curves when optimizing the magnet thickness. The model incorporates a series of recoil lines in the second and third quadrants. For each temperature, a major and few minor bh-curves are required [1]. A set of recoil lines are generated for each minor bh-curves (Fig.1). The slope of the recoil line is equal to that one of the linear part of bh-curve while the offset depends on the load line of the magnet operating point. In an FEA model, the magnet is presented by a set of operating points, and therefore each element of the mesh runs on its own bh-curve that could be different from the major one. This is typical for the multipole magnetization where the transition zone between the poles is difficult to saturate. The demagnetization analysis embraces few separate calculation steps. First the magnetization process is simulated [1]. As a result the magnet is represented by a table of magnetization components in each node of the mesh. The magnet table is imported from the magnetization model into the application FEA model and corrected to account for an operating temperature [2]. Then the magnet is simulated at the elevated temperature in presence of the demagnetization field energized by currents in the application. Each node of the mesh in the magnet area where the magnetic field is opposite to the magnetization is analyzed. If its operating point slips below the knee of demagnetization a corresponding recoil line is used to replace the bh-curve for this particular node. As a result a new magnetization table for the magnet is generated. Then it is used to analyze the performance of the application like torque, back-emf, etc. As an example, an 8-pole permanent magnet fan motor is considered (Fig.2a). Fig. 2b shows a magnet pole of a 1 mm thick injection molded NdFeB magnet ring after it was magnetized and imported into the motor model [2]. The distribution of magnetization changes after the magnet is subjected to the demagnetization field at 100-degree C. Fig. 3 shows the magnetization distribution across the pole in percentage of saturation before and after the magnet is subjected to the peak demagnetization field. The demagnetization effect was calculated based on the recoil line model for the fixed position of the magnet poles relative to the demagnetization field. The angle between the poles and demagnetization field may change in the motor (for example, for a trapezoidal current waveform, six-step drive, etc.) Therefore the last calculation step should be repeated for all possible angles between the poles and field to account for the total flux loss. This analysis helps to assess if the magnet withstands the demagnetization for the particular combination of the current and temperature. In summary, the algorithm developed accurately predicts the flux loss due to the thermal and demagnetization effects. It allows us to optimize the magnet size or/and to set the constraints for the maximum temperature and current.

I. INTRODUCTION

Because of inherently high efficiency and high power density, permanent magnet (PM) brushless motors have been widely accepted. However, they suffer from a key problem that the air-gap flux can hardly be controlled. The concept of hybrid field excitation (PM and field winding) has been proposed in which the field current is adjusted to control the air-gap flux [1]. Nevertheless, since the field winding needs continuous excitation, it degrades the efficiency. Recently, the class of memory motors has been proposed, which utilizes the property of low coercivity of the AlNiCo PM material in such a way that the magnetization of PMs can be tuned by applying temporary current pulses[2]. However, the AlNiCo PMs are prone to accidental demagnetization by armature reaction, and the process of magnetization involves complex control of armature currents. Also, its PM rotor is not mechanically robust enough to withstand high-speed operation [3].

The purpose of this paper is to incorporate both the hybrid field excitation and the dual-magnet arrangement into the memory motor so that the resulting hybrid dual-memory motor can offer the advantages of online PM and flexible air-gap flux adjustment, while eliminating the problems of accidental PM demagnetization, control complexity and mechanical integrity.

II. PROPOSED MACHINE

The proposed motor configuration is shown in Fig.1(a). Firstly, it adopts a DC winding to directly perform online magnetization or demagnetization, hence avoiding complicated vector control of armature currents and insignificant copper loss. Secondly, the use of dual-magnet arrangement, namely the NdFeB provides the main flux and the AlNiCo provides flux regulation, can effectively perform flux control. Thirdly, it adopts the double-layer stator outer-rotor topology which facilitates the integration of windings and PMs as well as direct-drive operation. Also, the double-layer stator can offer immunity of PMs from demagnetization by armature reaction. Finally, the use of solid-rotor design can provide high mechanical integrity to withstand high-speed operation.

Fig. 2(b). shows the equivalent magnetic circuits where F_{DC+} and F_{DC-} are the temporary MMF excited by the DC winding for magnetization and demagnetization, F_{PA} and F_{PN} are the MMFs of AlNiCo and NdFeB PMs. Hence, the control range of air-gap flux (Φ_{\min} , Φ_{\max}) can be analytically derived, which is very essential for initialization of motor dimensions and parameters.

III. RESULTS

By using finite element analysis, the magnetic field distributions under outward-magnetized (OM), non-magnetized (NM) and inward-magnetized (IM) AlNiCo PMs are shown in Fig. 2(a)-(c). The corresponding air-gap flux density distributions and the resulting no-load EMF are shown in Fig. 3, verifying that it offers effective flux and hence EMF control. Also, Fig. 2(d) shows the field distribution solely due to the rated armature reaction. It verifies that the PMs are immune from accidental demagnetization. By adopting the OM AlNiCo PMs to achieve flux strengthening, the start-up transient response can be significantly improved as depicted in Fig. 4. In contrast, by adopting the IM AlNiCo PMs to achieve flux weakening, the constant-power operating range can be extended to over 3 times the base speed as depicted in Fig. 5.

Study on Detachment of a Permanent Magnet-Wheel for a Wall-Climbing Mobile Robot using Magnetic Inducement.

H. Yi¹, J. Kim¹, S. Han²

1. Mechanical Engineering, Yeungnam University, Gyeongsan, South Korea; 2. Automobile engineering, Yeungnam College of Science & Technology, Daegu, South Korea

Robots are needed to automate works on a vertical plane of a large structure such as a ship and several devices such as suction cups [1][2] and magnetic disk [3] to make possible the robot to be attached to vertical plane have been developed in past years. Here, we propose a new design of the permanent magnet wheel for mobile robots to improve the adhesive force and facilitate the detachment of the wheel. Fig 1 shows the structure of permanent magnet wheel and operating principle for detaching using inducing pin. If the inducing pin is inserted, the part of magnetic flux from permanent magnet is induced to flow through the pins, which results in weakening of attaching force as shown Fig. 1 (a). To characterize the performance, the sample model of permanent magnet wheel and experiment apparatus are constructed as illustrated in Fig. 2 and Fig. 3 respectively. Specification of permanent magnet wheels are shown in table 1. In the design of magnetic wheel, the shape of wheel and the arrangement of magnets are mainly important. Therefore, we examine magnetic attaching force according to the number and the arrangement of magnets. The experimental apparatus is consisted of a computer to acquire data and control a motor, an oscilloscope to analyze values of attaching force, a gauss meter to measure attaching force and a load cell (50kgf). Using load cell, the attaching forces were measured according to the type of wheels. The table 2 shows the experiment results according to type of wheels without and with induction pins. Induction pins reduce the attaching forces by at least 70 percent which results in easy detachment of permanent magnet wheel.

Ironless and leakage free voice-coil motor made of bounded magnets.

G. Lemarquand¹, M. Remy², B. Castagnede¹, G. Guyader²

1. LAUM, Université du Maine, Le Mans, France; 2. Renault, Guyancourt, France

Voice-coil motors, such as those used in traditional electrodynamic loudspeakers, present a number of well-known drawbacks [1]. First, a significant part of the magnetic field created by the motor does not contribute towards making the membrane move. Second, the presence of iron in such motors leads to several kinds of non-linearities. These include Eddy currents, the magnetic saturation of the iron and the variation of the coil inductance with its position causing a reluctant effect. It is desirable for the force applied on the moving part to be an image of the driving current. However, if the inductance of the coil varies, a reluctant force occurs and interferes with the Laplace force. This can be compared to the cogging torque in brushless motors, arising from a reluctant effect, which prevents a smooth rotation of the motor and results in undesirable vibration and noise [2].

By suppressing the iron in the voice-coil motor, the inductance of the coil no longer depends on its position, resulting in the vanishing of the reluctant force and the other non-linearities due to iron listed previously. In addition, the inductance is diminished and consequently, so is the electrical impedance. Several structures of ironless voice-coil motors have already been proposed [3]. Another specification of the intended motor is for it to be leakage free (Fig. 1.a).

However, structures that involve sintered magnets can be difficult to assemble. By using bounded magnets this problem can be solved and furthermore, better cross section shapes and optimized magnetization of the structure can be realized, even though the magnetizer is harder to realize. With such magnets the magnetization is usually two-thirds lower than for sintered magnets. The aim of the work conducted is to design and study the magnetic performances of a loudspeaker motor having a magnet with an ellipsoidal cross section as shown in Fig. 1.b. Fig. 2 shows how this kind of magnet could be integrated into the loudspeaker. A double coil winding can be used with such a structure.

The ellipsoidal motor is discretized in order to enable analytical calculations of the magnetic field to be performed using the Coulomb's model of permanent magnets [4]. This discretization, using seven magnets of equal angular section for example, is shown in Fig. 3. For each magnet the magnetization is uniform and considered to be always parallel to the outer edge of the ellipsoid in order to avoid magnetic flux leakages. The surface charge density of each triangular magnet is then calculated.

A comparison of the magnetic performances of the two structures illustrated in Fig. 1 is then presented. The calculations are performed for two structures having the same cross section area. Results show that the ellipsoidal shape gives better results than the rectangular one. The value of B_{radial} is bigger across the entire coil displacement and its symmetry around the rest position of the coil is much better.

The magnetic field is then calculated for different values of the ratio between the lengths of the semimajor axis a and the minor axis h of the ellipsoidal magnet. Results show that B_{radial} gets bigger when the ratio augments. However, over a certain value of this ratio the increase in induction intensity is negligible compared to the rise of volume.

Generic Algorithm-Based Optimal Design of New Electromagnetic Engine Valve Actuator for Reduction of Transition Time.

J. Kim¹, K. Han², J. Chang³

1. Mechanical Engineering, Yeungnam University, Gyeongsan, South Korea; 2. Electrical Engineering, Florida Institute of Technology, Melbourne, FL; 3. Transverse Flux Machines Research Group, Korea Electrotechnology Research Institute, Changwon, South Korea

Electromagnetic engine valve actuator using permanent magnet as shown Fig. 1(a) is a new concept to overcome the inherent drawbacks of conventional solenoid-driven electromagnetic engine valve actuator such as high power consumption [1]. We presents generic algorithm and finite element analysis- based optimal design of new electromagnetic engine valve actuator in a limited space of the entire construction by multidisciplinary simulation using MATLAB and MAXWELL. This aim is maximizing the frequency of vibration in order to reduce the transition time of engine valve. The transition time is defined as the duration for the valve to move from closed position to opened position or from opened position to closed position and as the transition time is smaller, the engine valve actuator can accomplish higher maximum engine speed. The transition time of existing design is 3.9 milliseconds which achieve about 5,000 rpm of maximalum engine speed. The transition time of actuator valve is shortened by the increment of the frequency of vibration because the actuator is mainly operated by mass-spring oscillation.

Accordingly, the objective function in this optimization design is to maximize $\omega_n = (k/m)^{1/2}$. Here, k is the equivalent spring stiffness, and m is the moving mass. The available maximal stiffness of spring is proportional to the magnitude of magnetic latching force because the magnetic force by permanent magnet is designed 100 N larger at lower and upper end of stroke than spring force for latching purpose considering gas disturbance force and the moving mass includes the mass of armature and engine valve those are one rigid body. The design variables are showns in Fig. 1(b). and Several constraints to achieve a realistic design are required. When optimizing proposed structure, it is possible to synthesize designs based on some physics-based trial-and-error or the more traditional and familiar techniques such as conjugate-gradient and the quasi-Newton methods. However, neither way generally leads to optimal solution especially in the multi-parameter optimization problems. Unlike those local optimization techniques, GAs are neither highly dependent on the initial conditions nor constraints on the solution domain. For this reason, a GA, global search technique, is employed in this study [2]. Table 1 shows the optimized dimension of actuator. The size of armature is decreased which results in reduction of moving mass while width of teeth and core are increased. To demonstrate the enhancement of dynamic performance due to the optimization, dynamic finite-element analysis (FEA) was executed using the nonlinear FE analysis solver MAXWELL. The table 2 shows the comparison of characteristics of existing design and optimal design. The magnetic latching force at end position of stroke falls from 1525 N to 1262 N which reduces the obtainable maximal stiffness of spring by 18.4 % from 358 kN/m to 292 kN/m and at the same time, the moving mass including armature and engine valve falls by 52.1 % from 284 gram to 136 gram. Accordingly, the natural frequency is improved by 30 % and the transition time is shortened from 3.9 milliseconds to 3.56 milliseconds by 8.7 %.

Self-Assembly of Millimeter-Scale Components using Integrated Micromagnets.

S. B. Shetye, D. P. Arnold

Interdisciplinary Microsystems Group, University of Florida, Gainesville, FL

INTRODUCTION

Assembly of large number of small components is essential for mass-production of integrated, microelectronic devices. Self-assembly—where the parts are designed to autonomously assemble in a predetermined fashion—offers the potential for higher throughput and the ability to more effectively handle smaller parts (sub millimeter) compared to manual or robotic methods [1]. Existing self-assembly approaches use gravity, capillary, electrostatic and magnetic forces [2].

Unlike prior approaches, which used external magnetic fields to manipulate the components, this article demonstrates self-assembly using the intermagnetic forces between hard micromagnets embedded on the individual parts. To demonstrate this concept, 1 mm x 1 mm x 500 μ m silicon blocks are self-assembled onto a planar template substrate in a simple array pattern.

Magnetic assembly occurs when the magnets on two respective parts align such that the intermagnetic force exceeds the mixing force. Using a shaker assembly, an array of components is shown to assemble in dry environment in about 10 seconds with a yield of approximately 96 %.

COMPONENT FABRICATION

Wafer-level microfabrication on 500 μ m thick, 100 mm diameter silicon wafers is used to fabricate individual micromagnets varying from 25 % to 75 % of the chip surface area. Fig. 1. shows the fabrication process. Small cavities etched in the silicon surface are filled with SmCo magnetic powder to create embedded micromagnets [3]. The wafer is then diced to create the individual 1 mm x 1 mm block components. Substrates with arrays of “receptor sites” are made by gluing discrete components to plastic sheets in arrays of 4 x 3 and 3 x 3.

EXPERIMENT

Because of the inverted assembly setup, the minimum force required for self-assembly is assumed to be the weight force of the component ($\sim 12 \mu$ N). The estimated force using both analytical [4] and FEM methods for the 850 μ m x 850 μ m x 60 μ m and 500 μ m x 500 μ m x 60 μ m magnets is about 200 μ N and 123 μ N, respectively, which are both much higher than the weight force of the component.

The experimental setup shown in Fig. 2 is similar to the one presented in [5]. A small glass container with parts (≈ 5 times as the number of receptor sites) is placed on an electromechanical shaker. The substrate with its face down, is lowered into the glass container using a 3-D micropositioner and positioned at a height of about 9-9.5 mm above the parts. The shaker displacement at 3 Hz and 2 V is 1.8 mm p-p causing the parts to bounce up and down and self assemble onto the substrate. Fig. 3. shows the progression of magnetic self-assembly for $t = 0, 5$, and 10 s. Table 1 summarizes the results. The longer assembly time for the 3 x 3 substrate and lower yield is attributed to the denser packing of receptor sites, which causes any misaligned parts to deter the assembly of its adjacent parts until being knocked out of place.

CONCLUSION

The concept of magnetic self-assembly and successful experimental assembly of parts to substrate is demonstrated at the millimeter scale. The estimated force between the embedded micromagnets is much higher compared to the component weight force, thus driving the self-assembly mechanism.

Minimization of Cogging Torque in an IPM Machine.

C. Hwang¹, P. Li¹, C. Liu²

1. EE, Feng Chia University, Seatwen, Taichung, Taiwan; 2. EE, National Sun Yat-sen University, Kaohsiung, Taiwan

I. Introduction

High-speed interior permanent magnet (IPM) synchronous motors always use 2-pole rotor. However, machines equipped with two magnet poles exhibit a high level of cogging torque.

In this paper, the optimal pole-arc to pole-pitch ratio for minimum cogging torque in IPM machine is used as initial values of the design variables, then the Taguchi method is used for the determination of the initial optimal values[2], and Rosenbrock's method is applied to determine the near optimal settings of the design parameters [3].

II. Model of IPM Motor

Fig. 1 shows a three-phase, 2-pole/6-slot IPM motor. The initial design parameters are stator outside diameter = 90 mm, inner diameter = 53 mm, stack length = 65 mm, and rotor outside diameter = 52 mm. The core is made of nonoriented silicon steel, and two sintered NdFeB magnets with a remanence of 1.2 T and a relative recoil permeability of 1.05 are inserted in the rotor. The magnet thickness is 3 mm with an angular pole-arc of 150 electrical degrees. The rotating speed is 12000 rpm.

III. Design of Experiment

There are four factors, M, D, B, and G, corresponding four design variables are chosen as shown in Fig. 1, and each at three levels. Where M is the thickness of magnet in mm (2.5, 3.0, 3.5), D is the pole-arc of magnet pole in electrical degree (145, 150, 155), B is the width between magnet and air gap in mm (3.5, 4.0, 4.5), and G is the air gap length in mm (0.5, 0.5, 0.5). A standard Taguchi's orthogonal array L-9 used for the matrix numerical experiments is shown in Table I. The peak-to-peak values of cogging torque T_{cmax} are calculated for each experiment using finite element analysis as also shown in Table I.

IV. Analyze the Results

After conducting the matrix experiments and obtaining all the experimental data, analysis of means and analysis of variance are carried out for estimating the effect of design parameters and for determining the relative importance of each design parameter. Fig. 2 illustrates the main factor effects on cogging torque. It reveals that the factor-level combination (M1, D1, B3) contributes to minimization of the cogging torque.

Finally, Rosenbrock's method is applied to find the optimal values of the design variables. They are $M = 2.45$ mm, $D = 144.2$ electrical degrees, and $B = 4.31$ mm. The results are found using the FEM analyses. The value of cogging is 0.35 Nm. Fig. 3 compares the result of cogging torque.

Static Eccentricity Fault Diagnosis in Permanent Magnet Synchronous Motor using Time Stepping Finite Element Method.

B. Ebrahimi, J. Faiz, A. Zargham Nejhad

Department of Electrical and Computer Engineering, University of Tehran, University of Tehran, Tehran, Iran

This paper introduces a new index for noninvasive diagnosis of the static eccentricity (SE) in Permanent magnet synchronous motors. Use of this index makes it possible to precisely determine the eccentricity degree. The index is the amplitude of the harmonic components with a particular frequency pattern. The occurrence and increase of the fault causes a rise in amplitude of the harmonic components which can be used to diagnose the fault and determine its degree. A permanent magnet synchronous motor (PMSM) under static fault is modeled using time stepping finite element method. This modeling includes all geometrical and physical characteristics of the machine components, non-uniform permeance of the air gap and nonlinear characteristics of the PM material. Referring Fig1, the core of the fault diagnosis technique is TSFE method which is used to process the proposed signals. The transient equations of the external circuit showing electrical sources and circuit elements are combined with the field equations in FEM and mechanical equations due to rotor rotation, and stator phase current is estimated as unknown variable. Since the air gap magnetic field of the faulty motor is asymmetrical, current, torque and speed of the motor are also asymmetrical. These asymmetries produce many harmonics in the field, current and torque of the motor. The frequency pattern injected to the stator current can be the criterion function for non-invasive fault diagnosis. Fig2a and Fig2b show the frequency spectrum of the stator current for a healthy PMSM and the PMSM with 10%SE respectively. Comparison of these figures indicates that 10% SE results in harmonic components with considerable amplitudes in the stator current with frequencies 37.5Hz, 62.5Hz and etc. The amplitude of harmonics 37.5Hz increase from -88dB in the healthy motor to -65dB in the faulty motor. This increase is from -101dB to -68dB for harmonic 62.5Hz. This considerable increase of the harmonic components is a suitable index for SE fault diagnosis. Fig2c indicates that amplitudes of harmonics 37.5Hz and 62.5Hz are again increased. Comparison of Fig2b and 2c shows that 10% increase of the SE degree results in the increase of the harmonic component amplitude of 37.5Hz to -58dB and 62.5Hz to -61dB. Higher SE degree, 30%, shows that the trend of increase in harmonics 37.5Hz and 62.5Hz continue so that the amplitude of harmonic 37.5Hz reaches -54dB and 62.5Hz reaches -58dB. Amplitudes of harmonics 37.5Hz and 62.5Hz are a suitable index for fault diagnosis and determination of eccentricity degree. The frequency pattern of $(1 \pm (2k-1)/P)fs$ is suggested for SE fault diagnosis, where fs is the supply frequency, P is the number of poles and k is an integer. Harmonic frequencies 37.5Hz and 62.5Hz are computed from this pattern by substituting $fs=50, P=4$ and $k=1, 2, \dots$. Table I summarizes the amplitudes of harmonic components $(1 \pm (2k-1)/P)fs$ for $k=1, \dots, 7$. Referring to Fig 2, shows that SE increases the harmonic components of the stator current which causes oscillating torque. By increasing the SE degree, amplitudes of the harmonics in the stator current rise and more ripples are observed on the developed torque. For this reason the analysis of the torque spectrum of the healthy motor and a motor with 10%-30% SE are shown in TableII, respectively. TableII shows the rise of harmonic components $(1 \pm (2k-1)/P)fs$ in the torque of the faulty motor.

Six-degree-of-freedom motion analysis of a planar actuator with a magnetically levitated mover by six-phase current controls.

Y. Ueda, H. Ohsaki

Department of Advanced Energy, The University of Tokyo, Kashiwa, Japan

Introduction:

There are a large number of electronic devices employing numerous actuators. So, it has been required to improve their performance such as high-speed, high-precision, drive with multi-degrees of freedom, smaller and lighter structure, and so on. Direct drive with multi-degrees of freedom is an emerging technology that has been studied actively [1]. Planar actuators can be directly driven in the translational directions on a plane. Conventional planar actuators have a large number of armature coils [2] [3]. These actuators require large-scale power supplies, though, so they are not suitable for small actuators.

The purpose of this study is to design an actuator with a small mover capable of large planar motion and positioning with six degrees of freedom by six-phase current controls. So far, the large rotational and translational motions on a plane could be independently controlled [4]. This paper proposes a new control method of positioning on the plane with the mover levitated magnetically. The six-degree-of-freedom motions obtained by numerical analysis are also presented.

Stability of the magnetic levitation:

The fundamental structure of our proposed planar actuator is shown in Fig. 1. The mover consists of a two-dimensional Halbach magnet array. The stator has three sets of air-core two-phase armature conductors, which are arranged on a triple-layered printed circuit board. Therefore, this planar actuator would be suitable as a small actuator.

This planar actuator can be driven with the same principle as linear synchronous motors when two-phase currents are supplied to the two-phase armature conductors. Therefore, the electromagnetic force has sinusoidal dependence on the phase difference θ_d between magnetic fields generated by the armature currents and the Halbach array. The six-degree-of-freedom force can be calculated from Lorentz force. Numerical analysis of the static force characteristics for only the armature currents for x -drive was carried out. In this paper, the orientation of the mover was defined from the angles α , β and γ as counterclockwise rotations about the z -, y - and x -axes, respectively. The dimension and mass of the mover are 11 mm x 11 mm x 2 mm and 1.8 g, respectively.

Fig. 2 shows the analysis result of the translational force F_x , F_z and the torque T_y for $\alpha = \beta = \gamma = 0$ deg. The translational force F_x and suspension force F_z can be generated independently by controlling the amplitude and the phase of the two-phase currents. The positive F_z is generated when θ_d is in the range between 90 and 270 deg. Fig. 3 shows the analysis result of T_y vs. β characteristics for $\alpha = \gamma = 0$ deg and θ_d in the range between 90 and 270 deg. When β become larger T_y become smaller, and, so β motion is stable in this range. Slight β motion hardly influences F_x , F_z , T_x and T_z . Fig. 4 shows the analysis result of T_x , T_z vs. γ characteristics for $\alpha = \beta = 0$ deg and $\theta_d = 135$ deg. When γ become larger T_x become smaller, and, so γ motion is also stable. Slight γ motion hardly influences F_x , F_z and T_y . However, T_z is also generated. Therefore, it is required to suppress α motion to maintain the stability of the mover motion. Fig. 5 shows the analysis result of F_z and T_z vs. α characteristics for $\beta = \gamma = 0$ deg and $\theta_d = 135$ deg. When α become larger T_z become larger, and, so α motion is unstable. Fig. 5 also indicates that T_z is generated and F_z is not generated when α is equal to 25 deg. If the armature conductors for the yaw drive are tilted around z -axis by 25 deg from those for x -drive, T_z can be controlled, and, so α motion can be stabilized.

Conclusions:

This paper proposes a new control method of positioning on the plane and stably magnetic suspension of the mover based on numerical analysis result of the force characteristics. This control method enables to generate suspension force and three-degree-of-freedom force on a plane independently with stable torque for β and γ by six-phase current controls. Numerical analysis of six-degree-of-freedom motions of the mover has been conducted.

Optimal Halbach Permanent Magnet Shapes for Slotless Tubular Actuators.

J. J. Paulides, K. J. Meessen, B. L. Gysen, E. A. Lomonova
 Technical university Eindhoven, Eindhoven, Netherlands

This paper describes the merits of various halbach permanent magnet (PM) arrays applied to tubular PM actuators. These actuators are increasingly used due to their high efficiency, high power/force density, and excellent servo characteristics [1]. In this respect, it has been shown that the topology of the slotless tubular PM actuators using quasi-Halbach magnetization patterns have a number of attractive characteristics, such as a sinusoidal back-electromotive force waveform, which coincides with a very low electromagnetic force ripple, and the possibility of being optimized to achieve almost zero cogging force [2]. A further advantage is that quasi-Halbach magnetized magnets are virtually “self-shielding”, and therefore, the magnetic flux which passes through the translator back-iron is relatively weak. Hence, a nonmagnetic translator back-iron is considered. In most publications a square quasi-Halbach array is used, where this paper will describe the semi-analytically means to enhance the air-gap field by varying the permanent magnet shapes, as illustrated in Fig. 1, of the PMs in the Halbach array.

The semi-analytical method in this paper only examines the airgap field due to the PMs, where a linear demagnetization characteristic, fully magnetized PMs in the direction of magnetization, infinite iron permeability and motor axial length are assumed. As shown in Fig. 1, three regions are considered: the first includes the PMs, the second includes the airgap, and the third the slotless winding region. However, in slotless tubular actuators, both the windings and the airgap have a permeability equal to unity and, hence, the problem can be reduced to two regions, namely the permanent magnet region (R_r to R_m) and a source free region (R_m to R_s). The results are determined using the semi-analytical calculation approach [2] based on the magnetic vector potential, which provides for a very good agreement with the finite element analysis, as shown in Fig. 2. This analysis is also used to determine the optimal magnet to air ratio and magnet ratio (τ_m/τ_p) for various radii and magnet versus source free lengths. However, this analysis is difficult to implement when changing the magnet to a trapezoidal shape, therefore, an alternative semi-analytical method is used [3]. This approach provides the means to calculate the field of the individual magnets and by summation the total field can be determined, further the stator back-iron (infinite permeability) is included by the method of imaging [4]. The results of this analysis are shown in Fig. 3, where the influence of the angle α_m is shown on the optimal value of the airgap flux density. This figure clearly shows that the maximum airgap flux density and rms airgap field can be increased by 10% and 1.5%, respectively, while implementing trapezoidal instead of rectangular shaped magnets. However, probably more importantly, the shape of the Halbach trapezoidal permanent magnets can be used to adjust the shape of the airgap field, and hence, the harmonic content of the back-emf waveform can be minimized. The trapezoidal magnet shape, therefore, directly influences the force (density and ripple) and the acceleration of the tubular PM actuator. The full paper will present these results in various tables that can be used to select the appropriate angle for the trapezoidal magnet to minimize the airgap field harmonic content and maximize the RMS value for brushless AC excitation and to maximize the airgap field in the central 120° current conducting region for brushless DC excitation.

Development of Inverse Magnetostrictive Actuator.

H. Park, Y. Park, H. Choi

Mechatronics Engineering, Chungnam National University, Daejeon, South Korea

An electromagnetic actuator with coil such as magnetostrictive actuator converts electrical energy to mechanical energy, and to control magnetic forces. It, however, has some problems such as heat generation and bulky size. To overcome such problems, Ueno et al. proposed an electromagnetic actuator without coil. They harnessed inverse magnetostrictive effect of a magnetostrictive material (MM), as shown in Fig. 1 (a), and treated MM as a variable resistance [1]. This paper proposes an electromagnetic actuator with inverse magnetostrictive effect, as shown in Fig. 1 (b), and treats MM as flux source.

Fig. 2 (a) is a schematic view of the actuator, Fig. 2 (b) a photograph of the actuator. Spring model is used to model displacements and forces of MM and piezo, as shown in Fig. 3. It is assumed that the cover and bobbin in Fig. 2 (b) are rigid enough. Piezo is expanded along the $-y$ direction and generates a force (F_p) when a voltage is applied to it, while MM tends to expand along the y direction and generates a force (F_{G0}) due to PM. Total force at (F) is the difference between F_p and F_{G0} applied to MM. Thus, changed displacement applied force onto MM are expressed as, $x = F / (k_1 + k_2)$, $F_G = -k_2 F / (k_1 + k_2)$ (where, $x_p = -x_G = x$) (1)

Magnetic flux density of MM consists of two components; One is magnetic flux density by external force, and the other by permanent magnet. Therefore, magnetic flux in MM is expressed as,

$$\Phi_G = \int B_G dA = \Phi_\sigma + \Phi_H \quad (2)$$

Fig. 4 shows magnetic equivalent circuit of the proposed actuator. Direction of magnetic flux (Φ_σ) by external force is opposite direction of flux (Φ_H) by PM. Total magnetic flux in magnetic equivalent circuit is expressed as the sum of flux (Φ_{PM}) by PM, flux of MM (Φ_σ) by external forces and flux leakage (Φ_l).

$$\Phi_{TOT} = \Phi_{PM} + \Phi_\sigma + \Phi_l \quad (3)$$

Assuming that flux leakage is very small than flux by PM and flux of MM by external force, magnetic force at airgap by external forces can be obtained.

$$F_\sigma = 2\Phi_{PM}\Phi_\sigma + \Phi_\sigma^2 / 2A_{ag} \mu_0 \quad (\text{where, } \Phi_{PM}, \Phi_\sigma \gg \Phi_l) \quad (4)$$

This equation is used to predict the magnetic force at airgap. The predicted force is compared with the measured force (Fig. 5).

The applied voltages from a PI piezo amp are between 0 and 500 volts. The magnetic force at airgap is measured by using a PCB force sensor. When the input voltage is 500V, the different between predicted and measured forces is about 0.7N. Cause of those errors is analogized loss of magnetic flux in magnetic circuit that is leakage in flux path.

Interface effects in the magnetic properties of $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3/\text{SrTiO}_3$ heterostructures.

F.Y. Bruno¹, J. Garcia-Barriocanal¹, A. Rivera¹, Z. Sefrioui¹, C. Leon¹, J. Santamaria¹, N. M. Nemes², M. Garcia-Hernandez², M. Varela³, S. J. Pennycook³

1. GPMC. Dpto. Fisica Aplicada III., Universidad Complutense de Madrid, Madrid, Spain; 2. Instituto de Ciencia de Materiales de Madrid, Consejo Superior de Investigaciones Cientificas, Cantoblanco, Spain; 3. Condensed Matter Science Division, Oak Ridge National Laboratory, Oak Ridge, TN

Recently, large tunneling magnetoresistance (TMR) was observed at 4 K in magnetic tunnel junctions (MTJs) based on $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ (LSMO) electrodes separated by a thin SrTiO_3 (STO) barrier [1]. However, the reported TMR for these MTJs shows a rapid decrease with increasing temperature and vanishes around 200K, well below the Curie temperature (T_C) of the bulk electrodes. It has been suggested [2, 3] that this strong degradation of TMR with temperature might result from modified magnetic properties at the LSMO/STO interface. In this work we report on the growth of LSMO/STO superlattices with fixed LSMO thickness (6 unit cells (u.c.)) and changing the STO thickness from 1 to 24 u.c., to investigate the influence of STO in the magnetic properties of the LSMO layer.

Superlattices were grown on (100) oriented STO substrates using a high-pressure (2.9 mbar) pure oxygen sputtering system at a substrate temperature of 900 °C. This provides a thermalized and ordered growth at a slow rate (0.02 nm/s) which allows an accurate control of the layer thickness.[4]Figure 1 shows XRD spectra around the superlattice (001) Bragg peak for the $[\text{LSMO } 6 \text{ u.c.} / \text{STO } n \text{ u.c.}]_8$ superlattices. The multiple satellite peaks observed around the Bragg peak indicate the coherent heteroepitaxial growth of LSMO and STO layers with sharp interfaces. Magnetic properties were measured in a vibrating sample magnetometer with the field applied along the film plane. Hysteresis loops were measured at 10K (figure 2(a)) showing a ferromagnetic behavior for all samples. The saturation magnetization (M_S) at 10K is shown in the inset of figure 2(a). Saturation magnetization values M_S of $3.8 \mu_B/\text{at}_{\text{Mn}}$ are obtained for the superlattices with STO thickness (d_{STO}) of 1 u.c. and 2 u.c., close to the bulk LSMO value, while M_S shows a sharp decrease for larger d_{STO} towards a value of about $M_S = 2.6 \mu_B/\text{at}_{\text{Mn}}$. Figure 2(b) shows temperature dependent magnetization for the same superlattices. Samples were field cooled and measured warming up in 100 Oe. The Curie temperature (taken as a linear extrapolation of the maximum slope in magnetization curves to zero magnetization) is shown in the inset of figure 2(b). Interestingly T_C is found to be about 200 K and independent of STO thickness for d_{STO} larger than 10 u.c., while a clear rise in T_C is observed as STO thickness decreases towards 1 u.c.. The same trend is followed by T_p , the temperature at which a maximum occurs in resistance versus temperature measurements (see inset of figure 2(b)). This result might explain the observed vanishing of TMR in LSMO/STO/LSMO MTJs [1] above 200 K, since our data points to the degradation of the magnetic properties of LSMO close to the interface with STO. In fact, superlattices with thicker LSMO layers show higher T_C and T_p values (not shown), which suggests that the interface itself is responsible for the degraded magnetic properties observed when the LSMO layer is thin enough. Atomic resolution STEM and EELS measurements are currently under way to determine if the Mn oxidation state in the LSMO layer is modified close to the interface.

Control of the degree of out-of-plane anisotropy of CoFe/Tb multilayer by applying an external in-plane field during film deposition.

K. Lee, Y. Jang, J. Kim, S. Lee, B. Cho

School of Photonics, MSE, GIST, Gwangju, South Korea

In the most applications of a magnetic spin valve sensor, the magnetization of a soft sensing layer is oriented perpendicular to that of a hard magnetic layer. In order to obtain the cross configuration, several methods have been investigated, such as using the external bias field, shape anisotropy, and step edge anisotropy [1-4]. However, these methods have some drawbacks, such as complicated sensor design and lithographic process. Recently, a new type of spin valve, which has a structure with alternating out-of-plane and in-plane magnetization configuration, has been suggested [5-7]. Multilayer of transition metal (TM)/rare-earth metal (RE), such as CoFe/Tb and Fe/Tb, was used to form an out-of-plane anisotropy. The sensitivity and the in-plane field range of sensing is strongly dependent of the thickness of the RE layer. Thus, it would be important to investigate the properties of the out-of-plane anisotropy in the multilayer of TM/RE to optimize the sensitivity and the in-plane field range of sensing. In this work, we studied the out-of-plane anisotropy of $\text{Co}_{50}\text{Fe}_{50}/\text{Tb}$ multilayer film by changing the thickness of Tb layer and applying an external in-plane field of 200 Oe during the position of layers. A double bilayer of $[\text{Co}_{50}\text{Fe}_{50}(2\text{ nm})/\text{Tb}(t_{\text{Tb}})]_2$ was deposited by magnetron sputtering at a base pressure of 5×10^{-8} Torr. Figures 1(a) and (b) show isothermal magnetization at room temperature of $[\text{Co}_{50}\text{Fe}_{50}(2\text{ nm})/\text{Tb}(t_{\text{Tb}})]_2$ with $t_{\text{Tb}} = 1\text{ nm}$ and 3 nm , respectively. The multilayers were fabricated without applying an in-plane external field. As expected, the multilayer with $t_{\text{Tb}} = 1\text{ nm}$ shows a strong out-of-plane anisotropy, as shown in Fig. 1(a). Meanwhile, the sample with $t_{\text{Tb}} = 3\text{ nm}$ exhibits a similar hysteresis behavior regardless of the field orientation, as shown in Fig. 1(b). In general, the out-of-plane anisotropy in a multilayer is believed to be induced by a mixed interface and maintained by the exchange interaction between the adjacent transition-metal layers [8]. Thus, it is likely that, as the t_{Tb} increases over the critical thickness, the net magnetic moment of multilayer becomes to be tilted to in-plane direction, because the unmixed Tb moments in the layer leads to parallel alignment of the out-of-plane moment at the interface [8-9]. Figure 2(a) and (b) shows isothermal magnetization at room temperature of $[\text{Co}_{50}\text{Fe}_{50}(2\text{ nm})/\text{Tb}(t_{\text{Tb}})]_2$ with $t_{\text{Tb}} = 1\text{ nm}$ and 3 nm , respectively, which was fabricated with applying an in-plane external field of 200 Oe during deposition of layers. In contrast to the case in Fig. 1(a), the sample with $t_{\text{Tb}} = 1\text{ nm}$, fabricated with the in-plane external field, shows a strong in-plane anisotropy, as shown in Fig. 2(a). This indicates that the formation of the out-of-plane anisotropy at the mixed interface of TM/RE bilayer is affected critically by the small external field, applied during the deposition. The multilayer with $t_{\text{Tb}} = 3\text{ nm}$ shows no preference in the in-plane and out-of-plane anisotropies, as shown in Fig. 2(b). Although the hysteresis behavior in Fig. 2(b) is quite similar to the case in Fig. 1(b), it can not be accounted in terms of the unmixed Tb moments scenario. At present, we do not understand the origin of the spin orientation of the multilayer with $t_{\text{Tb}} = 3\text{ nm}$, fabricated with the applied field. However, it would be worthwhile to notice that the degree of the out-of-plane anisotropy can be controlled by changing the thickness of RE metal layer and applying an in-plane external field during deposition. Based on our preliminary data as in Figs. 1 and 2, we found that the out-of-plane anisotropy in the multilayer of $[\text{Co}_{50}\text{Fe}_{50}(2\text{ nm})/\text{Tb}(t_{\text{Tb}})]_2$, which was believed to be induced by the mixed interface, can be affected critically by the small applied field during deposition. Because the degree of out-of-plane anisotropy was found to be changed by adjusting the thickness of RE layer and the applied field, it will be discussed in detail how the thickness and field parameters affect the spin orientation in the TM/RE multilayer.

Synthetic antiferromagnetic (SAF) layers have been generally applied to the spintronics devices using a structure of spin valves or magnetic tunnel junctions, such as HDD read sensor, and magnetic random access memory (MRAM). Magnetic tunnel junctions (MTJ) with SAF layer consist of seed layer/PtMn/PL1/NM/PL2/MgO/FL/capping layer, where FL is the ferromagnetic free layer, PL1 and PL2 are the two ferromagnetic pinned layers antiferromagnetically coupled through a non-magnetic (NM) layer due to the RKKY interlayer exchange coupling. Because the SAF structure [1,2] has an antiparallel alignment of the magnetization of PL1 and PL2, it has an advantage of a reduction in the magnetostatic coupling between the pinned layer and the free layer. Moreover, the SAF structure has another advantage for the SAF free layer, because it can achieve a low net magnetization for the low switching field and shows a higher thermal stability than a single FL. These characteristics are more important as the size of magnetic device is reduced to the nano-scale regime.

Since the large tunneling magnetoresistance ratio (TMR) was reported in the MgO-MTJ with amorphous ferromagnetic materials, such as CoFeB [3], the amorphous ferromagnetic materials have been substituted for the crystalline ferromagnetic materials, such as CoFe, NiFe, because the amorphous electrodes are critical to develop the highly textured MgO tunnel barrier. However, SAF structure using the amorphous materials shows much weaker interlayer exchange coupling strength when compared to the SAF structure using the crystalline phase. Therefore, it is necessary to develop the method for the enhanced exchange coupling strength in the SAF structure using the amorphous materials.

In this study, we have investigated the effect of Cr insertion on the exchange coupling strength in SAF structure. The stacking structure of MTJ was seed layer/PtMn/CoFe/(Cr)-Ru-(Cr)/CoFeB/MgO/CoFeB/Ta. Some samples were annealed in a vacuum for 2hr in the range up to 400°C under the magnetic field of > 0.5 Tesla. The magnetic and structural properties were characterized by a vibrating sample magnetometer (VSM), and high resolution transmission electron microscopy (TEM), respectively. The MTJs were patterned into 0.3 x 0.8 μm^2 cell sizes for the measurement of electrical properties, such as TMR, RA.

Figure 1 shows the magnetization curves of as-prepared MTJs with the different condition of Cr insertion layers. The magnetic properties of SAF layer depend on the insertion position and the thickness of Cr layer. When the Cr layer is located between the top interface of Ru and amorphous CoFeB, the exchange coupling strength are reduced, however, at the bottom interface of Ru and crystalline CoFe, the exchange coupling strength are enhanced. The saturation field (H_{sat}) of reference MTJ with Ru 9A shows ~1900 Oe, but that of MTJ with Cr(2A,bottom)/Ru(7A) shows the enhanced value of ~2300 Oe. The saturation field (H_{sat}) values are shown in Figure 2. This trend is not changed after magnetic vacuum annealing process at the relatively low temperature, but the different trend is observed after the high temperature annealing. The effects of the inserted Cr layer are investigated based on the structural analysis using HR-TEM, and the TMR properties.

Granular thin films, in which magnetic single-domain nanoparticles (“superspins”) are dispersed in a non-magnetic matrix, are a very active current research topic, because their magnetic and magnetotransport properties suggest various technological applications. They are represented, e.g., by discontinuous metal insulator multilayers (DMIMs) that resemble frozen ferrofluids to a large extent. DMIMs consist of metallic layers with different degrees of discontinuity intercalated between insulating spacer layers. When the metallic layer consists of closely spaced ferromagnetic granules, different types of collective behaviour appear due to magnetic interparticle interactions (of dipolar or tunnelling exchange origin): superparamagnetism (SPM), supersinglass (SSG) or superferromagnetism (SFM) [1,2]. DMIMs have the advantage that their magnetic behaviour can be controlled by modifying the nominal thickness of the deposited ferromagnetic metal [3].

Recently, we have prepared DMIMs of the system $[\text{Fe}(t)/\text{MgO}(3 \text{ nm})]_N$, with the nominal thickness (t) of the iron layer ranging from 0.4 nm to 1.5 nm, and the number of bilayers (N) chosen to keep the total amount of iron constant between the samples. The layered granular thin films have been grown by sequential pulsed laser deposition with a KrF laser from the corresponding targets. An ultra-high vacuum atmosphere (10^{-9} Torr) and laser fluence on the target around 8 J/cm^2 has been used to deposit the multilayers at room temperature on Corning glass substrates.

Structural and magnetic characterization of the samples has been performed by X-ray reflectivity (XRR), high resolution transmission electron microscopy (HRTEM) and magnetization measurements using a SQUID magnetometer. From XRR the layers thickness and interphases roughness have been obtained by fitting of the experimental results using the LEPTOS software (BRUKER AXS).

The HRTEM observations have been performed using a TECNAI F20 microscope. As an example we show in Figure 1 a cross-section view of the sample with iron nominal thickness $t=0.81 \text{ nm}$. The multilayer structure is clearly shown, and polycrystalline growth of Fe and MgO is observed. The size distribution and dispersion of the metallic clusters were studied by HRTEM plan-view on single Fe/MgO bilayers deposited on carbon grids with the same Fe-to-MgO ratios as in the multilayers (see Figure 2).

The magnetization measurements have allowed us to perform a preliminary characterization of the different magnetic states present in the samples. For $t \geq 0.9 \text{ nm}$ the DMIMs present a ferromagnetic behaviour with remnant magnetization and a low coercive field ($\approx 12 \text{ Oe}$). These results indicate a physical percolation of the Fe grains producing a continuous ferromagnetic iron layer. The zero-field cooling (ZFC) and field cooling (FC) curves clearly show irreversible behaviour at low temperatures (see Figure 3). The blocking temperatures (T_B), obtained from the splitting between the ZFC and FC data, decrease with t , indicating a decrease of the mean particle volume. The fit of ZFC/FC curves using Curie-Weiss law allows to estimate the average granules size for the films with $t < 0.7 \text{ nm}$. The results of the estimations correlates with the data obtained from direct HRTEM investigations.

FMR Investigation of $(\text{Ga}_{1-x}\text{Mn}_x)\text{As}$ Tri-layers.

M. Cubukcu¹, K. Khazen¹, H. von Bardeleben¹, J. Cantin¹, M. Elsen², H. Jaffrès², J. George², L. Thevenard³, A. Lemaître³

1. Institut des Nanosciences de Paris (INSP), Université Paris 6, UMR 75-88 au CNRS, Paris, France; 2. Unité Mixte de Physique CNRS-Thales, associée à l'Université Paris XI, Palaiseau, France; 3. Laboratoire de Photonique et Nanostructures, Marcoussis, France

Ferromagnetic(FM) semiconductors $(\text{Ga}_{1-x}\text{Mn}_x)\text{As}$ based magnetic tunnel junction, which consists of tri-layers with two ferromagnetic $(\text{Ga}_{1-x}\text{Mn}_x)\text{As}$ layers separated by a non magnetic (Ga,As) layer, are interesting objects for future spintronics application. In the as-prepared state $(\text{Ga}_{1-x}\text{Mn}_x)\text{As}$ thin films have rather low critical temperatures and a magnetization much lower than $5\mu\text{B}/\text{Mn}$ ion. A decisive step for the optimization of the magnetic properties is a thermal annealing in the 250°C temperature range. The efficiency of such annealing depends also on the surface conditions which in the case of multilayer structures are imposed at least for the lower layer by the structure itself. But the top layer might equally be affected differently due to the particular properties of the barrier layer[1-2]. We have investigated by ferromagnetic resonance(FMR) spectroscopy the affect of annealing on such tri-layers. A further interesting subject is interlayer exchange coupling(IEC) which might be expected to become important for ultra-thin barrier layers. We have studied tri-layers with two different barrier layer thicknesses to address this subject.

The tri-layers were grown by low temperature MBE at 250°C and had the following structure: a $(\text{Ga}_{1-0.05}\text{Mn}_{0.05})\text{As}$ 100nm bottom layer and a 30nm $(\text{Ga}_{1-0.05}\text{Mn}_{0.05})\text{As}$ top layer separated by a Be doped $(\text{In,Ga})\text{As}$ barrier layer of 4nm or 6nm thickness. The tri-layers were studied in the as-grown state and after a low temperature(250°C /1h) standard thermal annealing which has been found to be optimal for the annealing of $(\text{Ga}_{1-x}\text{Mn}_x)\text{As}$ single layers. These tri-layers had been previously studied by tunneling magnetoresistance(TMR) measurements. The FMR measurements were performed at 9GHz in the 4K to 150K temperature range. The spectra were taken for both the in-plane and out of plane orientations of the applied magnetic field and the FMR parameters were obtained from a classical Smit-Beljers analysis. The FMR investigations of the tri-layers allow a more detailed analysis of these layers as compared to SQUID measurements give access to the four magnetocrystalline anisotropy constants(K_i) and the critical temperature(T_c).

I. As-grown tri-layers: We observe for both types of layers two distinct FMR spectra which from their respective intensities can be associated with the uniform mode spectra of the lower and upper layers. The observation of two distinct FMR spectra demonstrates that in spite of identical growth parameters the magnetic properties of the two layers are not identical which we attribute to the different strains in the layers. They show further that IEC is not important under these conditions. The saturation magnetizations were $27\text{ emu}/\text{cm}^3$ and $29\text{ emu}/\text{cm}^3$ for bottom and top layers respectively. The critical temperatures of the two layers were 70K and 95K respectively. The analysis of the angular variations of the FMR spectra allows us to determine the magnetocrystalline anisotropy constants and their variation with temperature for the two layers.

II. Annealed tri-layers: The properties of both layers were modified by the annealing treatment. The measurement of the respective T_c of the layers, both by FMR and SQUID, reveals an enhancement only for the top layers($T_c=135\text{K}$). The FMR intensity and the SQUID measurements show that the magnetization is increased by the factor 1.15 for the top and by a factor 1.05 for the bottom layers. Fig.1 shows the dominant anisotropy constants of the layers for the sample with 4nm thick intermediate layer. These values are obtained from angular dependence of the resonance spectra for different applied field orientations. Here again the modification is for both top and bot-

tom layers but more important for the top layer. These values are compared with the $(\text{Ga}_{1-x}\text{Mn}_x)\text{As}$ reference mono-layer[3] and some metallic systems in order to better understand the causes for the magnetic properties modifications. The hole concentration[p] and strains($\Delta a/a$) in the layers are estimated using the anisotropy constants and the mean field model predictions. The results show that despite the small difference of strains in the bottom layer before and after annealing the hole concentration is the same. But [p] and $\Delta a/a$ are significantly modified for the top layers. These results are consistent with the previous studies on the annealing effect on multi-layers. Contrary to the conclusions drawn from the TMR results we find no evidence for interlayer exchange coupling in the FMR measurements.

Interplay between magnetic anisotropy and interlayer exchange coupling in amorphous CoSi / Si multilayers.

L. M. Álvarez-Prado, C. Quirós, L. Zárte, J. I. Martín, J. M. Alameda
Departamento de Física, Universidad de Oviedo, Oviedo, Spain

Interlayer Exchange Coupling (IEC) of magnetic layers across semiconducting spacers with thickness in the nanometer range is an interesting subject since it strongly modifies the magnetization reversal processes of multilayered films but its origin still remains unclear. Recent studies have focused on the Co-Si system, reporting unequivocal indications of the presence of weak antiferromagnetic (AF) coupling for the case of amorphous CoSi magnetic alloys separated by Si spacers [1-2]. Such a weak coupling leads to one of the most peculiar properties of this Co-Si system: the fact that coupling fields (\sim Oe) are significantly smaller than anisotropy fields (typically 10-30 Oe), reversing the typical balance observed in other AF multilayers. As a consequence of this particular energetic balance, the study of the interplay between magnetic anisotropy and interlayer coupling for the Co-Si system is specially interesting.

Three samples have been prepared in order to gain insight on this interplay. First one is a single magnetic film (with Si capping and buffer) having the following structure: (3 nm Si / 5 nm Co₇₃Si₂₇ / 3 nm Si / Si (111) substrate). The two other samples are multilayers of two magnetic periods separated by a semiconducting Si spacer (again with Si capping and buffer): (3 nm Si / 5 nm Co₇₃Si₂₇ / 3 nm Si / 5 nm Co₇₃Si₂₇ / 3 nm Si / Si (111) substrate). Although the two multilayers have the same nominal structure, in one case the magnetic easy axis of both magnetic layers is parallel, but in the second multilayer the in-plane magnetic easy axes of the top and bottom magnetic layers are perpendicular.

First thing to point out is that the single magnetic film shows the typical behaviour of samples with in-plane uniaxial anisotropy. This is shown in fig. 1, where magneto-optical transverse Kerr effect loops have been measured by applying the magnetic field at different angles respect to the sample easy axis. In fact, 90 deg. corresponds to a magnetic hard axis with an anisotropy field of about 10 Oe, whereas at 0 deg. the loop is perfectly squared with a coercive field of 0.4 Oe. The origin of this uniaxial anisotropy is related to the growth geometry [1], since oblique incidence (around 30 deg. off substrate normal) has been used to sputter the Si target.

The loops for the sample consisting of two magnetic periods with parallel anisotropies are shown in fig. 2(a). In this case, no significant changes are observed concerning the hard axis. However, for the easy axis, and also for the intermediate angles, the shape of the loops is drastically modified with respect to the one period case. Now a clear plateau is observed at around zero magnetic field, indicating the stabilization of the AF alignment. The switching fields are in the 2-3 Oe range, confirming the weak nature of the coupling.

Finally, a third sample has been prepared, but now with crossed individual in-plane uniaxial magnetic anisotropies, by making a 90 deg. rotation around substrate normal immediately before the growth of the top magnetic layer [3-4]. In this case, as it can be seen in fig. 2(b), the reversal process is strongly modified as compared to the other multilayer (see fig. 2(a)) since only when the magnetic field is applied along the -45 deg. direction, that is, one of the bisecting directions between the easy axis of both layers, the AF alignment is stabilized. This procedure shows an easy way to modify the magnetization reversal process and the angular range where the AF alignment is stabilized. It is also worth mentioning that this trend has been obtained by micromagnetic simulations.

The properties of magnetic multilayers can be easily manipulated by varying the thickness of the magnetic and/or nonmagnetic layers as well as the number of layers [1–3]. Increasing the thickness d of a single magnetic layer, a spin reorientation transition (SRT) from out-of-plane to in-plane magnetization occurs above a critical thickness $d > d_{\text{SRT}}$ [4]. An interesting study of magnetic ordering, using Mössbauer spectroscopy and magnetic force microscopy (MFM), has been performed in [5] on Co/Au multilayers with different bilayer repetition number N . With increasing N an increase of the mean out-of-plane component of magnetization was observed.

In this paper the influence of the Co layer thickness as well as the number of repetitions N on the magnetic properties of $[\text{Co}/\text{Au}]_N$ multilayers was investigated systematically. The studies were focused on the key characteristics of magnetic hysteresis loops and domain structure parameters using both, MFM and magneto-optical Kerr microscopy.

The multilayers $[\text{Co}(d)/\text{Au}(3 \text{ nm})]_N$ with $d = 1, 2, 3 \text{ nm}$ and $N = 1–12$ were prepared by dc magnetron sputtering in UHV conditions on oxidized silicon substrates. The SRT was found to occur at a thickness d_{SRT} of about 1.4 nm.

The magnetic properties were analyzed at room temperature by employing different complementary magnetic characterization techniques. The magnetization reversal processes were studied using a magneto-optical Kerr effect (MOKE) based magnetometer and/or vibrating sample magnetometry (VSM) as a function of magnetic field applied either parallel H_{\parallel} or perpendicularly H_{\perp} to the sample surface. The visualization of the magnetic domain structure was performed by wide-field Kerr microscopy in the polar and longitudinal modes with out-of-plane and in-plane magnetization sensitivity, respectively. Atomic and magnetic force microscopy (AFM/MFM) were used for surface structure analysis and magnetic domain structure imaging beyond the optical resolution. Either H_{\parallel} or H_{\perp} applied field induced changes of domain structures were studied.

The repetition number N and cobalt thickness d strongly influence both, the domain structure and the magnetization processes. For $d = 1 \text{ nm}$ and $N = 1$, below the SRT, a domain structure with magnetization perpendicular to the sample plane and a rectangular hysteresis loop are observed. With increasing N , we observed: (i) a decrease of the domain period; (ii) an increase of the saturation field H_s ; (iii) an increase of the nucleation field H_N ; starting from negative values (for small N with square hysteresis loops) up to positive with amplitude for larger N close to H_s .

The evolution of domain structure together with corresponding hysteresis loops as a function of N (for $d = 2 \text{ nm}$) are illustrated in Figure 1. For $N \leq 6$ domains with in-plane magnetization are observed. A crossover from in-plane to out-of-plane magnetization ordering was observed for N between 6 and 12. The magnetostatic forces induce a domains ordering transition to a band domain structure with perpendicularly aligned magnetization and submicrometer size. Submicrometer domain periods were measured for all samples with $N = 12$ and different d .

The evolution of the magnetization curves with H_{\perp} and increasing repetition number is illustrated in Fig. 1D – F. The following changes are observed with increasing N : (i) a decrease of the saturation

field H_s ; (ii) an increase of the domain structure nucleation field H_N ; (iii) an increase of the saturation Kerr rotation.

In conclusion, an influence of the magnetostatic interaction on the magnetization behavior was observed in $[\text{Co}/\text{Au}]_N$ multilayers. By increasing the repetition number beyond $N = 12$ an out-of-plane magnetization ordering is created. The fundamental differences in magnetization behavior with different Co thicknesses will be discussed in detail. Similar effects related with a spin-reorientation phase transition were studied experimentally [6] and by means of micromagnetic simulations [7] for larger cobalt layer thickness.

Magnetostatic waves in the magnetic/nonmagnetic periodic structures.

M. Krawczyk

Faculty of Physics, Adam Mickiewicz University, Poznan, Poland

We propose a new method for solving Walker equation [1] for the magnetostatic potential, ψ (Eq. (1)). From this equation with spatially depended permeability tensor, $\hat{\mu}$ we can calculate dispersion relation of magnetostatic waves (MW) propagating in magnonic crystals (MC), i.e. structures composed of periodically distributed different magnetic or magnetic and nonmagnetic components. This equation is solved by the plane wave method adopted from photonic crystal band structure calculations: we use Bloch theorem and Fourier series to transform the Walker equation to the reciprocal space; the final infinite set of equations are transformed into eigenvalue problem Eq. (2) for the MW frequency (ω) and then solved numerically. We show possibility of applying this method for determining MW spectra in one dimensional (1D) and also in two dimensional (2D) magnonic crystals by checking convergence with increasing number of plane waves used in Fourier expansions, for different configurations: e.g. superlattices or dipolar systems composed of magnetic dots (or antidots) periodically distributed in a nonmagnetic (or magnetic) medium. The presented results of numerical calculations refer mainly to the superlattices composed of ferromagnetic materials separated by a nonmagnetic interlayer. The results include the effect of material and structural parameters on the MW

spectrum of the considered structures for different directions of MW propagation. The forming of the magnonic bands for the cases of the backward (Fig. 1), forward and surface (Fig. 2) MWs (well known from the ferromagnetic thin films [2]) in magnonic crystals are presented, their dependencies on direction of the wave vector are exploited, as well. We interpret the resulting spectra with in the magnonic model with the help of the calculated magnetic field distributions (Fig. 3 and 4). The calculation results allow to better understanding of features of MW propagating in 1D and 2D magnonic crystals, which could be useful in designed a magnetostatic wave-based and a spin-wave logic devices [3,4].

The effect of small doping of Rare Earth element on the structure and magnetic properties of thin films of transition metal alloys is an interesting topic though Re-TM alloys have been well studied as permanent magnet and magneto-optical recording media. This paper reports the study on the magnetic anisotropy and magnetization dynamic damping of thin films of NiFe alloy doped with different content of Gd by Ferromagnetic Resonance (FMR). The FeNi-Gd films with buffer and capping layers of 5 nm thick Ta were deposited on silicon substrates by magnetron sputtering with base pressure of 1.0×10^{-5} Pa. The thickness of the films was kept at 30 nm. The Gd content was adjusted by varying the number of Gd chips on NiFe target and checked by SEM and X-ray diffraction. The content of Gd in the NiFe-Gd films was 0, 2.9%, 5.7% and 9.3%, while the proportion of Ni and Fe was kept at 83:17. FMR were performed ex situ with a Bruker ESR Equipment of model ER-200D-SRC at microwave frequency of 9.78GHz. The dependences of resonance field and linewidth on various orientations of the magnetic field were obtained.

The film of NiFe-2.9%Gd was identified as in crystalline structure with lattice constant slightly larger than the pure NiFe film, indicating some Gd atoms are dissolved in the NiFe lattice. A small amorphous halo in XRD pattern shows that a small amount of amorphous phase appears. Two other films with higher Gd content are identified as in amorphous state. The open circles in Fig. 1(a) to (d) display the experimental angular dependence of FMR field on out-of-plane orientation θ_H . It shows that as the content of Gd increases, the resonance field decreases strongly from 12220 Oe to 6960 Oe when the field is along the film normal, and the trend of the decrease of resonance field with θ_H tends to be more flat, indicating that the effective magnetization in the NiFe-Gd films drops or perpendicular anisotropy enhances with increasing Gd content.

The open circles in Fig. 2 display the experimental angular dependence of FMR linewidth on field orientation. It shows that the linewidth increases rapidly when the field orientation leaves from the film normal and reaches a maximum when the field rotates to near 10-20 degree, then the linewidth decreases slowly. The maximum of linewidth of each film changes from 330 Oe to 110 Oe, as the content of Gd increases.

Theoretical fitting of the angular dependences of FMR field and linewidth by Landau-Lifshitz-Gilbert equation agrees well with the experiments as shown by the solid lines in Fig. 1 and Fig. 2. Various parameters were obtained by the theoretical fitting of resonance field and FMR linewidth. The results show that the gyromagnetic ratio, as well as Lande g factor, rise as the content of Gd increases, with $\gamma = 1.84 \times 10^7$ (Oe \times s)⁻¹ at 0% and $\gamma = 1.94 \times 10^7$ (Oe \times s)⁻¹ at 9.3%. The obtained perpendicular anisotropy constant increases strongly with Gd content. Gilbert damping factor determined by the theoretical fitting of resonance linewidth, also indicates an increase with Gd content, from $G = 1.07 \times 10^8$ s⁻¹ at 0% to 1.59×10^8 s⁻¹ at 9.3%, suggesting a parallel changing tendency of effective magnetization and magnetic damping. Details will be described in the full text.

Hard Magnetic Nanocomposite [NdFeBNbCu/FeBSi]_{xn} Multilayer Films with Low Crystallization Temperature.

H. Chiriac, M. Grigoras, N. Lupu, M. Urse

National Institute of Research & Development for Technical Physics, Iasi, Romania

INTRODUCTION

Nanocomposite magnets consisting of a fine mixture of magnetically hard and soft phases are attractive materials for permanent magnet development [1,2]. For hard magnetic thin films a lower crystallization temperature is desired for the reduction of the grain size and applications connected with Si technology. In this paper the influence of the thickness ratio of the layers and annealing conditions on the magnetic properties of Ta/[NdFeBNbCu/FeBSi]_{xn}/Ta films is reported. The aim of this study is the achievement of the hard magnetic thin films with low crystallization temperature and a homogenous distribution of the soft and hard magnetic phases.

EXPERIMENTAL DETAILS

Sandwich magnetic films have been prepared in vacuum by successive depositions using the r.f sputtering technique. Ta films with the thickness of 20 nm were used as buffer and capping layers. The structure of the samples was investigated by X-ray diffraction (XRD) technique. The magnetic characteristics were determined by a VSM. The samples have been annealed for 20 min (optimum annealing time) at temperatures between 630oC and 700oC. In order to improve the specific magnetic properties, the samples were treated at 630oC and then cooled in a magnetic field of 8 kG applied in the film plane.

RESULTS AND DISCUSSION

The magnetic properties have been determined for films of various thickness of NdFeBNbCu layers varying from 30 to 180 nm and of the FeBSi layers from 2.5 to 20 nm. The best results were obtained for two samples with ratios of the thickness NdFeBNbCu/FeBSi layers of 90/5 and 180/15. The annealing temperature dependence of coercivity H_c and Mr/Ms ratio of [NdFeBNbCu(x)/FeBSi(y)]_{xn} films (with x = 90 nm and 180 nm and y = 5 and 15 nm) are showed in Fig. 1. The best hard magnetic characteristics were obtained for [NdFeBNbCu(180)/FeBSi(15)]_{x3} films annealed at 680oC and reasonable values were also obtained for [NdFeBNbCu(90)/FeBSi(5)]_{x6} films annealed at 630oC. For the [NdFeBNbCu(90)/FeBSi(5)]_{xn} films, a reduction of 50oC in the annealing temperature and an increase of the hard/soft phases ratio from 12 at 18, lead to an enhancement of remanence Mr and relatively good values for H_c of 17,1 kG.

The XRD patterns for [NdFeBNbCu(x)/FeBSi(y)]_{xn} films (x = 90 nm and 180 nm; y = 5 and 15 nm) annealed at 630oC and 680oC, respectively, present the same type of phases, but their volume is lower for [NdFeBNbCu(90)/FeBSi(5)]_{x6} film. For the [NdFeBNbCu(90)/FeBSi(5)]_{x6} film annealed at 630oC for 20 min., the average crystalline size of Nd₂Fe₁₄B phase is of about 22 nm while for [NdFeBNbCu(180)/FeBSi(15)]_{x3} film annealed at 680oC for 20 min. is about 31 nm. The average crystalline size of the soft magnetic phases is between 8 and 10 nm. The smaller thickness of hard and soft layers (90/5) leads to an enhancement of the diffusion process during the crystallization treatment at 630oC.

For samples annealed at 680oC only a positive dM was measured indicating the existence of the exchange coupling between the soft and hard grains. For sample annealed at 630oC an initially negative dM for a magnetic field between 0 and 14.8 kG was measured indicating the existence of magnetostatic interactions between soft and hard grains and then a positive dM was observed. Fig. 2 shows the hysteresis loops of [NdFeBNbCu(90)/FeBSi(5)]_{x6} film annealed at 630oC (a), and then cooled in magnetic field of 8 kG (b). The cooling in magnetic field leads to a noticeable

enhancement of the M_s of about 12 emu/g and H_c of about 1.37 kG. The kink of the hysteresis loop from II quadrant disappeared and a better squareness was observed.

Although the [NdFeBNbCu(180)/FeBSi(15)]_{x3} film annealed at 680oC has the best magnetic properties, the [NdFeBNbCu(90)/FeBSi(5)]_{x3} film annealed at 630oC and then cooled in field can be a good hard magnetic material for applications connected with Si technology as micromagnets for MEMS.

Magneto-optical techniques allow the investigation of the reversal process in magnetic surfaces and granular systems and of their electronic structure. In the case of magnetic metals and their surfaces the use of VIS or nIR lights allow to explore the interband and intrabands transitions that involves the 3d band. Due to the magneto-optical effect is related with the spin-orbit coupling, this technique is quite sensible to structural and chemical orders which determine also the magnetic anisotropy [1]. In this work we investigate the magneto-optical properties at different wavelengths of nanometric films based in epitaxial FePt and Fe-FePt bilayer that exhibit perpendicular anisotropy. Magnetic circular dichroism technique (MCD) is used because it allows to investigate the magneto-optical properties and the reversal process of the entire layers.

FePt films of 10 nm were deposited by RF sputtering directly on a MgO (100) single-crystal in order to obtain the epitaxial growth. The growth was performed at substrate temperatures in the range 415°C and 430 °C. The films were obtained by alternating the deposition of very thin Fe and Pt layers with nominal thickness of about 0.2 nm. The chosen ratio between the individual thickness corresponds to a nominal atomic composition of Fe₅₃Pt₄₇. The ordered L10 phase grows epitaxially [2] with the c-axis perpendicular to the substrate. Lower chemical order was observed in the film annealed at 430° C. On this film a second layer of 5 nm of Fe was deposited which constitutes the bilayer Fe-FePt.

The MCD hysteresis loops at 1.7 K were recorded using different continuous lasers covering the VIS-nIR spectrum range (476 nm - 904 nm). Details of the experimental set-up are described in [3]. The MCD hysteresis loop of the FePt film annealed at 415° C and measured with a wavelength 476.5 nm is represented in the figure 1. A square hysteresis loop is observed with a negative saturation MCD (-5.3 mrad) for positive magnetic fields. The large squareness ratio, near 1, and the large coercive field of 2.9 T confirm the high quality of the ordered c-axis epitaxial film and the orientation of the easy axis in this direction. The shape of MCD hysteresis loop measured using 632.8 nm is very similar to the measured with 476.5 nm, but the saturation MCD is positive and approximately 5 times smaller (+1.18 mrad).

In the figure 2 the MCD hysteresis of the Fe-FePt film measured with 514.5 nm, 632.8 nm and 904.0 nm are represented. The hysteresis loop measured with the blue beam exhibits positive MCD in the saturation while with the red and n-IR beams that values are negative. Moreover the absolute saturation MCD increases with the increase of the wavelength being 13.9 mrad, -20.6 mrad and -23.4 mrad for the beams with wavelength 514.5 nm, 632.8 nm and 904.0 nm, respectively. The obtained hysteresis indicate the presence of two critical field, HC1 \approx 1.3 T and HC2 \approx 0.64 T being the coercive field 0.13 T. The reversal process does not indicate a full exchange coupling between the hard and soft layers. In fact micromagnetic calculations [4] indicate that 5 nm Fe layer is a thickness for which decoupling could be possible. Finally the shape of the hysteresis loop measured with 514,5 nm is slightly different of the loops measured with largest wavelengths, which are equal. The MCD values measured with 514,5 nm in the magnetic field range between HC1 and HC2 are smaller than the measured with larger wavelength. This suggests that modification of the MO signal due to the change of the wavelength is not similar in the Fe and FePt layers.

Comparing the results, quantitatively the Fe-FePt film shows largest MCD signal than the FePt film. This difference can be due to larger Fe contain but it is not enough for explain the differences. Moreover in the Fe-FePt film the MCD changes from positive to negative values for largest wavelengths and the absolute MCD increases. The opposite behaviours are observed in the FePt film. Spectroscopic measurements are in progress to clarify these results.

Structural and Magnetic Properties of Fe/Polyimide Multilayer Thin Film.

J. Kim, S. Kim, N. Oh, H. An, J. Kim, D. Jeong, C. Kim, C. Yoon
Materials Science and Engineering, Hanyang University, Seoul, South Korea

Multilayer films consisting of alternating magnetic and nonmagnetic layers have attracted much attention since the discovery of giant magnetoresistance (GMR) effect. When these magnetic layers become thinner, the volumetric magnetic energy becomes small enough to cause for the superparamagnetic behavior to appear in the multilayer. In general, superparamagnetism is indicated by a hysteresis loop with reduced low-field susceptibility and virtually zero coercivity due to volumetric reduction of the magnetic layers [1]. In present study, we demonstrate that continuous 4-nm-thick Fe multilayer embedded within a flexible polymer matrix can exhibit superparamagnetic behavior at room temperature for possible use as a magnetic pump membrane.

The Fe/Polyimide (PI) multilayer thin films were produced by alternating the spin-coating of polyimide (PI) precursor (p-phenylene biphenyltetracarboximide type polyamic acid) and the deposition of Fe film by direct-current magnetron sputtering. The Fe/PI multilayer was heat-treated at 400°C for 1 hour in vacuum (~10⁻³ Pa) to obtain fully cured PI film. The final PI thickness was controlled by changing the concentration of the precursor solution. The Fe and PI post-annealed thickness were verified using transmission electron microscopy (TEM) and the magnetic properties were investigated by using a vibrating sample magnetometer (VSM).

Figure 1 shows magnetic hysteresis loops obtained from samples containing three layers of Fe films with different thicknesses. As the thickness of the Fe film decreased, the saturation magnetization decreased nearly proportionally. At 4 nm, the magnetization no longer saturated, reaching a superparamagnetic state. Since small magnetic nanoclusters in an insulating matrix are expected to be superparamagnetic [2], it is unusual that a continuous Fe film should exhibit superparamagnetism. We believe that the superparamagnetic state originated from loss of magnetic moments at the PI/Fe interfaces. Because polyamic acid reacts with the Fe film during imidization, a fraction of the Fe film near the interfaces oxidized to reduce the magnetic moment of Fe [3]. In fact, when the thickness of the Fe film decreased below 4 nm, the continuous film was replaced by development of the nano-sized Fe₂O₃ particles.

Figure 2 (a) and (b) show cross-sectional TEM images of the Fe/PI multilayer containing 10 and 20 Fe layers. The images clearly demonstrate well-defined multilayer structure with regularly spaced 4-nm-thick Fe films. The PI thickness between two adjacent Fe films was 7 nm. The hysteresis loops measured from the two film stacks indicated superparamagnetic state with susceptibility of 3.0 × 10⁻³ (unit) for the 10 Fe layers and 1.2 × 10⁻² for the 20 Fe layers. The magnetization of the 20 Fe layers was nearly twice that of the 10 Fe layers. The magnetic measurement data suggests that the magnetic properties of the Fe/PI membrane can be altered as needed by changing the number of the Fe films inserted within the PI matrix.

Shown in Fig 3 is the magnetic membrane fabricated by dissolving the Si substrate by the back of the film stack. In order to provide the stiffness and the mechanical stability to the magnetic membrane, the top of film Fe/PI multilayer was coated with ~1 μm PI film.

We demonstrated that a superparamagnetic multilayer can be fabricated by inserting regularly spaced continuous Fe films into a PI thin film. Such magnetic polymer membrane can potentially be utilized in remotely activated magnetic pump operating at micrometer scale.

 1. Department of Physics, Southeast University, Nanjing, China; 2. Department of Physics, University of York, York, United Kingdom; 3. Department of Electronics, University of York, York, United Kingdom; 4. National Laboratory of Solid Microstructures, Nanjing University, Nanjing, China

The effect of small doping of Rare Earth element on the structure and magnetic properties of thin films of transition metal alloys is an interesting topic though Re-TM alloys have been well studied as permanent magnet and magneto-optical recording media. The magnetic anisotropy of FeCo and FeCo-Gd films were investigated by using Ferromagnetic Resonance (FMR). The FeCo and FeCo-Gd films were deposited on silicon substrates by magnetron sputtering with base pressure of 1.0×10^{-5} Pa. FeCo layers were grown on the Si substrates at a rate of approximately 0.23 nm per second and the sputtering speed for FeCo-Gd layers was 0.07 nm/sec. Both the buffer and capping layers were 5 nm thick Ta. The Gd content was adjusted by number of Gd chips on FeCo target then checked by SEM. The thicknesses of Fe₅₀Co₅₀ films were determined as 4nm, 20nm, 30nm and 100nm respectively with the same composition, while the thickness of FeCo-Gd was kept as 30 nm with changing content of Gd as 5%, 10%, 12% and 15%. X-ray diffraction shows a well-defined crystalline (110) peak for FeCo layers, while for FeCo-12% and 15%Gd films no X ray diffraction peak appears except a broad halo, implying amorphous state. However for Gd content smaller than 12%, there are both a FeCo crystalline peaks and a small amorphous phase halo in X ray diffraction pattern, indicating the coexistence of crystalline FeCo and amorphous FeCo-Ga phases.

FMR were performed ex situ with a Bruker ESR Equipment of model ER-200D-SRC at microwave frequency of 9.78GHz. It is interesting that for FeCo film and FeCo-Ga with lower content of Gd only a half of the resonance peak near zero field was observed for all the out-of-plane FMR spectra with field scanning up to 14000 Oe, but the peak moved with field orientation as shown in Fig. 1. When the content of Ga increases to 12%, the whole resonance peak appeared as shown in Fig. 2. It is assumed that for FeCo films its high values of perpendicular anisotropy and M_s lead to the near zero field resonance peak. By assuming the near zero field resonance as natural resonance due to high anisotropy in FeCo film the perpendicular anisotropy constant K was roughly estimated by the expression

$$\omega = \gamma H_k = 2\gamma K / M_s$$

By using the bulk values of saturation magnetization M_s [1] and gyromagnetic ratio[2] of Fe₅₀Co₅₀, the value of K was determined as 3.2×10^6 erg/cm³, which is really a reasonably large value. Then the theoretical FMR resonance field could be calculated by Landau-Lifshitz equation. We found the experimental angular dependence of resonance field can be reproduced very well theoretically.

Based on Landau-Lifshitz equation, the theoretical fitting of the angular dependences of FMR field of FeCoGd films with content of 12% and 15% were also made and various parameters were obtained. It is found that the saturation magnetization decreases with increasing content of Gd from 1400Gs at 12% of Gd to 1100Gs at 15% of Gd and the gyromagnetic ratio, as well as Lande g factor, rises as the content of Gd increases, with $g=2.16$ at 12% and $g=2.27$ at 15%. The obtained perpendicular anisotropy constant increases strongly with Gd content. The theoretical calculation and analysis will be discussed in the full text.

The energy loss by drag force of superconductor flywheel energy storage system with permanent magnet rotor.

J. Lee, Y. Han, S. Jung, T. Sung, B. Park
Korea Electric Power Research Institute, Daejeon, South Korea

The energy loss is one of the most important problems for the practical use of Superconductor Flywheel Energy Storage system (SFES). The energy loss of the SFES is mainly generated by drag force in the part of magnetic field such as Superconductor Magnetic Bearing (SMB) and PM type Motor/Generator (PMSM/G)[1]. The energy loss by drag force in PMSM/G is much larger than that by drag force of superconductor bearing. In this paper, we assessed the characteristics of the energy loss by drag force generated in SFES and especially the energy loss by drag force according to a change of stator core size of PMSM/G. To do this, the vertical axial type superconductor flywheel energy storage system with journal type superconductor bearing like Fig. 1 (a) is manufactured. To quantitatively assess the energy loss by drag force in the stator core with permanent magnet rotor, after measuring the energy losses by drag force in superconductor bearing and the degree of a vacuum, the energy loss by drag force in the stator core with permanent magnet rotor empirically is measured. Fig. 2(a) shows installation method of the stator core and the PM rotor in flywheel to assess energy loss by drag force according to various stator core sizes. Fig. 2(b) shows PMSM/G model composed of the stator core with the laminated Si-steel and permanent magnet rotor with the diametrically magnetization in lower part of flywheel axis. Like Fig 2(b), when the inner radius R_i and outer radius R_o of stator core, we measured the rotational speed reduction and calculate the energy losses by drag force. where used cores for the test are $R_i=30$ [mm], $R_o=42$ [mm] core(Type A), $R_i=30$ [mm], $R_o=52$ [mm] core(Type B), $R_i=40$ [mm], $R_o=48$ [mm] core(Type C), $R_i=40$ [mm], $R_o=52$ [mm] core(Type D), and $R_i=40$ [mm], $R_o=62$ [mm]core(Type E).

Table 1 shows the hysteresis loss coefficient and the eddy current loss coefficient given by Fig. 3 for each core. From the results of Fig. 3, when inner radius is fixed and outer radius of stator core is increased, energy loss of the SFES is decreased. But from the results of Fig. 4 when inner radius of the core is varied, degree of energy loss in the high speed area and the low speed area is different due to difference of eddy current and hysteresis coefficient. Therefore small inner radius type core is advantageous in flywheel system for high speed rotation and large inner radius type core is advantageous in flywheel system for low speed rotation. From the results, through only change of stator core size, the energy loss by drag force can be reduced. It is confirmed that the energy loss by drag force can be reduced by means of suitable core design according to rotational speed of the SFES, and it will be very useful to design the low loss PM type motor/generator for the SFES.

Analysis of eddy-current loss in a double-stator cup-rotor PM machine.

S. Niu¹, K. Chau¹, J. Jiang²

1. Depart. of Electrical and Electronic Engineering, The University of Hong Kong, Hong Kong, China; 2. School of Electromechanical Engineering and Automation, Shanghai University, Shanghai, China

I. INTRODUCTION

Due to its high power density and high efficiency, the double-stator cup-rotor PM machine has been identified as one of the most promising candidates to work as the integrated-starter-generator (ISG) for hybrid electric vehicles. However, because of its special structure, this machine generally suffers from difficulty in electromagnetic field analysis. Recently, the CFT-TS-FEM has been developed to analyze the dynamic characteristics of PMBDC machines [1]. Increasingly, a grid model of PMs has been incorporated into the CFT-TS-FEM to analyze the eddy-current loss in PMs of electric motors [2].

The purpose of this paper is to propose and analyze a new double-stator cup-rotor PM machine. In particular, the CFT-GM-TS-FEM will be newly developed to analyze the eddy-current loss of a 3-phase 24-slot 22-pole double-stator cup-rotor PM motor.

II. MACHINE STRUCTURE

Fig. 1(a) shows the structure of the proposed double-stator cup-rotor PM machine in which there are two concentric stators and one cup-shaped rotor. Firstly, the cup-shaped rotor can effectively shorten the magnetic circuit length, hence improving the torque density. Secondly, a fractional-slot winding, namely the slot-pitch is 11/12 of the pole-pitch, is adopted which can minimize the cogging torque. Finally, in order to analyze the eddy-current loss with different winding distributions, the single-layer winding and the double-layer winding are separately assessed as shown in Fig. 1(b) and Fig.1(c).

III. ANALYSIS APPROACH

The CFT-GM-TS-FEM is developed. In the rotor domain, the key is to model the PMs and rotor iron core by a grid having N bars along the circumferential direction and M slices along the axial direction. The grid model is shown in Fig. 2. It can be seen that the eddy-current flow can form a complete loop which enhances the accuracy to calculate the eddy-current loss. Thus, the current density in the PM is calculated and the corresponding eddy-current loss is obtained.

IV. RESULTS

Fig. 3 shows the eddy-current losses in the PMs and the rotor iron core with the single-layer winding. The corresponding eddy-current losses with double-layer winding can be obtained similarly. It can be seen that the eddy-current loss in the PMs increases greatly within the commutation time. It is due to the fact that during the commutation of phase currents, there is a drastic change in the armature field and also the magnetic field in PMs, hence greatly increasing the eddy-current loss. Also, it can be found that the eddy-current loss with the double-layer winding is much less than that with the single-layer winding. The reason is that the single-layer winding has more concentrated winding distributions, which causes greater local armature reaction and hence higher eddy-current loss. However, due to the fact that the single-layer winding has higher self-inductance and lower mutual inductance than the double-layer winding, it offers improved controllability for ISG application. Thus, the single-layer winding is used for experimentation.

Fig. 4 shows the simulated phase current waveforms (with and without considering the eddy-current loss) and the measured one when the machine operates at the rated conditions. It can be seen that the simulated waveform, that has considered the eddy-current loss, can closely match with the

measured one. Table I shows the comparison between the calculated and measured efficiencies in the proposed machine with the single-layer winding. It verifies that the calculated efficiency, that has considered the eddy-current loss, closely agrees with the measured one.

Comparison of stator-permanent-magnet brushless machines.

C. Liu, K. Chau

Dept. of Electrical and Electronic Engineering, The University of Hong Kong, Hong Kong, China

I. INTRODUCTION

Due to high efficiency and high power density, permanent-magnet (PM) brushless machines have been widely used. The corresponding stator-PM versions, including the doubly-salient PM (DSPM) and PM hybrid brushless (PMHB), take the definite advantage of high mechanical integrity. Their outer-rotor topologies are particularly attractive, since they enable direct driving for electric vehicles [1] and wind power generation [2]. However, a quantitative comparison of these two emerging machines is absent in literature.

The purpose of this paper is to quantitatively compare the outer-rotor DSPM and PMHB machines based on the same peripheral dimensions. Moreover, their cost analysis will be revealed.

II. FEATURES

Fig.1 shows the topologies of the proposed machines. The DSPM is simply excited by PMs, whereas the PMHB is hybrid-excited by both PMs and DC field windings. So, the PMHB can provide flexible air-gap flux control. Also, it utilizes an additional air bridge in shunt with each PM to amplify the flux weakening ability. For comparison, both machines adopt the 36/24-pole fractional-slot winding structure.

III. COMPARISONS

Based on the same peripheral dimensions, the outer-rotor DSPM and PMHB machines are designed. Their key design data are summarized in Table I. Since the DSPM can accommodate more PMs than the PMHB, its power density is higher. However, this merit in power density is offset by the high cost of PMs. From Table II, it can be seen that the total material cost of the PMHB is only 57.2% of the DSPM. Actually, the corresponding costs per unit torque and unit power are less than that of the DSPM. Therefore, the PMHB is more cost-effective to produce the desired torque and power.

Fig.2 shows the magnetic field distributions of the two machines. It can be seen that the PMHB has a good ability of flux control. Also, Fig.3 shows their air-gap flux density. It can be found that the PMHB has a very wide range of flux regulation (up to 9 times). Due to the use more PMs, the DSPM can produce higher torque. Nevertheless, as shown in Fig.4(a), the PMHB can utilize flux strengthening to increase the torque up to 85.7% of the DSPM even though its PM volume is only 19.2% of the DSPM. Also, as shown in Fig.4(b), the PMHB can significantly extend the operating range up to 4000 rpm, and provide flux weakening at high speeds to achieve higher efficiency than the DSPM.

Fig.5 shows the no-load EMFs of these machines at different speeds. Because of uncontrollable flux, the DSPM generates the EMFs which are speed dependent. With flux control, the PMHB can uniquely achieve a constant EMF, namely flux strengthening at 300 rpm and flux weakening at 2700 rpm. This property is particularly useful for wind power generation. On the other hand, Fig.6 shows the transient starting torques (normalized by the rated values) for a load of 40 Nm when the armature current is limited to 2 times the rated value. It can be seen that the PMHB can produce a very high starting torque with flux strengthening. The corresponding normalized value is even higher than that of the DSPM. This property is particularly useful for cranking hybrid electric vehicles.

Segmentation of magnets to reduce losses in permanent magnet synchronous machines.

P. Sergeant, A. Van den Bossche

Department of Electrical Energy, Systems and Automation, Ghent university, Gent, Belgium

The currents in the magnets on the rotor surface of permanent magnet synchronous machines (PMSM) are generated by on the one hand higher order stator space harmonics introduced by the stator slots (studied in [1] and [2]), and by on the other hand high frequency components in the supply voltages in case of supply with pulse width modulation (PWM), studied in this paper. The aim is to focus on the effect of axial and circumferential segmentation of the magnets on the losses in the magnets and the (massive) rotor yoke. The losses should be minimal because a too high temperature in the NdFeB magnets deteriorates their magnetic properties.

For a PMSM with known geometry, a study of losses in the magnets requires the exact knowledge of the magnet conductivity. To determine the conductivity accurately, firstly one magnet - identical to the magnets in the PMSM - was tested separately outside the PMSM. Secondly, the obtained conductivity was used in a time-harmonic numerical model to study the losses inside the PMSM for sinusoidal waveforms. In a last part, the losses for square waveforms are approximated by a superposition of losses for sinusoidal waveforms.

By the identification of the magnet conductivity outside the PMSM, disturbing factors such as large eddy currents in the rotor yoke and uncertainty on the air gap are eliminated. The circuit consists of the magnet on a top of a finger shaped yoke in laminated grain oriented magnetic material with an excitation and a measurement winding. A 3D time-harmonic finite element model (FEM) was made of the setup. The determination of the conductivity is an inverse problem that can be solved from the measured losses against frequency and the 3D numerical model. For sinusoidal flux with constant amplitude, Fig. 1 shows that for a magnet conductivity of 0.6 MS/m, the measurements and simulations correspond well.

With this conductivity, the second part of the research - the study of losses in the (segmented) magnets inside the machine - can be carried out. To avoid a computationally demanding 3D time-harmonic model of the entire PMSM, a 2D and a 3D numerical model are combined like in [2]: the field pattern in the air gap is found from a 2D FEM of the entire PMSM. This pattern is used as a source term in a 3D FEM of the magnet and rotor iron only. At the high frequencies of PWM however, the eddy currents are too large to neglect their influence on the imposed induction like in [2]. Therefore, the 2D model is a time harmonic simulation (not static as in [2]) that has also the correct conductivity for rotor yoke and magnet.

The losses are shown in Fig. 2 for 10 kHz sinusoidal frequency. The measured loss in case of unsegmented magnets (1622 mW) is close to the simulated one (1735 mW) in the figure. Correspondence was observed for frequencies in the range 100 Hz to 50 kHz. Creating axial and circumferential segmentation in the magnets causes a large reduction of losses in the magnet, especially when the segments are in circumferential direction (Fig. 2). The losses in the massive rotor yoke are small compared to the losses in the magnet. With increasing amplitude of the input voltage, the losses increase quadratically with the voltage as expected for eddy current losses.

In a third step, losses in the PMSM have been measured for square waves. The correspondence with superposition of losses in the sinusoidal case - only valid in case of linear system - is acceptable: at 10 kHz for example, the losses for a square wave of 10 V rms are 1.825 W while the losses for the superposition of relevant sinusoidal waveforms up to 90 kHz are 1.801 W. The full paper will present a more detailed study of losses for square waveforms, also for different rotor angles of the PMSM.

Measured and simulated eddy current loss of the magnet tested under constant flux amplitude in a magnetic circuit outside the motor correspond well for a magnet conductivity of 0.60 MS/m.

The eddy current loss in the magnets decreases strongly for increasing number of circumferential magnet segments m and decreases weakly for increasing number of axial magnet segments n

Cogging Torque Reduction in Brushless DC Motors Due to the Magnetization Distribution in Permanent Magnets.

T. Ishikawa¹, K. Yonetake¹, M. Matsunami¹, M. Tsuchiya²

1. Electronic Engineering, Gunma University, Kiryu, Japan; 2. Tokyo Parts Industrial Co., LTD., Isesaki, Japan

1. INTRODUCTION: Brushless DC motors with permanent magnet are widely used in industrial applications and computer peripheral devices. They become smaller and higher power by use of high-grade magnet. As a result, the torque ripple is increased. This ripple can lead to mechanical vibration, acoustic noise and problems in drive systems. Therefore, it is necessary to reduce the torque ripple. The torque ripple contains both cogging torque and commutation torque components, and the cogging torque is the primary ripple component of the brushless DC motors. In the literature, several methods have been proposed to reduce the cogging torque such as changing stator teeth shape, changing magnets shape, shifting magnets and skewing [1]-[4]. Another method of reducing cogging torque has been studied by changing the magnetization distribution in the permanent magnets [5]-[8]. In [8], we have shown that the cogging torque changes large, small and then large again, when the magnetized region of permanent magnets becomes large. In the analysis, the magnetization distribution has been assumed as a linear function. However, the calculated value of cogging torque does not quantitatively agree with the experimental ones. This paper assumes the magnetization distribution as a sigmoid function, whose shape changes smooth. First, this paper experimentally investigates the cogging torque by changing the excitation voltage of magnetizer. Next, this paper analyzes the cogging torque and magnetic flux density by assuming the magnetization distribution in the magnet as the sigmoid function and compares with the measured ones of the experimental motor.

2. COGGING TORQUE FOR THE EXCITATION VOLTAGE OF MAGNETIZER: Fig. 1 shows the cross section of the exterior-rotor type brushless DC motor with 12 poles and 9 teeth. The Nd-Fe-B permanent magnets are radially magnetized. Fig. 2 shows the measured cogging torque characteristics of the motor when it uses the permanent magnets magnetized with the excitation voltage of 800V, 1000V and 1200V, respectively. The cogging torque magnetized with the excitation voltage of 1000V is small in comparison with those of 800V and 1200V. Therefore, it is found that there is the optimum level of the excitation voltage to reduce the cogging torque. The optimum voltage is about 1000V for the experimental motor.

3. ANALYSIS OF COGGING TORQUE CHARACTERISTICS: The magnet is divided into 30 segments, and the residual magnetization ratio in each segment is assumed by (1). In the equation, a_1 , a_2 and a_3 are the maximum value, shift and inclination of the sigmoid function, respectively. The simulation is performed by setting the arbitrary values of three parameters of sigmoid function and by calculating with 2-D nonlinear FEM. Figs. 3 and 4 show the components of flux density and cogging torque. When the parameter $a_1=1.3$, $a_3=0.255$ and a_2 changes from 0.55 to 0.67, the calculated flux density and cogging torque have good agreement with the experimental ones for the excitation voltage of 800 through 1200V. When the parameter a_2 becomes large, the magnetized region becomes large. This corresponds to the high excitation voltage.

4. CONCLUSIONS: It is shown experimentally that the cogging torque can be very small by choosing the excitation voltage of magnetizer to be the optimum level. This paper has proposed that the magnetization distribution is expressed by the sigmoid function, when the excitation voltage of magnetizer is changed. It is possible to explain the cogging torque characteristics quantitatively by changing the parameter of sigmoid function according to the excitation voltage.

Negative Stiffness of Toroidally-Wound BLDC Machine.

M. Noh, H. Lee

Mechatronics Engineering, Chungnam National University, Daejeon, South Korea

Toroidally-wound brushless direct-current (BLDC) machines are compact, highly efficient, and can work across a large magnetic gap [1,2]. For these reasons, they have been used in flywheel energy storage systems and left ventricular assist devices [3]. The common feature of these systems is a spinning rotor supported by a set of (either mechanical or magnetic) bearings. From the viewpoint of dynamics and control, it is desirable to increase the first critical speed of the rotor. The first critical speed of the rotor is determined by the radial stiffnesses of the bearings and the rotor mass. The motor also affects the first critical speed if the rotor is displaced from the rotating center, because the rotor magnet tends to stick to the stator iron. This radial instability can be expressed as a negative stiffness.

In this paper, we analytically derive the flux density distribution in a toroidally-wound BLDC machine. Using this flux distribution, we can obtain an analytic expression for the negative stiffness of the motor after assuming that the radial displacement of the rotor perturbs the flux density distribution linearly.

For a two-pole, radial gap, toroidally-wound machine as shown in Fig. 1, the flux density distribution in the air gap can be obtained by solving the potential equation $\nabla^2\psi = \nabla \cdot \mathbf{M}$, where ψ is defined as $\mathbf{H} = -\nabla\psi$ and \mathbf{M} the magnetization vector. Since the machine has two poles, the magnetization vector can be written as $\mathbf{M} = H_c \cos\theta$. Applying appropriate boundary conditions, the above potential equation can be solved analytically. This analytic solution is verified against a finite element analysis.

Once the flux density distribution is obtained, we can introduce a small perturbation due to the radial displacement (see Fig. 2). The perturbed flux density distribution can be integrated along the rotor surface to calculate the force due to the radial displacement. If we differentiate this force with respect to the displacement, we can calculate the negative stiffness of the machine. Finite element analyses show the validity of the negative stiffness model.

A STUDY ON THE DESIGN OF AN INSET PERMANENT MAGNET TYPE FLUX-REVERSAL MACHINE.

T. Kim

Electrical Engineering, Gyeongsang National University, Jinju, South Korea

I. Introduction

Flux-reversal machine (FRM) is a doubly salient machine with permanent magnets on the stator. The permanent magnet flux linkage in the stator phase concentrated coils reverses polarity with the rotor traveling [1]. Its simple structure makes it cost effective and suitable for mass production. It has a low self and mutual inductances, hence a low electrical time constant and high fault tolerance. However, there is notable permanent magnet flux leakage (fringing) and cogging torque caused by its structure. This flux leakage deteriorates the power density and torque ability of the FRM. The cogging torque also produces a pulsating torque ripple resulting in vibration and acoustic noise that is detrimental to the machine performance. In this paper, the new inset permanent magnet type FRM to improve the performance of the FRM is proposed both theoretically and experimentally. To analyze the characteristics of the proposed FRM, a two-dimensional finite-element method (2D FEM) is used. From the analysis and experimental results, it is shown that the proposed FRM has an improved performance.

II. The proposed FRM

Fig. 1 compares the proposed inset magnet type FRM with the conventional one. This new FRM has the permanent magnets parallel to the stator magnet flux lines and thus is much more difficult to demagnetize. To prove the performance improvement of the proposed FRM, these FRMs were designed to have the same specifications (such as stator and rotor outdiameter, stack width, and winding turns) except the amount of the permanent magnet used.

III. Results and Discussion

The torque and back electromotive force (BEMF) constant of the FRM are the same. So we can know the torque ability from the BEMF waveform. Fig. 2 compares the BEMF of the conventional and that of the proposed FRM at 1500 rpm. There is no difference in the generated BEMF although the amount of the permanent magnet used in the proposed FRM is the half compared to the conventional one. This is because the flux leakage in the air-gap is reduced and the magnetic circuit becomes effective. Fig 3 and 4 show the cogging torque and iron loss, respectively. It is shown that the proposed FRM also has small cogging torque and iron loss. This is due to the small variation of the air-gap flux density in the proposed FRM. From these analysis results, we can know that the proposed inset type FRM is much more effective to improve performance such as power density, torque ability, and cogging torque. Also it is very useful for material (permanent magnet) cost reduction.

A Comprehensive Comparison of Flux-Switching and Flux-Reversal Brushless PM Machines.

H. Wei, C. Ming, Z. Wenxiang, Z. Jianzhong, J. Hongyun
School of Electrical Engineering, Southeast University, Nanjing, China

PURPOSE:

The brushless PM machines having magnets in rotor, either being surface-mounted or interior, have been widely studied and used, which are classified as rotor-PM machines. However, the location of the magnets and the poor thermal dissipation compromise the performance and applications of the rotor-PM machines. Fortunately, a new type brushless PM machines, which can be classified as stator-PM machines, are emerged, including the doubly-salient permanent magnet (DSPM) machine [1], the flux-reversal permanent magnet (FRPM) machine [2], and the flux-switching permanent magnet (FSPM) machine [3]. All of the stator-PM machines have the commonness in the followings: (i) The magnets are located in the stator instead of rotor; (ii) The rotors are composed of the laminations with saliency, similar to that of the switched-reluctance machines; (iii) The concentrated windings are employed to reduce the end-windings; (iv) The electromagnetic torque is dominated by the interactions between the magnets field and armature currents, i.e., the PM torque, and the reluctance torque can be negligible. Although the stator-PM machines are proposed as competitive candidates to replace the rotor-PM counterparts, the performance evaluation between the three stator-PM machines is only restricted on FSPM machine and DSPM machine [4]. Therefore, in this paper the electromagnetic performance of a FSPM and FRPM motors are compared and evaluated.

METHOD:

Both the FSPM and the FRPM motors chosen to be investigated have the same stator teeth number, rotor poles number, stator outer diameters, stack lengths, and rotor inner diameters. The common specifications are listed in Table 1. Based on the FE analysis, the static characteristics of the two motors with the same volumes are compared and evaluated, including the magnetic field distribution, airgap flux density waveform, phase PM flux-linkage, phase back-EMF, inductances, cogging torque, and electromagnetic torque, etc. In addition, due to the different locations and volumes of the permanent magnets, the corresponding ratios of the torque vs. magnets consumption, torque vs. mass, etc, are also taken into account.

RESULTS:

Fig. 1 shows the topologies of the DSPM and SPM motors and the field distributions at no-load. According to the predicted and the experimental results, it is found that the two motors have some important commonness, which are different from those of DSPM motor: (i) The coil PM flux-linkage of the both motors are bipolar; (ii) The flux-linkage and back-EMF harmonics in coils composing one phase windings can be canceled, resulting in the phase back-EMF waveforms are essentially sinusoidal for both motors as shown in Fig. 2, although the concentrated windings are employed; (iii) The back-EMF per turn of the FSPM motor is significantly larger than that of the FRPM counterpart, which indicates the torque capability of the FSPM motor is prior to that of the FRPM motor. Hence, the FRPM is specifically designed to have the same peak value of phase back-EMF as that of FSPM motor with more copper as shown in Fig. 3. In the full-paper, a detailed comparison between the two motors will be presented and evaluated.

Optimization and electromagnetic analysis of stator interior permanent magnet machine with minimum cogging torque.

J. Zhang, M. Cheng, W. Zhao

school of electrical engineering, Southeast University, Nanjing, China

Introduction: The doubly salient permanent magnet (DSPM) machine, which incorporates the switched reluctance machine with permanent magnet (PM), has been advent since 1990's. As there is no winding, no brush and no PM on the rotor, the DSPM machine offers the advantages of high power density and high reliability [1]. In [2], a double salient flux-switching permanent magnet (FSPM) machine with bipolar flux variation is proposed, which may improve the power density dramatically. However, the FSPM machine suffers from large cogging torque and high PM material consumption. Then it is unsuitable for the FSPM machine to apply in large power capability, such as modern wind turbines. In [3], a new stator interior permanent magnet (SIPM) machine, which may be understood as an improved FSPM machine, is proposed. The SIPM machine has reduced cogging torque while the power density is still keeping higher as the FSPM machine. The purpose of this paper is to carry out the optimization of the SIPM machine for minimizing the cogging torque and analysis the electromagnetic performance.

Method: In this paper a new SIPM machine is proposed as shown in Fig. 1(a). It is shown that the SIPM machine has the same salient-rotor as switched reluctance machine. The stator, if neglecting the PM which is inserted into the stator tooth, is nearly same as the brushless DC machine. The retained iron bridge keeps the stator in a whole and improves the stiffness of the machine. The extended tooth pole shoe not only decreases the airgap flux density, but also reduces the PM material cost, since the higher airgap flux density may cause large flux leakage and saturation in iron core. The SIPM machine may be optimized by selecting proper variable parameters, namely PM thickness, PM length, stator tooth width and slot opening. Before the optimization begins, the original design of the SIPM machine may be seen same as the FSPM machine since there has close ties between two machines. During the optimization, the variable parameters are designed to keep the output power same as the original design. The finite element analysis (FEA) is then used to analysis the electromagnetic performance of the machine under certain parameters.

Results: Fig. 1(b) shows the magnetic field distributions of the SIPM machine. Fig. 2(a) shows the cogging torque ripples of the SIPM machine according to the variation of the PM thickness. It is shown that the thinner PM thickness is more favor for minimizing cogging torque. Fig. 2(b) shows the cogging torque ripples according to the variation of the stator slot opening. It is shown that there has an optimal slot opening where the minimized cogging torque is achieved. A prototype machine is designed, built and tested. The comparison of cogging torque is shown in Fig. 3. It can be seen that the experimental results agree with the predicted ones very well, therefore have verified the correctness of the theoretical analysis.

Introduction

The line-start interior permanent magnet synchronous motor (LSIPMSM) presents an interesting and energy-high-efficient alternative for induction motors (IMs) widely used in low-cost electric drives, where the usage of a voltage-source inverter is too expensive. The LSIPMSM unites the advantages of the IM (robust construction and line-starting capability) and the usual interior permanent magnet synchronous motor (high values of torque per unit current density, power factor and efficiency; especially when compared to IMs with small rated power). The LSIPMSM has permanent magnets buried below the squirrel-cage, thus it operates in steady-state as a usual synchronous motor, where the rotor speed is mainly voltage source frequency dependant; the squirrel-cage is used for line-starting and damping of dynamic oscillations at fast load changes.

However, the design of LSIPMSMs is somehow troublesome, because of various performance degrading effects when the motor is line-started (permanent magnet breaking torque [1,2], breaking reluctance torque, asynchronous and synchronous parasitic torques). A wider usage of LSIPMSMs therefore demands an accurate and experimentally verified design procedure, because the motor designer has to find many compromises in the design process. If a LSIPMSM should replace an existing IM, then the LSIPMSM has to be able to line-start and synchronize under load. Furthermore, the LSIPMSM has to have a higher or at least an equal torque per unit stator current density value and a higher efficiency value in its steady-state synchronous operational region.

Three- and single-phase LSIPMSM design procedure

The formalized three- and single-phase LSIPMSM design procedure is the main focus of the proposed paper. The proposed procedure was experimentally validated by conducting measurements on prototypes. The three- and single-phase LSIPMSMs and IMs had equal: stator lamination geometry, stator winding design, skewing factor, squirrel-cage design and equal materials, respectively; which enabled the direct comparison of LSIPMSM and IM performance characteristics. As far as the authors of this paper are aware, such a design procedure supported by measurements of three- and single-phase LSIPMSMs and IMs with equal squirrel-cage design, has not been reported yet. The design procedure includes the usage of the finite element method (FEM) for an accurate energy balance determination in different steady-state operating points of LSIPMSMs, where the LSIPMSM problem is considered as 2D. 3D effects are included in form of concentrated parameters. Lumped parameter models are employed in analysis of dynamic states of LSIPMSMs, where the electrical and also the mechanical subsystem are considered. The proposed LSIPMSM design procedure represents a compromise between the solution accuracy and the time which is needed to obtain the solution. Several details of the proposed procedure are to some extent similar to the individual methods used in [1-4].

The full paper will present all details of the LSIPMSM design procedure and also the used experimental methods for determination of parameters and characteristics of three- and single-phase capacitor-run and capacitor-start LSIPMSMs. Furthermore, the predicted calculation results in steady and dynamic states are going to be compared to measurement results.

Some measurement results

The aforementioned LSIPMSM design procedure was validated by experimental results. Also it was experimentally confirmed that all the tested LSIPMSMs had sufficient line-starting capability. The measured characteristics of three-phase and single-phase capacitor-start LSIPMSMs and IMs efficiency (EFF), power factor (PF) and their product (EFF*PF) in steady-state are shown in Fig. 1a and Fig. 1b, respectively. The three-phase IM was rated for 1,1 kW and the single-phase capacitor-start IM was rated for 0,55 kW; both at 1400 rpm and 50 Hz supply. Figs. 1a and 1b evidently show that the LSIPMSM's efficiency and power factor are superior when they are compared to the IM's efficiency and power factor values. In thermal equilibrium the three-phase LSIPMSM's winding overtemperature was around 35°C lower than the IM's; the single-phase capacitor-start LSIPMSM's winding overtemperature was around 28°C lower than the IM's. A detailed analysis will be provided in the full paper.

Design and analysis of large capacity line-start permanent magnet synchronous motors.

Q. Lu, Y. Ye
college of electrical engineering, Hangzhou, China

Introduction

The iron and steel industry needs a lot of large-capacity motors to drive fans and pumps, so that the efficiency of motors is important to save energy. Now high efficiency induction motors are popular. Due to their efficiency and power factor are improved to their limitation by optimization, the higher efficiency line-start permanent magnet synchronous motors(LPMSM) will replace them. LPMSM starts up by induction torque and runs by synchronous torque, which has advantages of both induction motor and permanent motor.

Design and analysis of LPMSM

Since the permanent magnet produces reverse torque during starting, the LPMSM's starting capacity with load is lower than that of induction motor. The starting torque has two minimum values, one at low speed and the other at a little higher than half of synchronous speed. If the minimum starting torque is lower than load torque, the LPMSM can't start successfully. Therefore, the most important is to obtain its' dynamic starting torque when designing LPMSM. In order to lower the manufacture cost, the LPMSM keeps the structure of induction motor as possible, but its stator is skewed by one rotor slot pitch to reduce the cogging harmonic.

Fig.1 shows the 2D dynamic FEM model of the designed 4-poles, 250kW LPMSM. Since the 2D dynamic FEM model can only consider the effective length of lamination, the windings end should be calculated by analytical method. To stator windings, the resistance and leakage inductance per phase are obtained and then added to every phase windings. To rotor squirrel-cage bars, the resistance and leakage inductance of end ring are calculated and then they are inserted to rotor windings. In this dynamic FEM model, the mesh of rotor bars need be small enough to consider skin effect. The air gap length is divided into four equal parts, which two parts near stator is motionless and the others belong to moving parts. Fig.2a), b), c) shows magnetic field at no load, no-load air gap flux density, back-EMF respectively.

When the LPMSM is used to drive fans, the initial load is assumed 30% of rating load and then increases along with the speed square. After applied this load, the dynamic starting process is obtained by FEM method, the results are shown in Fig.3. After the oscillation at low speed due to permanent magnet, the motor increases to synchronous speed 1500r/min. The starting time is longer than that of induction motor. The starting current and electromagnetic torque are much bigger than rating values. Fig.3 b) shows half of the rating current because the model is half of this motor. The calculation value of whole motor is 424.3A, which is smaller than that of induction motor, 437.5A. The simulated efficiency, power factor are 0.96, 0.932, which is higher than that of induction motor.

By the model, the effect of permanent magnet is investigated, including the position and size. The air gap flux density becomes higher when permanent magnet is closer to rotor bars. The factual distance between permanent magnet and rotor bars is limited by flux density. The height of permanent magnet also affects the air gap flux density, but it has the optimal value. The results will be described in full paper.

Prototype and conclusion

A prototype is making in factory now. By experiment of induction motor, the 2D dynamic FEM model is proved correct. Therefore the results of LPMSM are believable. Since LPMSMs have

higher efficiency and power factor than induction motors, the energy will be saved by adopting them in industry.

An Application of the Latin Hypercube Sampling Strategy for Optimal Design of Large Scale Permanent magnet pole using Adaptive Response Surface Method.

P. Shin¹, S. Woo¹, Y. Zhang², C. Koh²

1. Electrical Engineering, Hongik University, Chungnam, South Korea; 2. Electrical and Computer Engineering, Chungbuk National University, Chungbuk, South Korea

1. Optimization Algorithm and Strategy

An efficient hybrid optimization algorithm is applied to a large scale permanent magnet of BLDC motor(6MW) which is used for the propulsion system of electric trains or vessels. The proposed hybrid optimization algorithm consists of an optimal Latin Hypercube Sampling(LHS) strategy based on multi-objective Pareto optimization and an adaptive response surface method(RSM) with $(1+\lambda)$ evolution strategy[1,2]. The optimal LHS strategy is to insert the sampling points adaptively in successive “zoom-out” design space and to improve the quality of distribution of sampling data[2]. The algorithm has 4 steps: 1) to generate the initial sampling points using LHS, 2) to construct the response surface and to find a pseudo-optimal point using $(1+\lambda)$ evolution strategy, 3) to check the convergence, 4) to generate additional sampling data within the reduced design space at the neighborhood of the pseudo-optimal point. Once the pseudo-optimal point is found, it is used as a central point for the definition of “zoom-out” design space, in which the additional sampling points are inserted by means of LHS algorithm. Then, the response surface is constructed again and the procedure repeats until the true global optimal point is found. The response surface method also uses the multiquadric radial basis function to interpolate the objective function in design parameter space[3,4].

2. Numerical Example and Results

In order to verify the developed algorithm, a 6 MW BLDC motor is simulated with 4 design parameters(arc length and 3 variables for magnet) and 4 constraints for minimizing of the cogging torque. The rotor has 32 magnet poles, whose cross-section is 60mm x 260mm, and the stator has 196 slots. The optimization procedure has two stages; the first is to optimize the arc length of the PM and the second is to optimize the magnet pole shape by using the proposed hybrid algorithm. In the first stage, as shown in Fig. 1(a), the angle P_A is taken as a design variable with a constraint to make sure of the minimum volume of the PM.

The objective function, F_{1st} is

$$\text{minimize } F_{1st} = \sum \{(W_i - W_0)/W_0\}^2, \text{ subject to } 0.4 \leq P_A \leq 10.0 \text{ deg.} \quad (1)$$

where W_i and W_0 are the stored magnetic energy in the motor at i -th computing position and the average magnetic energy, respectively. As result of the 1st stage, the arc length of the magnet is optimized to 2.67 degrees as shown in Fig.1(b).

In the second stage, the pole shape of PM is optimized under the constraints of the optimum arc length. The PM pole shape is parameterized with 3 design parameters (h_1, h_2, h_3) as shown in Fig. 2(b). The design target is defined as:

$$\text{minimize } F_{obj} = \sum (W_i - W_0), \text{ subject to } 0 \leq h_1 \leq 2, 0 \leq h_2 \leq 5, 0 \leq h_3 \leq 10 \text{ [mm]} \quad (2)$$

The design sensitivity is also computed by using the results of FE analysis to get a more elaborate response surface with less sampling points. In the 1st iteration of the optimization procedure, a response surface is constructed by using 125 sampling data points generated by LHS experiment and the first pseudo-optimal point is obtained at $(h_1, h_2, h_3) = (0.0, 3.8, 5.5)$. In the second iteration, 44 additional sampling points are inserted at the neighborhood of the first pseudo-optimal point in the reduced design space by a factor of 0.85. At the 3rd iteration with 48 additional sampling points, the final optimal point (0.6, 2.1, 6.2) is obtained. The optimized cogging torque is tremendously

reduced to 390(Nm) from 2,158 (Nm) of the initial model. Fig. 2(a) shows the sampling points and corresponding response surface, and Fig. 2(b) shows the optimized shape of PM with the final design values and the initial shape. It seems that 3 iterations are good enough to obtain the optimal design parameters in the proposed hybrid optimization strategy.

Consequently, the proposed hybrid optimization algorithm has novel advantages in its good convergence and low computing cost compared with other methods.

Development of an axial-flux brushless motor for low-profile fan applications.

2. Metal Industries Research & Development Centre, Kaohsiung, Taiwan

With the rapid development of electronics, numerous noteworthy designs of cooling components have been also proposed to protect systems from overheating. High performance cooling products such as heat pipes, heat sink modules are being constantly developed, but fans remain one of the most economical ways to remove heat. In the past, fans could be satisfied by conventional radial-flux brushless motors. However, as the drive specifications have become more demanding, it has been difficult to design a radial-flux motor that can achieve the required decrease in thickness. Hence, the axial-flux motor became a more attractive choice due to its low profile [1] [2]. In this paper, a slim axial-flux brushless motor is developed for low-profile fan application, as shown in Fig.1. The structural motor design has to eliminate any surplus space, which a three-phase printed circuit board (PCB) winding is utilized.

Prior to prototype development, a full assessment of the electromagnetic design to calculate the geometrical parameters is essential. Without considering the impellers, the present study is primarily concerned with the design of the fan motor for which to achieve desired performance subject to constraints, such as limited space, flux saturation, and driving voltage. In the design process, the thickness of the motor is assumed to be smaller than 2.5 mm and possess an exterior diameter of less than 1.2 mm, for compact size purposes. The motor constant, which describes how efficiently a motor produces torque, is taken as the objective function. The genetic algorithm is used to find the suitable variables based on the objective function where the constraints and independent variables are given analytically with an equivalent magnetic circuit. Finite element analysis (FEA) is then applied to validate the analytical calculations. In order to confirm the design results, the slim axial-flux motor and low-profile fan were constructed as shown in Fig.2. The fan motor utilizes a three-layer PCB winding which is 0.6 mm in height. Each layer has six concentric coils. The number of turns per coil is determined by 21 turns. A sintered NdFeB magnet is applied to provide sufficient flux energy, and a commercially available drive IC has been adapted to make the motor rotate successfully. Figure 3(a) shows the back-EMF waveform which was measured at a speed of 1000 Hz. The peak value was 0.63 V which meant that the back-EMF constant was 0.39. This paper applies the mathematic motor model to estimate the characteristics of the fan motor. Substituting the winding resistance and back-EMF constant into the motor model, reasonable performances of the proposed motor could be found. Figure 3(b) shows the estimated relationships between torque and speed when the input voltages were 5 and 3.3 Volts. More Characteristics of the fan motor are also presented in Fig.4. In conclusion, the simulated and measured results suggest that the developed fan motor may be a promising component in cooling applications.

Sliding Mode Control for Optical Image Stabilization Actuators.

H. Yu^{1,2}, T. Liu¹, C. Chiang¹

When photographers take pictures in dark, the blurred images will easily cause from hand jitter especially in longer exposure time. Thus, optical image stabilization actuators (OISAs) become the most popular mechanically compensative approach to improve the image quality of cameras, recently. The representative methods for OISA have lens shifting [1] [2], and image sensors shifting [3] [4]. However, lens shifting method is not appropriate for structural miniaturization and slimming in mobile phone cameras (MPCs) with mega-pixel resolution because a compensative lens which causes non-linearity is adopted to compensate the optical axis. Relatively, image sensor shifting method is more suitable than the lens shifting method; hence the OISA design method in this work is proposed by shifting image sensor. Several literatures concerning OISA are emphasized mainly OISA design methods [3] [4], and they are devoted to minimize structural dimensions and maximize electromagnetic force with low power consumption. Although proportional-integral-derivative controllers and digital lag-lead compensators have been proposed to position dual axes in OISA system, but they lack robustness to compensate non-uniform friction, uncertainty, and external disturbance. Therefore, this work aims at the sliding mode control (SMC) using pole placement to achieve fast time response and accurate position despite vibration from hand jitter and friction in the OISA system [5]. In order to suppress image caused by hand jitter, the mechanical structure of the OISA has been designed as shown in Fig. 1. The mechanism of the OISA system is mainly composed of a movable platform and a stationary base. The movable platform for carrying image sensor equipped with an upper cover, a printed circuit board (PCB) with coils, a thrust ball bearing, and a lower base. The movable platform is actuated on two-dimensional plane while driving current is applied to the coils which layout on the PCB. Four permanent magnets are symmetrically assembled on a stationary base to create a strong magnetic field for actuating the image sensor on the movable platform. Moreover, two gyro sensors of yawing and pitching mounted on the OISA system sense the vibration, and two Hall effect sensors of both horizontal and vertical directions fixed on the PCB can be adopted to track the position of the movable platform by measuring the magnetic fields of the permanent magnets, and then inform the current position of the image sensor to computer exactly. All elements are tightly integrated in a small package, and work together to precisely control the position of the image sensor on the movable platform. Once the optical axis of a MPC is off center by vibration, OISA adjusts the center of image sensor to the optical axis. The computer processes the signals which acquire from the gyro and hall sensors via signal acquired cards, and SMC algorithm has been developed to position accurately. Accordingly, sliding functions of dual axes are arranged in terms of errors and are based on the pole placement technique by choosing the desired eigenvalues to obtain sliding margins. Additionally, the sliding surface can be reached in finite time for matching uncertainty and disturbance; hence the simulated block diagram by using SIMULINK is shown in Fig. 2(a). As a consequence, the SMC algorithm works well despite uncertainty and disturbance, and the resulting time responses of simulation and experiment are shown in Fig. 2(b). The setting time is 0.2sec when the movable platform of the OISA moves at 0.5mm stroke.

Characteristic Comparison between the Spiral and Lamination Stator in Axial Field Slotless Machines.

S. Lee¹, J. Hong¹, T. Lee², J. Park²

1. Automotive Engineering, Hanyang university, Seoul, South Korea; 2. Mechanical Engineering, Hanyang university, Seoul, South Korea

Axial flux type machines are used for VCR, CD player, and the spindle motor applications due to the small size and rugged construction features [1]. Therefore, many papers dealt with the characteristic comparison regarding several axial flux type machines compared with radial gap permanent magnet (PM) machines [2], [3]. However, the study on the electromagnetic, mechanical, and manufacturing characteristics according to the change of the stator structures is not performed.

For easy manufacture, the lamination stator is more useful than the spiral stator but the lamination stator in axial flux type machines increases the eddy current loss. On the other hand, the spiral stator increases the magnetic resistance under the same stator volume compared with the lamination stator because the compress condition between layers in radial direction is not precise by the complexity of manufacture. Therefore, the required current quantity and the machine efficiency are determined by the relationships between the eddy current loss and the back electromotive force (back-EMF) according to the use of the spiral or the lamination stator.

In order to reduce the noise generated from the vibration, the structural resonances move to higher frequencies by increasing the stiffness. Although the weight, the volume, and the whole shape of the spiral and the lamination stator are nearly same, the resonant frequencies of each stator are different due to the difference of the stiffness by structure features.

In this paper, the characteristic comparison, which consists of back-EMF, copper and core loss, current shape, resonant frequency, SPL, and manufacturing cost etc., is experimentally shown between the spiral and the lamination stator in an axial field slotless machine. Therefore, this research is usefully applied to the study on the initial design stage of axial flux type machines.

Fig. 1(a) shows the configuration of the rotor in an axial field slotless single air-gap machine which has 12 poles and 9 slots and mechanical air-gap between PM and coil is 1.5 mm. It is operated by sine-wave method and its nominal operating speed is 100 ~ 2000 rpm and rated torque is 3.0 Nm at the 500 rpm. Fig. 1(b) expresses the spiral and the lamination stator which are made of the same silicon steel. The stack length in axial direction is 2.5 mm and the width of stator in radial direction is 12.75 mm. When the thickness of one layer 0.5 mm, the lamination stator is stacked by 5 layers in axial direction and the spiral stator consists of 51 layers in radial direction.

In order to measure the back-EMF and core loss, Fig. 2(a) shows the experimental configuration. The axial machine is revolved by the dc machine. When dc machine rotates alone and with the axial machine at the same speed, the difference of input power of dc machine is occurred by the core loss. Fig. 2(b) shows the configuratin of noise experiment in the anechoic room. The background noise is 21 dBA and measured 0.5 m away from the axial machine by microphones. As a load of the axial machine, a fan is coupled with the axial machine.

As the electromagnetic characteristics, Fig. 3(a) and (b) show the back-EMF and core loss according to the change of operating speed under the no-load condition. Although the mechanical width of two stators is the same, the spiral stator has the magnetic air-gap between layers due to the complexity of manufacture. Therefore, back-EMF constant of the axial machine using the spiral stator is entirely 10% lower than the lamination stator. However, the perpendicular surface for alternating magnetic field and the magnetic path of eddy current in lamination stator are bigger than the spiral stator. Especially, the core loss of the lamination stator is increased by a function of the

square against operating frequency but that of the spiral stator is entirely proportional to the operating frequency.

As the mechanical characteristics, resonant frequencies of the lamination stator move to almost 10% higher than the those of the spiral stator because the stiffness of the axial machine by changing from the spiral stator to the lamination stator is enhanced. The more detailed results and discussion will be given in the full paper.

Investigation and comparison of inductance calculation methods in interior permanent magnet synchronous motors.

T. Sun, S. Kwon, J. Lee, J. Hong

Department of Mechanical Engineering, Hanyang University, Seoul, South Korea

I. Introduction

The dominant influences in the correct prediction of the steady-state characteristics and precise vector control for the interior PM synchronous motors (IPMSM) are the d- and q-axis armature inductances [1]. Due to the nonlinear electromagnetic characteristics including the saturation and cross-coupling effect in the rotor of IPMSM [3], the d- and q-axis armature inductances of IPMSM become much difficult to be calculated accurately.

In spite of the fact that the corresponding evaluation methods have been discussed for last two decades, there is still no standard for calculation processes of the inductances of IPMSM. Although some papers [4] claimed that the accurate results were calculated by analytical methods, the finite element analysis (FEA) still is the most trustable method. Among the proposed FEA methods, three can be classified. They are frozen permeabilities method, vector control method, and differential flux-linkage method, respectively. First, the principle and calculation process of each method will be investigated briefly in this paper. The solving method of FEA, computation time and complexity can be compared. After considering the end winding leakage inductance, the calculated results of all three methods then will be compared with experiment results and analyzed. In this paper, the preferred AC standstill method will be applied to reveal the accuracy of each calculation method. The final conclusions of this paper will be helpful to choose proper method to evaluate d- and q-axis inductances of IPMSM.

II. Investigation of Evaluation Methods

A. frozen permeabilities method

[1] proposed a method to calculate the pure flux linkages due to the exciting current by removing the magnetomotive force of PM. Considering the different operating points, the total permeabilities are changed with different current values. Thus, the magnetic flux distribution produced by armature current can be calculated in linear analysis. Depending on the relationship between the co-energy and current, the inductances can be calculated [1]. The absence of the flux linkages of PM, however, reduces the saturation and hence generates calculation error.

B. vector control method

Based on the d- and q-axis steady-state equation of IPMSM, the vector control method was proposed in [2]. It can be seen that the d- and q-axis inductances can be calculated directly depending on the relationship of vectors. The drawback of this method is the constant flux linkage of PM, which should have varied with operating point.

C. differential flux-linkage method

In this method, the flux linkages of PM in two nearby operating points are regarded approximately as the same. Thus, the inductance can be calculated as the ratio of differences in flux linkages to currents of these two operating points [3]. This method is limited by the hard determined current variation steps. In practice, it is also difficult to realize the precise current controller.

III. Comparison of Results and Discussion

The photo and cross-section of the analyzed IPMSM in this paper are shown in Fig. 1. The adopted experiment scheme, AC standstill method, is shown in Fig. 2. Fig. 3 show the calculated d- and q-axis inductances by the vector control method. The sensitivity of inductances requires critical simulation conditions including temperature, current vector angle and current amplitude. The other

simulation and experiment results will be published in the extended paper. Except the accuracy, more details will be compared and discussed.

Two-DOF micro magnetostrictive bending actuator for wobbling motion.

T. Ueno¹, C. Saito², N. Imaizumi², T. Higuchi¹

1. University of Tokyo, Tokyo, Japan; 2. Namiki Precision Jewel Co., LTD, Tokyo, Japan

A 2-DOF micro-magnetostrictive bending actuator using an iron-gallium alloy (Galfenol) was investigated. Galfenol is an iron-based magnetostrictive material with magnetostrictions greater than 200 ppm, a high relative permeability $\mu_r > 70$ and a Young's modulus of ~ 70 GPa. This material is machinable by conventional cutting techniques, and can operate under tensile, bending, and impact loads without degradation in performance. A micro actuator using Galfenol, therefore, has advantages over a PZT type actuator in design simplicity, low drive voltage requirements, high robustness, and a wide temperature operating range. Here we propose 2-DOF micro magnetostrictive bending actuator as shown in Fig. 1. The actuator consists of two orthogonal bimorphs of Galfenol and Ni and winding coils. The actuator is basically a rod of Galfenol of 1 mm square and 13.5 mm length (magnetically easy axis in longitudinal direction). The two ditches of 0.375 mm depth on which Ni plates of same thickness bonded are made by ultra-high precision cutting technique. The bimorphs yield bending deformation with current flow (magnetic field is applied) because the elongations (magnetostrictions) of Galfenol (positive 200 ppm) and Ni (-40 ppm) are constrained by the bonding surface. The actuator is aimed to provide two orthogonal bending deformations which can be used as positioning (the tip is controlled in XY plane), or wobbling motion for micro motor, or drilling device. The static and dynamic displacements of the tip (X and Y) in the case of one side fixed (cantilever, see Fig.1) were measured by fiber optical sensors. The result of Fig.2 contains two cases when the currents flow to X or Y coil. Even the current flows in one coil, two bending deformations simultaneously occur because the magnetic field is applied to both bimorphs. Basically, the displacement (e.g. X) with the current induced to coil (X) with correspondent position is larger than another (Y), because of higher magnetic field. Clear butterfly curves were observed with the maximum of 6 μm (X) and 17 μm (Y). The displacement of Y is larger than X because the bimorph of Y is located near the fixture. Figure 3 shows frequency responses of the displacement against current. The resonances of two first bending modes are relatively close 2.61 and 2.86 kHz. This result indicates that wobbling motion (round trajectory of the tip) with magnified displacement could be obtained at frequency range between two resonances. The configuration and magnetic circuit (open loop) here is primitive to see bending behavior, which will be improved for practically applications.

Introduction

It is well known that the accurate calculation of the field distribution is essential for the design of the linear electromagnetic machines (LEMs). With the availability of powerful software tools, numerical analysis of the field distribution has become common practice. However, while numerical techniques, such as finite element (FE) analysis, provide an accurate means of determining the field distribution, with due account of saturation etc., they remain time-consuming in case of being employed for investigating the influence of the design parameters on the machine behavior. Contrary to this, analytical techniques do not provide accurate field solutions considering saturation due to analytical burden and several assumptions. However, the machine performances according to design parameters can be predicted rapidly by using analytical field solutions, which are favorable in terms of initial design of the machines.

Many analytical techniques have been investigated to predict field distribution in the LEMs. D.L. Trumper [1] dealt with the design and analysis of flat linear machines using the TRT invented by the Melcher. Their derivation procedures can be easily adapted to the cylindrical LOA shown in Fig. 1, which has Halbach magnet array as a mover and single-phase slotless windings as a stator.

Therefore, using transfer relations derived in terms of a magnetic vector potential and a two-dimensional cylindrical coordinate system, this paper derives the analytical field and thrust solutions of the cylindrical LOA. Analytical results compare well with corresponding non-linear FE analysis. In particular, back-emf and thrust measurements are given to confirm the analysis.

The simplified analytical model of cylindrical LOA

Fig.2 shows the analytical model simplified by the symmetry of the cylindrical LOA shown in Fig. 1. The PM region carries a primed coordinate frame which is displaced from the base coordinate frame by a vector $-z_0\hat{z}$. The magnet array is represented by an infinite Fourier series in radial (M_r) and axial (M_z) magnetization components. A similar Fourier representation is also applied to J .

Transfer relations formula

The transfer relations which relate the fields evaluated at the surfaces identified in the model of Fig. 2 are developed in [2] as follows;

$F_0(x,y)$ and $G_0(x,y)$ are the geometric parameters and here I_1 and K_1 are modified Bessel functions of the first and second kind, of order one and I_0 and K_0 are also modified Bessel functions of the first and second kind, of order zero.

Results and discussion

Fig.3 shows the comparison of predictions with non-linear FEA for flux density due to PMs and stator currents. As shown in Fig.4 (a), the back-emf is measured by driving actuator as a generator at a given speed that depends on the speed of the other actuator driven as a motor. Fig.4 (b) shows the comparison of predictions with non-linear FE calculations and measured results for the thrust according to load current and back-emf according to mover speed.

In good agreement with the predicted values from the analyses, the measured results confirm the validity of the TRT analysis. The more detailed results, discussion and mathematical expressions will be given in final paper.

CHARACTERISTIC ANALYSIS OF A FLUX-REVERSAL MOTOR WITH FOUR-SWITCH CONVERTER.

H. Kang², T. Kim¹, B. Lee²

1. Electrical Engineering, Gyeongsang National University, Jinju, South Korea; 2. Sungkyunkwan University, Suwon, South Korea

I. Introduction

Flux-reversal machine (FRM) is a new brushless doubly salient machine with permanent magnets on the stator. The permanent magnet flux linkage in the stator phase concentrated coils reverses polarity with the rotor traveling [1]. Its operation is similar to that of the brushless DC motor, so it can be driven by alternating pulses of rectangular currents of 120 degree base and with a 120 degree shift between three phases of the stator. The pulse width modulation (PWM) pattern is also used in six-switch converter to control the speed of the motor. However, in recent years, many different converter topologies have been developed and various PWM control strategies have been proposed to reduce the converter construction cost by using minimum number of switches. One of them is four-switch converter topology with a novel PWM control technique based on the current controlled PWM method [2]. In this paper, we introduce the performance of the FRM under the four-switch converter compared to the six-switch converter. To analyze various characteristics, two-dimensional time-stepped voltage source finite element method (2D FEM) is used.

II. Six-switch and Four-switch Converter

Fig. 1 shows the six-switch and four-switch converter topology for three-phase FRM. The four-switch converter has two switch legs (four switches). And one phase of the motor is always connected to the midpoint of the dc-link capacitors.

III. Analysis Results and Discussion

Fig. 2 compares the calculated phase current in each converter. The current regulation is performed by using hysteresis current control. The purpose of regulation is to shape quasisquare waveform with acceptable switching band. In the case of the four-switch converter, in order to compensate the back-EMF current of phase C, phase A and phase B currents should be sensed and controlled independently and the switching signals of S1 (S3) and S4 (S2) should be created independently. So the switching ripple band is larger than that of the six-switch converter. Fig. 3 shows the torque ripple waveform. The four-switch converter has higher torque ripple and lower average torque at the same input voltage. This is due to the switching ripple band. Fig. 4 shows the iron loss characteristic. The hysteresis loss in the stator and the rotor is similar in both converters. In the stator, however, the eddy current loss of the four-switch converter is much larger than that of the six-switch converter. This can be explained from the fact that the magnetic flux changes quickly under the four-switch converter. Therefore, to improve the performance of the FRM with four-switch converter, more compensated PWM control strategy should be developed. The experimental results will be also shown to confirm the validity of the analysis results in the full paper.

Iron Loss Calculation in an Amorphous Transformer Using Coupled Preisach Modeling & Finite Element Method.

Y. Cho, S. Mun

Electrical Engineering, Hanbat National University, Daejeon, South Korea

The analysis of the thin lamination model of the amorphous transformer by Finite Element Method (FEM) requires the many region division and much calculating time, and it has difficulty in calculating for modern computer. This paper deals with the iron loss calculation of an amorphous transformer using a coupled Preisach modeling & FEM. For the analysis by FEM of the amorphous transformer, of which the lamination is very narrow, many element (i.e. division region) and computation time are required. In order to solve these problems, the lamination model of the amorphous transformer is transformed into an equivalent anisotropy model with permeability.

The simple lamination model and equivalent anisotropy block model are shown in Fig.1.

By using the packing factor p ,

$\mu_{rx} \approx 1/(1-p)$, $\mu_{ry} \approx p\mu_r$, $p = w_i/w_i + w_a$

Where, w_i and w_a denote the iron and insulation width, respectively.

The amorphous transformer permeability μ_r has been calculated using Preisach modeling[1]-[4], and the packing factor p is 0.85.

Reduction of Lateral Force using V-skew in Permanent Magnet Linear Synchronous Motor.

D. Lee, K. Jang, G. Kim

Electrical Engineering, Changwon National University, Changwon, South Korea

Permanent Magnet Linear Synchronous Motor(PMLSM) has high efficiency, high energy density and high control ability. But, detent force is always produced by the structure of slot teeth and end effect. As detent force is acted as noise and vibration of the apparatuses, it is decreased the control ability because it acts as thrust ripple. Therefore, the detent force reduction techniques is essentially demanded in PMLSM[1].

Generally, skewing PM is widely used as the method of detent force reduction. But, if it is skewed PM, the force is generated as two components: one is a thrust in moving direction; the other is a lateral force in perpendicular direction of moving direction. The lateral force develops additional mechanical loss as breaking force and it has bad influence on the characteristics of PMLSM. But, these calculation cannot be solved by 2-dimensional Finite Element Analysis(FEA).

In this paper, the V-skew PM arranges of PMLSM to eliminate lateral force are proposed and 3-dimensional FEA is applied to analyze the PMLSM. The results are compared with experimental values to verify the proposed method.

Fig. 1 shows the PM arrangement on the stator. No-skew model, a general skew model and the V-skew model which is proposed in this paper is shown. The structure of stator and mover except the PM arrangement are same.

Fig. 2 shows measurement equipments of the PMLSM. Detent force is measured by using the load cell (model: CAS, SB-20L), the encoder, and the indicator as shown in Fig. 2 (b). The mover is fixed to the load cell. And the detent force is displayed on the indicator. The displacement of mover is measured by using the encoder and its magnitude is 1mm.

Table 1 shows detent force, thrust and distortion factor of thrust according to the PM arrangement. The thrust distortion factor of general skew and V-skew model decreased remarkably than No-skew model because the 5th and 6th harmonics components of thrust are decreased greatly. In the thrust of table 2, the analysis value of thrust is 900.12[N] and experimental one is 869.2[N] at rated current in the case of the general skew model. That is, the difference of two values is 30.92[N]. This difference is due to friction force by lateral force. However, in the case of the no-skew and V-skew model, the analysis values are agreed well with experimental values because the lateral force is not produced.

Fig. 3 displays the peak-values of thrust versus armature current variation. To ignore the effect of the detent force, the peak to peak values are compared. The thrust of general skew model is decreased more than those of the other models according to the increase of current as shown in Fig. 3.

The measurement of lateral force by using load cell is difficult because of mechanical structure. So, the lateral force is analyzed by 3D FEA. Fig. 4 shows the lateral force according to the PM arrangement. The peak-value of lateral force of general skew model is 31.95 [N]. The other side, the lateral force of No-skew and V-skew model becomes 0[N] because they have symmetry structure about Z-axis direction. Theoretically, the lateral force of No-skew and V-skew model must amount to "0"[N], but they have some values because the FEA has computation error.

Conclusively, in the case of the V-skew model, the detent force and distortion factor of thrust are smaller than No-skew model. Also, the lateral force is almost zero.

Axial-gap type permanent magnet motor modeling for transient analysis.

S. Won, J. Choi, J. Lee

Electrical Eng., Hanyang University, Seoul, South Korea

1. Introduction

Nowadays the portable devices are getting popular and accordingly needs for the axial-gap motors for portable devices are getting increase[1].

However, the analysis methods for the axial-gap type motors are not simple. Unlike the radial-gap type motors which can be easily transformed to 2-dimensional analysis model, the axial-gap type motors have many restrictions in transforming to 2-dimensional analysis model. Moreover, the 3-dimensional analysis of the motors takes quite a long time even though very fast microprocessors are used. There has been several attempts to solve this problem, some researchers have proposed new methods for analyzing axial-gap type motors or flat type vibration motors[2][3].

The authors propose novel modeling method for the axial-gap type permanent magnet motors which uses one coil mesh and one magnetic field distribution map. The magnetic field distribution map is acquired from static 3-dimensional finite element analysis.

This method is very powerful because the 3-dimensional transient analysis of the axial-gap type motor which is a laborious and time-taking job can be finished in minutes using this method.

2. Method description

As shown in fig. 1, most of axial-gap type permanent magnet motors have no magnetic core in the winding coils in order to remove the axial unbalance force caused by magnetic fluxes between permanent magnet and magnetic core. The motor torque mostly depends on the Lorentz force which is product of the magnetic flux density and winding current. Thus, if the tetrahedral mesh of the winding coil is used for the Lorentz force calculation, the force density at the particular point of the coil can be easily obtained by the coil mesh element of the point and the winding current. By summing all the product of the force values and the radius of the point, the axial-gap type motor torque and the back-emf can be calculated quickly.

After that, using this torque and back-emf values, the transient analysis of the motor can be performed combined with the external electric circuit. This process is very faster than the finite element analysis; the total time of the transient analysis is tremendously short.

3. 2 phase vibration motor

To verify this method, the authors performed the simulation with the 2 phase vibration motor which is widely used in the cellular phone nowadays. This motor produces the vibration by rotating the eccentric rotor which containing the coils. Fig.2 shows the vibration motor exploded structure. This motor has 4poles and 2 coils but because the coil is doubly winded, the motor actually has 4phase characteristics.

The vibration motor has some current noises due to the commutator and brushes while phase is shifting. This current noise is very important because this is related to the life time of the motor. In the simulation, the authors made up the electric circuit which functions the commutator and brush, as a result, the calculated back-emf and current noise values were obtained. Fig. 3 shows the result. The extended paper will contain the comparison with the measured values.

4. Conclusion

The axial gap-type permanent magnet motors are very important devices in modern industry. The thinner the electric devices are, the more axial gap-type motors are needed. So, it is impossible to predict the performance of the axial-gap type permanent magnet motors. This paper is very useful to the researchers who search the method to analyze the axial-gap type motors.

Analysis of Total Harmonic Distortion in microspeaker considering electromagnetic mechanical acoustic coupling effect.

J. Kwon¹, S. Hwang¹, G. Hwang²

1. Mechanical Engineering, Pusan National University, Busan, South Korea; 2. Computer Engineering, Youngsan University, Yangsan-city, South Korea

With the increase of the interest in sound quality, the approach of Total harmonic distortion (THD) analysis is becoming more important in microspeaker. Harmonic distortion is occurred by uneven magnetic field and nonlinear diaphragm response. For previous research, uneven magnetic field is analyzed along the voice coil position and then magnetic distortion is found by using spectra of flux linkage [1]. However, magnetic distortion affect mechanical response and then mechanical response change the magnetic distortion. Thus, to find exact solution, it should be considered coupling effects of magnetic distribution and mechanical displacement. In this paper, harmonic distortion is analyzed by considering magnetic and mechanical coupling effects.

In General, the structure of microspeakers is similar to that of loud speakers in view point of electromagnetic and mechanical system. When electric current flows in the voice coil, electromagnetic force is generated by Fleming's left hand rule. The magnetic force excite voice coil on diaphragm and then vibrate diaphragm. Finally sound is made by vibrating. Voice coil current can be also determined by solving voltage equation of the equivalent circuit. The voice coil motion generates the back electro motive force (EMF). Because inductance and back EMF are very small, they are able to be neglected. Thus, in this paper, it is assumed that input current is perfect sinusoidal signal. Fig. 1 shows the means of the flux density along the voice coil position. In this figure, because the magnetic field generated by voice coil current is very small, it is neglected. It is assumed that the magnitude of the response displacement is linear to magnitude of exciting force. The phase of displacement is not concerned in exciting force. The initial exciting forces are obtained by inputting response displacement of 0.1N forces.

The spectra analysis of exiting force is performed by Fourier transform. The converged solution is found by iteration. Fig. 2 shows the converged solutions of displacement and magnetic force at 300Hz.

The spectra of the force at 300Hz are presented at fig. 3. THD is the proportion of sound pressure level (SPL) at higher order frequencies to SPL at fundamental frequency. Fig 4 shows simulated and experimental THD along the frequency variable. THD at lower frequencies than resonance is high, because higher order frequencies include resonance frequency. At higher frequency band, THD is low due to small displacement. For high sound quality, THD is important design factor. To make low THD in microspeaker, it is able to predict by analysis approach. In this paper, harmonic distortion is analyzed by considering magnetic and mechanical coupling effects. Simulated results of THD are compared with experimental data. Results show that THD in lower frequency range is higher due to high displace on voice coil and high mechanical response of high order frequency.

Introduction

For a next stage of biomagnetic measurements, easy handling of devices is required. Especially, operations by hand, without liquid helium and outside a magnetically shielded room (MSR) are eagerly desired. Mobile high- T_c SQUID system is one of the methods to realize it.

Wide dynamic range is needed for mobile SQUID system because of its weakness against magnetic noise. In recent years, wide dynamic range systems have been demonstrated by several groups using background magnetic field compensation scheme [1, 2]. These systems are too complex for multi-channel biomagnetic measurement. On the other hand, we had developed a digital flux-locked loop (digital FLL) system that only reads magnetic field with wide dynamic range for low- T_c SQUID [3]. However, careful designing is needed for high- T_c SQUIDs which have smaller output voltage and worse noise performance than low- T_c SQUIDs.

We have obtained optimum parameters experimentally and operated a high- T_c SQUID using a digital FLL system as a first step to develop the mobile SQUID system. A large dynamic range is achieved and magnetocardiogram (MCG) signal is successfully detected using this system.

Digital FLL system with high- T_c SQUID

We made a prototype system for confirming its wide dynamic range and high resolution. It was composed by a small cryostat, a high- T_c SQUID, a digital FLL electronics and a computer.

A vacuum bottle was used as the cryostat for mobile SQUID system. It could be had by hand and its capacity of liquid nitrogen was about 0.5 L.

The effective magnetometer area of the SQUID was 0.54 mm^2 , and sensitivity B/Φ was $3.84 \text{ nT}/\Phi_0$. The maximum voltage modulation was $7.0 \text{ } \mu\text{V}$.

Our digital FLL system includes a double-counter method which achieves wide dynamic range by flux-quanta counting using a one-chip microcontroller and a computer. The digital FLL electronics was composed by a generally used 8 bit one-chip microcontroller, a 12 bit A/D converter, a 16 bit D/A converter, and inexpensive devices easily obtained. A time delay of the digital feedback loop was $8.4 \text{ } \mu\text{s}$.

On this electronics, output amplification of the D/A converter was set at 16 bit / $1.4 \Phi_0$. Input amplifiers which amplify the output voltage of SQUID and connected to the A/D converter determine the dynamic range and slew rate of the system.

Its maximum slew rate was calculated as $5.5 \text{ k}\Phi_0$ in the case of theoretically optimum value of input amplifiers. It was 119 dB for $5 \text{ V} / 12 \text{ bit A/D converter}$ and the SQUID's maximum voltage modulation. However, too large amplification increases a noise level of the system. It must be tuned to experimentally optimum condition to have both wide dynamic range and low noise level.

Fig.1 shows performances of the system. Fig.1(a) shows noise spectra at the cases of amplifications of 119 dB, 109 dB and 100 dB. They were measured in an MSR. Fig.1(b) was active areas of each the amplification. They mean the system can measure magnetic signal just in these areas respectively. The lines of 109 dB and 100 dB were measured, but 119 dB was calculated. With 119 dB amplifiers, digital FLL system could not step the Φ_0 accurately, because of its wrong noise per-

formance. The 109 dB line and the 100 dB line showed similar noise performance, but 109 dB amplifiers brought the system wider dynamic range. We chose 109 dB amplifiers for the prototype system.

MCG measurement

To demonstrate a large dynamic range and a high resolution of this system, we measured MCG waveform in the case of existing large magnetic noises. The demonstration was carried out in an MSR, and applied about 30 nT_{pp} at 0.5 Hz and 5 nT_{pp} at 50 Hz magnetic sinusoidal waves as dummy noises of background magnetic field. Fig.2(a) shows a measured waveform before digital filtering. Fig.2(b) shows a waveform that is band-pass-filtered (5 Hz to 40 Hz) and averaged 195 times. We can see QRS complex of MCG clearly. These figures are proof that the system was clearly measured about 60 pT MCG waveform in a large magnetic noise condition.

Discussion and conclusion

We developed a prototype of wide dynamic range high- T_c SQUID system for biomagnetic measurements. It achieved a wide dynamic range that can detect MCG waveform in the case of existing large noises. Although high- T_c SQUIDs generally have smaller output voltage than low- T_c SQUIDs, dynamic range can be increased by optimum system designing.

However, practical biomagnetic measurements need much higher noise performance. This system is well suitable for multi-channel system, so that noise performance will be improved by statistical signal processings.

Double relaxation oscillation SQUID mounted on Pulse Tube cryocooler.

M. J. Eshraghi, I. Sasada

Applied science for electronics and materials, Kyushu University, Kasuga, Japan

Superconducting quantum interference devices have been applied to diagnose heart diseases and brain functions as detecting MCG and MEG fields [1,2]. Instead of using liquid helium to keep low temperature for operating the SQUID system, a refrigerator such pulse tube cryocooler may be used.

In the pulse tube cryocooler, helium gas flows in and out of the compressor and the valve motor via a high pressure and a low pressure hose [3]. And the valve motor receives the power from the inverter via the power lines. The valve motor is controlled by a three-phase inverter to rotate in 0.9 Hz. The inverter acts with 10 kHz switching frequency and its harmonics surprisingly reaches up to around 20 MHz. The conducted switching noise current causes a critical interference with the operation of the SQUID sensor which is installed in 4 K stage of the pulse tube cryocooler.

Large part of the unbalanced noise current flows in the neutral line, however, a part of the current leaks out into the flexible hoses. Fig. 1 shows the current noise shapes of the power lines and the flexible hoses around the moment of the switching timing of the inverter.

By decreasing the impedance of the neutral line, it should be possible to force the some part of the unbalanced current to flow into the neutral line and to reduce the amount of the conducted noise current to the PT-Dewar.

After covering the three phase lines and the neutral line with a copper mesh cover and connecting both ends of the copper mesh cover to the neutral points at both ends, the conducted noise currents are measured in the high and low pressure flexible hoses and the power lines (Fig. 2). It is proved that there is approximately six times reduction in the conducted noise from the compressor and the inverter to the valve motor.

Finally, the SQUID operates normally as drawing an ideal demonstration, as shown in Fig. 3. The magnetic noise of 1.8Hz ;which is the frequency of Helium gas excursions; has been measured by Double Relaxation Oscillation SQUID mounted on the cold head of the Pulse Tube. The amplitude of this noise is around 1 nT. We are performing some experiment on the temperature variation of the heat regenerative material during the cycle of the pulse tube to prove that this noise come from the magnetic phase transition of the regenerative material due to the temperature fluctuation caused by passing cold helium gas[5]. At this level we used copper stage for mounting SQUID on the cold head of Pulse tube. The copper itself generates random magnetic noise because of self generated current inside the bulk; these currents will be increased by reducing the temperature [4]. So we are changing the copper stage by CFRP one to reduce the noise floor below the -80db to be appropriate for measuring heart magnetic field (fig 4.).

Quantitative magnetic immunoassays with a SQUID by means of mutual inductance calculations.

A. Bruno, H. R. Carvalho, S. R. Louro, C. Paulo

Physics, Pontifical Catholic University of Rio de Janeiro, Rio de Janeiro, Brazil

Magnetic particles have been found useful in many bioscience applications including immunoassays, cell separation, DNA and RNA purification. The basic principle consists of providing the external surface of the particle with ligands having affinity to the target molecules. Once the particles are mixed with a sample containing the target molecules, they bind to the magnetic particles. After that, the magnetic complex can be easily separated using a magnetic separator, and the magnetic field generated by the particles can be measured.

Recently, SQUID systems have been proposed to perform magnetic immunoassays. They are based in the magnetic flux obtained by remanence [1], relaxation [2], and susceptibility measurements [3]. Usually the immunoassay quantitative result is reached by obtaining the mass of particles through an experimental calibration curve, which relates the measured magnetic flux to the estimated mass of particles. The mass of particles indicates the number of target molecules present in the sample.

In this paper we propose to quantify the immunoassays by estimating the specific magnetization of the samples, after calculating their remanent magnetic moments by means of mutual inductance calculations between them and a SQUID. Most of SQUID commercial magnetometers estimate the magnetic moment of a sample by modeling it as a magnetic dipole. The magnetic moment is then obtained by performing a curve fitting procedure to the signal obtained as the sample is displaced through the magnetometer coil. However, as pointed out in a recent publication [4], if the sample is large when compared to the magnetometer coil, the magnetic dipole model is no longer valid and the magnetic moment is underestimated.

We recently developed a SQUID magnetometer for magnetic immunoassays which allows fast measurements of the remanent magnetization of a sample [5]. We used a bare two-hole SQUID sensor and the measurement is carried out by displacing the sample through one of the SQUID holes inside the liquid helium bath. Since the sample has about the same size of the SQUID hole, we cannot use the magnetic dipole approximation, in order to calculate its magnetic moment. Instead, we used the standard tables and formulas prepared by Grover [6] for mutual inductance calculations between two coaxial cylindrical current sheets to estimate successfully the magnetic moment of our samples.

Commercial silica coated magnetic particles were used in the experiments [7]. They are routinely used to bind nucleic acids, and also viruses, bacteria, etc. According to the manufacturer, the content of magnetite of each particle is about 80% in weight. We measured their size distribution using a laser particle size analyzer which shows a normal-like distribution and a median particle size of 0.90 μm . Using magnetite and silica densities the median size of magnetite within the particle was estimated in 0.77 μm . Magnetite particles in this size range are classified as pseudo single domain particles. The magnetic properties of those particles at low temperatures have been studied extensively [8]. Their reduced remanence (remanent magnetization / saturation magnetization) is expected to vary from 0.39 to 0.33 when their median sizes vary from 0.22 μm to 3.0 μm respectively. Using a typical reduced remanence particle size dependence [9] we estimated ours in 0.35. In order to avoid precipitation and aggregation, a viscous media consisting of polyethylene glycol was used to disperse the magnetic particles. As sample holders, we used glass microtubes. About 10 μl of the

particle suspensions were transferred to the microtubes, leading to a cylindrical sample with 1.3 mm diameter about 7 mm long.

The magnetite mass present in the sample was obtained by: $m = \mu / (0.35 \times 98)$, where μ is the measured remanent magnetic moment in Am^2 and 98 Am^2/kg is the specific saturation magnetization of magnetite at 4.2 K. Fig. 1 shows the flux obtained as the microtube is displaced relative to the SQUID (symbols) and the fit by mutual inductance calculations (solid line) from where the magnetic moments are obtained. The legend shows the masses obtained with the above relation.

Introduction

Superconducting quantum interference devices (SQUIDs) are widely used for biomagnetic measurement, such as magnetocardiogram (MCG) and magnetoencephalogram (MEG). In many cases, biomagnetic measurement systems use low- T_c SQUIDs and need liquid helium to cool them. However, the expensive price of liquid helium and its difficulty in handling hinder the usage of SQUIDs in area of biomagnetic measurement. On the hand, high- T_c SQUIDs made by oxide superconductors are easily cooled by cheaper liquid nitrogen. Although the high- T_c SQUID has such an advantage, it has problems when it is used in biomagnetic measurements, because they are lower sensitive, more difficult to product and more fragile than low- T_c SQUIDs. To solve these problems, we are developing MgB₂ SQUIDs [1] by using high quality as-grown films [2]. The T_c of our films produced by a molecular beam epitaxy (MBE) is 37 K. This temperature is adequate to be cooled by pulse-tube cooler, which requires no liquid cryogen and has advantages in low magnetic noises from mechanical vibration compared to other types of coolers [3]. We have developed the MgB₂ SQUID system cooled by a pulse-tube cooler. MCG signal is successfully detected using this system.

MgB₂ SQUID system cooled by cryocooler

Fig.1 shows the block diagram of the MgB₂ SQUID system cooled by a pulse-tube cooler. A commercially available pulse-tube cooler was used. The cold head of the cryocooler is connected to the compressor via a valve unit. Because the valve unit produces magnetic noises, the cold head and the refrigerator part is installed in a magnetically shielded room, and the valve unit is set outside of it. They are connected by using a long copper tube.

An MgB₂ SQUID and a pickup coil are installed inside the cold cylinder connected to the refrigerator. The pickup coil is made of Cu as thin film on a glass-epoxy substrate, although a pickup coil is usually made of superconducting material to detect low frequency magnetic field. Because this plate can be cooled at the same temperature as the cold cylinder, resistance may be decreased enough to measure biomagnetic signal. The pickup coil has a 10 turns square eddy loop that is in 30 x 30 mm² area to detect magnetic field, and a single turn input coil to apply the magnetic signal to SQUID. The MgB₂ SQUID chip is put right above the input coil. Therefore magnetic field and coldness are transmitted from the pickup coil plate to the MgB₂ SQUID.

This refrigerator can reach about 5 K without any loading. Temperature of the sample stage is controlled by a heater.

DC coupling between SQUID chip and preamplifier is used and a flux-locked loop (FLL) circuit works in direct readout mode. To operate the SQUID, some parameters are digitally controlled by a computer through the digital FLL electronics.

Results

The lowest temperature of this system was 5.6 K. Characteristic evaluations of the MgB₂ SQUID were carried out at 28.6 K. The bias current was 370 μ A, the maximum voltage modulation was

10.2 μ V. A sensitivity B/Φ was about 19.3 nT/ Φ_0 at 2 Hz. The cutoff frequency of the pickup coil was 0.5Hz.

Fig.2 shows a magnetic noise spectrum of the system measured in a magnetically shielded room. The white flux noise was about 9.5 pT/Hz^{1/2}. The largest peak is power line noise at 50 Hz. Other peaks were observed at 1.2 Hz and its harmonics. The origin of these noises is enigma.

Fig.3 shows an MCG waveform measured by this system. This waveform was obtained by applying a software band-pass filter (2 to 40 Hz) and 560 times averaging. QRS complex is shown clearly, and this figure proves that the system can detect MCG waveform.

Conclusion

MgB₂ SQUID system cooled by a pulse-tube cooler is proposed. It is composed with a Cu pickup coil and careful design for noises. MCG waveform was measured by this system at 28.6 K.

Biomagnetic Signal Detection Using Very High Sensitive MI Sensor for Medical Applications.

T. Uchiyama¹, S. Tajima¹, S. Shibata¹, L. Ji¹, K. Bushida²

1. Electrical Engineering, Nagoya University, Nagoya, Japan; 2. UNITIKA LTD, Tokyo, Japan

Introduction

Superconducting quantum interference device (SQUID) magnetometers have ultra high sensitivity, which is useful for detection of biomagnetic signal. For example, magnetocardiography (MCG) is a noninvasive technology that measures the magnetic field of the heart by SQUID. It was developed for the general purpose as a noninvasive, non-contact diagnostic tool of obstructive coronary artery disease (CAD), and especially of cardiac ischemia. The SQUID has been also used to measure and localize seizure activity in the human brain. In usual cases, SQUID magnetometer needs both magnetic shield equipment and a refrigerator.

Recently, micro magnetic sensors due to Magneto-Impedance (MI) effect have been developed by Mohri et.al. MI sensor has future such as high sensitivity, high stability, high spatial resolution, small size, lightweight and low power consumption. The integrated MI sensors being used commercially in the mobile phone today. The optimal sensitivity of the MI sensor of around 100pT has been reported⁽¹⁾. The development of very high sensitive MI sensor system is expected to detect biomagnetic signal for the purpose of both convenient and accurate health care medicine. In this paper, we demonstrate the performing of biomagnetic recording by use of MI sensor.

Result and Conclusion

In order to investigate sensitivity of 1 cm long amorphous wire MI sensor with 600 turns of pick-up coil, we have measured the spectrum of output noise. The rms noise of the MI sensor is estimated to be $3\text{pT}/\text{Hz}^{1/2}$ at 1Hz, while high-resolution imaging SQUID microscope has rms noise of $0.1\text{pT}/\text{Hz}^{1/2}$ at 1Hz⁽²⁾.

The cardiogram signal is clearly detected by MI sensor when the sensor head is very close to chest surface. The wave form of the cardiogram, which was measured under the no shield environment, is shown in Fig.1(a) and Fig.1(b). The futures of QRS and T waves correspond with electrocardiogram. The maximum field strength of several nT is almost 50 times larger than the magneto-cardiogram measurement by SQUID system having Sensor-to-Chest spacing of around 50 mm. The maximum magnetic field strength of magneto-cardiogram increases with decreasing Sensor-to-Chest spacing. The maximum field strength of several nT was measured for a rabbit heart using SQUID microscopy brought the sensor within less than 100 μm of epicardium⁽²⁾

It is interesting to measure biomagnetic field around the blood vessel, because fMRI blood oxygen level-dependent (BOLD) signals are utilized for neuroscience to study brain activity. BOLD fMRI does not measure neuronal activity directly but depends on cerebral blood flow, cerebral blood volume, and cerebral metabolic rate of oxygen consumption.

The wave forms of the magnetic field at the hand surface around the vein measured by MI sensor are shown in Fig.2. The main frequency components of the waves are heart beat frequency component and respiration frequency component. Compared with the magnetic field measured before lunch and it measured after lunch, the amplitude of respiration frequency component evidently increased after lunch. It seems that the biomagnetic field around the vein is related with both blood flow and metabolism.

In conclusion, very high sensitive MI sensor has feasibility of biomagnetic signal detection and it will be available to check heart disease or to study blood-flow related phenomena in metabolism.

Dpto. de Ingeniería Química y Medio Ambiente, Universidad del País Vasco, San Sebastián, Spain; 4. Department of Electricity and Electronics, Basque Country University, Bilbao, Spain

Areas of technological applications of magnetic materials have been significantly extended with the development of magnetic biosensors [1]. In the majority of biosensors with a magnetic sensitive element, the working principle is based on the detection of stray fields of magnetizable nanoparticles; these are employed as biomarkers [1-3]. The magnetoimpedance effect (MI) [4] was proposed both for magnetic label and label free detection of biological substances [3, 5-6]. Some of the MI prototypes were designed using Co-based amorphous ribbons without protective covering, the most economic design for disposable single stripe usage. Therefore it was necessary to study MI and corrosion stability of such materials in biofluids. Although some corrosion studies were done using traditional electrochemical methods [7] there was no work done on comparative analysis of the magnetic properties, MI and corrosion stability of the ribbons of the same composition. In this work magnetization curves and MI effect in $\text{Fe}_{2.5}\text{Co}_{64.5}\text{Cr}_3\text{Si}_{15}\text{B}_{15}$ amorphous ribbons in as-quenched state and after electrochemical surface modification in different regimes were comparatively analyzed.

$\text{Fe}_{2.5}\text{Co}_{64.5}\text{Cr}_3\text{Si}_{15}\text{B}_{15}$ amorphous ribbons were prepared by melt spinning technique. Their amorphous states were checked by X-Ray diffraction (Fig. 1). Samples of $100 \times 1 \times 0.025 \text{ (mm}^3\text{)}$ were used for magnetic and MI measurements before and after electrochemical surface modification in a conventional three-electrode glass cell. A phosphate buffered saline (PBS) solution has been used as an electrolyte being 0.138M of NaCl, 0.0027M of KCl for 0.1M of PBS. The pH value of this solution was 7.3 and the temperature was maintained at 37°C during the treatment in order to simulate the human body living conditions. The working electrodes were polarized from the corrosion potential (250 mV) at a scan rate of 0.5 mVs^{-1} in the anodic direction up to the values of 0.4, 0.5, 0.6 and 1 V. The surface morphology of all samples was studied by optical and scanning electron microscopy. The longitudinal hysteresis loops were measured before and after treatments using the conventional inductive method at a frequency of 20 mHz (Inset Fig 1. a). The electrochemical treatments do not change the very small coercivity of the ribbons but they cause certain changes in the magnetization processes. It is clear the different intervals: above 0.6 Oe (saturation field) and below ± 0.1 Oe (high permeability interval) for 1V treated sample.

The MI was measured by a standard four point technique [5]. Driving current flow (amplitudes of 0.2 to 10 MHz) and external magnetic field application directions were parallel to the ribbon axis. The impedance changes for each field value were calculated using the Ohm's law at a constant value of the selected driving current intensity of 5-60 mA (I_{rms}). The MI measurements were carried out in decreasing (down branch) and increasing (up branch) fields, starting at the maximum positive field. The MI ratio, $\Delta Z/Z$ was defined as follows: $\Delta Z/Z = 100 \cdot (Z(H) - Z(H_{\text{max}})) / Z(H_{\text{max}})$, where Z is the impedance modulus and $H_{\text{max}} = \pm 73$ Oe is the maximum external magnetic field, at which the sample is magnetically saturated.

Selected results of the MI studies are shown in Fig. 1b-c. It is seen that MI responses for selected driving current and frequency depend on the value of the maximum voltage corresponding to the

electrochemical treatment. The tendency for low field interval of ± 5 Oe is the higher the maximum voltage the higher the $\Delta Z/Z$ value. Even more clear difference in MI behavior for the ribbons after surface modification in different regimes was observed for dependence of the maximum of the $\Delta Z/Z$ ratio on driving current intensity: the higher the maximum voltage the higher the $\Delta Z/Z$ value. The MI behavior is explained on the basis of a simple model taking into account the classic skin penetration depth, the possible contribution surface anisotropy and the roughness changes.

Biomedical Engineering, Yonsei University, Wonju, South Korea

The commercial and medical pulse diagnostic apparatus (PDA) includes a pressure sensing sensor including a silicon layer, which is adhered closely to the upper skin at the radial artery and close up the air layer tight to sense the pressure change of the air layer, which depends on the vibration of a pulse wave[1].

This research shows the process of achievement and analysis of 3-dimensional spatial pulse wave archived by a spatially arterial pulse diagnostic apparatus (SAPDA), wherein a pulse sensing part array consists of multiple Hall device and is located over a skin contacting part which consists of a magnetic material[2].

To achieve the objectives of the SAPDA, the detecting sensor is characterized by comprising a skin to examine the pulse. This system is composed of pulse sensing part, skin contacting part and spatial part. A pulse sensing part, located some distance over the skin contacting part and formed as an array type with at least one Hall device, and other part, a spatial part is located between the skin contacting part and the pulse sensing part, as shown in Fig. 1

Fig. 1 shows the schematic of a cross section of one embodiment of SAPDA sensing part with array Hall devices and 3-dimensional image treatment system. The sensing part of SAPDA is composed of 15 arrays of the A3516 model Hall sensor and the cylindrical type permanent magnets having a size of 1.5 mm dia.×1 mm thick. The flexible spacer between the sensors and the magnets can control the applied pressure of the arterial tube as the doctors' three fingers press the arterial tube. So to realize the ideal pulse diagnosis system it is necessary for the system to have a device to apply certain pressure on the sensors, and both the pressure applied by the device and the pressure obtained from the artery should be recorded. The distance between the elements of an array is about 2 mm, and all the cylindrical magnets have an intensity of 100 Oe.

On the other hand, by varying the contact pressure height of a permanent magnet on the skin, a new method of characterizing the spatial pulse wave based on the degree of floating, the width, and the depth was introduced. These, unlike the traditional pulse diagnosis, do not involve the analysis of diastolic blood pressure and pulse wave velocity.

We measured signals at the "Chon", "Gwan", and "Chuck" region, as shown in Fig. 2(a) using the testing product of SAPDA system, passed signals through the voltage detecting hardware system as shown in Fig 1(b). made a differential input, an automatic zero set, a noise filtering, a high power gain and output attenuation, output them with 12 bit resolution at 30 FPS (frame/s), RS232C, simulated the result with a predetermined computer processing, and obtained three dimensional image of Fig. 2(b). By the computer processed 3-dimensional image of signals detected by SAPDA, wherein is marked one point pulse to analyze the temporal pulse wave, we can select it. Fig. 2(c) show an example of measuring time (second) versus temporally typical signal of one point pulse obtained from the analysis for an arbitrary 3-dimensional pulse image of one position of small size permanent magnet.

So far, the preferable embodiments of the SAPDA have been described herein, but it will be evident that the SAPDA cannot be defined only by the described embodiments herein, and it will be understood that the SAPDA herein described are generally applicable and executed as various

modified embodiments by those skilled in the art. For example, materials and numerical values for a skin contacting part, a pulse sensing part and a spatial part can be various within the technical thought of the SAPDA. Also, Fig. 2(c) shows the signal of one point obtained by the analysis of composition of color 3-dimensional images of testing product of SAPDA. The spatial change of the pulse height in arterial pulse incurred one permanent magnet within 1 mm. We confirmed that one example of measuring pulse signal was reproducible and provided many information for oriental medical diagnosis. To resolve the subtle and subconscious arterial pulse, a more controlled study should be conducted and the real spatial data obtained through future research and development. This work was supported by the Korea Foundation for International Cooperation of Science & Technology(KICOS)in 2007.

Various Types of Hall Sensors for Single Particle Detection.

O. Kazakova¹, J. Gallop¹, D. Cox^{1,2}, A. Cuenat¹, L. Brown¹, K. Suzuki³, L. Bernau⁴, I. Utke⁴
 1. NPL, Teddington, United Kingdom; 2. Surrey University, Guilford, United Kingdom; 3. NTT Basic Research Laboratories, Kanagawa, Japan; 4. EMPA, Thun, Switzerland

We present our first results in realizing a measurement system based on two different types of Hall sensors, made of a conventional 2DEG InAs/GaSb-based heterostructure and a novel metallo-organic Co-C composite. While in the 2DEG system the ordinary Hall effect is due to the Lorentz force acting on charge carriers in a semiconductor, the latter system additionally demonstrates a strong extraordinary Hall effect originating in spin-orbit interactions in a ferromagnetic material [1]. The work aims to optimize fabrication and measurement performance of both types of sensor. The quantum well AlGaAs/InAs (12 nm)/GaSb (18 nm)/AlGaAs heterostructure was grown by molecular beam epitaxy on an undoped InAs (001) substrate [2]. Arrays of large Hall crosses (100x20 μm^2) connected in parallel were fabricated by optical lithography and reactive etching (Fig. 1a). The good ohmic contacts were achieved using germanium layer on the electrical pads. The metallo-organic Co-C Hall crosses were fabricated by direct writing in a FIB system. The Co-C deposit is obtained by decomposing of dicobalt octacarbonyl [$\text{Co}_2(\text{CO})_8$] with an electron beam [2]. Using this technique we were able to fabricate Hall sensors with the cross area down to (300 nm)² (Fig. 1b).

The best-achieved resistance is 2 k Ω and 2.8 k Ω for Co-C and 2DEG complete devices, respectively. The Hall voltage was measured as a function of the magnetic field applied perpendicular to the sample plane (Fig. 2). All devices demonstrate a significant offset voltage, which is predominantly proportional to device bias current indicating non-orthogonality between voltage taps and the current flow. Very small offsets (a few μV) arise even at $I_H = 0$, presumably due to thermoelectric effects. Hall voltage is linearly dependent on I_H proving a good ohmic contact between the metal electrodes and the Hall cross material. For the Co-C device, the Hall voltage saturates at $B \approx 1$ T. However, no sign of saturation have been observed in 2DEG devices up to $B = 2$ T. The present sensitivity S_B in the linear region is about 0.014 V/AT and 34.2 V/AT for Co-C and 2DEG crosses, respectively. This corresponds to Hall coefficients $R_H(\text{Co-C}) \approx 4 \times 10^{-9} \Omega\text{m/T}$ and $R_H(2\text{DEG}) \approx 4 \times 10^{-7} \Omega\text{m/T}$, thus being two order of magnitude better in the 2DEG heterostructures. The presence of hysteresis in the V_H - B curve indicates significant remanent magnetization in the Co-C deposit. The relatively low Hall coefficient and the remanent magnetization are potential drawbacks for a noninvasive biosensor. Thus, further optimization of material properties is required for successful design of a metallo-organic Co-C Hall sensor.

Further we investigated the room-temperature noise in InAs/GaSb Hall sensors in the frequency range 1 Hz – 13.0 kHz. For all bias currents the 2DEG devices exhibit a $1/f$ like spectrum at low frequencies and a white noise region at higher frequencies. We calculate that for $I_H = 0$ the average spectral density of the voltage noise is $S_V = 1.3 \times 10^{-8} \text{ V}/\sqrt{\text{Hz}}$ at $f = 4 - 8$ kHz, which is only twice larger than the expected Nyquist noise at room temperature. Both the observed $1/f$ and white noise values increase with the bias current, although the latter has a less strong current dependence. $1/f$ voltage noise shows a clear linear dependence on bias current at $f \approx 100$ Hz. Similar behaviour in 2DEG systems was previously attributed to bulk mobility fluctuations within the channel, arising from scattering of 2D phonons. Chen et al. [3] find that the $1/f$ component of the noise spectrum is strongly temperature dependent and also can be affected by illumination of the 2DEG. At higher frequencies (>2 kHz) the noise increases much slower with current providing the best operating regime for such a sensor if it can be used with a lock-in technique involving kHz modulation.

In the white noise region for the measured S_V value and $I_H = 0.5$ mA, the minimum detectable magnetic field change in a 1 Hz bandwidth equals $\Delta B = 2.4 \times 10^{-6}$ T.

Our results show that the InAs/GaSb Hall devices are capable of detecting a single magnetic bead of diameter down to 200-400 nm. Although the Co-C devices are as yet not as sensitive, the ease with which a simple nanoscale Hall cross may be fabricated from this material suggests that further investigation is worthwhile.

Abstract —The paper present a devices for detecting the cardiorespiratory activity by means of a microwaves Doppler detector of motion, which should permit the detection without an intimate contact with the patient.

Keywords — microwave, Doppler frequency, noninvasive monitoring, cardiorespiratory activity, I.

INTRODUCTION

The cardiorespiratory activity is an important parameter for the observation of the human body activity [1]. The absence of breathing, apnea, represent the obstruction of the air flow which passes through the nose or through the oral cavity to pass to the lung, for an interval longer than 20 seconds. It is difficult to forecast the absence of the breathing which can be deathly in a few minutes. Few clinical aspects are relevant for cardiorespiratory monitoring.

- after anesthesia, both the respiratory centre and the respiratory muscles can be affected, leading to a rise in the CO₂ concentration and a drop in the O₂ concentration;
- another clinical situation that affect respiratory activity is the sedation of the patients during the examinations such us magnetic resonance imaging.

II. EXPERIMENTAL SETUP

The microwave transducer makes use of the Doppler effect in the microwave range in order to detect the complex motion of the thorax anatomic structures as the result of the cardiorespiration activity [2]. The main element of the installation consists of the Doppler transducer made of a microwaves devices realized in stripline technology.

The utilization of high frequency electromagnetic waves implies certain difficulties connected to the electromagnetic waves propagation through the biological structures, to the complex phenomena of reflection, refraction, absorption, diffusion and interference that can occur on the skin, in depth of certain tissues, a different electromagnetic field absorption (at the input and output) of the wave by the human body. In order to ensure a minimum level even below the one permitted by standards for the electromagnetic field intensity, one has to use generators of small power, of the order of a some of milliwatts. We preferred to use a frequency of some GHz, given the fact that the phenomena specific to the microwaves propagation are more obvious at this frequencies; yet, another reason is determined by the simplicity of the Doppler transducer at these frequencies. At this frequencies the skin depth in muscles, lung and blood is of a few millimeters, reaching 2-9 mm in fat. One can notice a good correlation between the complex Doppler signal and the signal due to the respiratory activity. The signal given by the manometer follows the respiratory activity, its maximum values corresponding to the thorax outward motion by air inspiration and its minimum values corresponding to the reverse thorax motion.

III. RESULTS

The records from Fig. 1, were made in the apnea condition after inspiration. The diagrams present the signals picked-up by the photoplethysmograph as a reference signal, and the Doppler signals corresponding to the zone against the thorax. In most of the diagrams, one can remark a time alteration of the amplitude of the signal pick-up by the photoplethysmograph; this is the result of the apnea state installed at the beginning of every measurement. From the A, B... L, diagrams one can remark vari-

able amplitude of the Doppler signal depending on the transducer's position as related to the thorax.

As it might be observed, the highest signal amplitude is in the zones E, F, H zones meaning the region were the heart is placed, due to the heart's contraction motions and to the larger blood volume pumped through the organism by means of the aortic artery. At the same time increased signal values are recorded in the K zone corresponding to the direction of the descending thoracic abdominal aorta.

(Fig. 1. Cardiac activity map of the Doppler signal)

The experimental results confirm the possibility to use a microwave Doppler detector of motion for detection, recording and explaining the signals produced by the cardio-respiratory activity. The method permits to detect the apnea and sleep apnea, the breathing frequency, as well as the heart activity. The radiant energy is much below the admitted limits; the energy density at the horn antenna output is 3 mW. One can also remark a good correlation between the complex Doppler signal and the ECG signal, the breathing and the pulse photoelectric transducer.

Investigating the cortical connectivity in the brain by combined TMS and EEG.

K. Iramina^{1,2}, T. Arimatsu¹, H. Sato¹, A. Hyodo², T. Hayami³, S. Ueno⁴

1. Department of Intelligent Systems, Kyushu University, Fukuoka, Japan; 2. Graduate School of Systems Life Sciences, Kyushu University, Fukuoka, Japan; 3. Digital Medicine Initiative, Kyushu University, Fukuoka, Japan; 4. Department of Applied Quantum Physics, Kyushu University, Fukuoka, Japan

Cortical reactivity and the functional connectivity in the brain are able to be investigated by the combined measurement of EEG and transcranial magnetic stimulation (TMS). When the TMS was applied to the motor area, the posterior parietal cortex (PPC) and the cerebellum, this study focused on the differences in the cortical reactivity of these areas. It is difficult to measure evoked EEG by magnetic stimulation because of the large artifact induced by magnetic pulse. We used an EEG measurement system to eliminate the electromagnetic interaction emitted from TMS. A temporary intercepting the input of the amplifier was equipped in the preamplifier of EEG which was controlled by the trigger signal from the magnetic stimulation device. Applying such improved EEG, it proved that artifact can be removed. However, large residual artifact got mixed in electrodes near the stimulus point of TMS. To remove this artifact, independent component analysis was applied to the measurement signals and only the artifact component was removed from the EEG signals. In addition by using ICA, we could reduce the artifact from the EEG signal. EEG signals on the all electrodes over the head within 10 ms after TMS stimulation were able to be obtained.

We investigated the differences in the cortical reactivity of the motor area, the posterior parietal cortex and the cerebellum when the TMS was applied to each area. 60 channels EEG over the whole head are measured, and the EEG topography on the surface of the head and current distribution on the cortex were calculated. EEG data were filtered from 0.1 Hz to 350 Hz, and the data were averaged with the trigger at TMS onset. Stimulus intensity of TMS was determined based on the threshold intensity of the muscle movement when the motor area was stimulated. The stimulus intensity was 80 % of the motor threshold. A figure-of-eight 70 mm coil was used (inner diameter: 53mm, outer diameter: 73 mm) and was kept tangentially over the scalp. The magnetic flux density at the center of each coil was around 1T. Direction of the induced current of TMS was from posterior to the anterior of the head.

Fig.1 shows the EEG waveforms superimposed of 60 channels data when the motor area, the right PPC and the cerebellum were stimulated respectively. It was possible to measure the evoked EEG after the stimulation 10 ms. Fig. 2 shows the current distribution map on surface of brain when the motor area, the right PPC and the cerebellum were stimulated respectively. Based on the EEG topography, when motor area was stimulated, we could observe that the evoked potential transmitted from the stimulated hemisphere to its contralateral hemisphere. However, such spreading was not clearly observed when posterior parietal cortex and cerebellum were stimulated. Distinct differences in cortical reactivity of motor, posterior parietal cortex and cerebellum to magnetic stimulation were observed. When motor area was stimulated by TMS, it was observed that the spreading of the evoked electrical activity to the contralateral hemisphere in about 20 ms. However, when the posterior parietal cortex was stimulated, transmitting to the contralateral hemisphere was not observed. When the cerebellum was stimulated, evoked electrical activity propagates to the anterior in the ipsilateral hemisphere and the contralateral motor area. These results suggest that the motor area has strongly interhemispheric connection and the posterior parietal cortex has no inter-hemispheric connection. For the cerebellum, cerebellum-cerebrum connection, intrahemispheric and interhemispheric connections has observed by TMS and EEG measurement.

Magnetic micro-machines (MMM) have been proposed as effective tools for low-invasive medical applications, as they can be easily driven by an external rotating magnetic field, without cables or on board power supply. These machines are small objects (4-10 mm), generally built with two main components: a central magnetic part, properly magnetized, and a screw shaped structure. These elements are functional to the MMM's displacement, as the rotation is obtained by fixing the magnetization perpendicularly to the body's axis, and by applying an external rotating field which induces a synchronous rotation. The rotation is then converted into an axial motion through the screw shaped geometry. The frequency, the magnitude, and rotation plane of the external field are used to control speed and direction of the MMM, allowing to drive them along complex paths [1]. For these properties, MMM have been shown to be used effectively in low-invasive medical applications, like hyperthermia, drugs delivery, tumor cells mechanical destruction [2,3].

Due to the small dimension required, manufacturing of MMM can be really complex and expensive, often involving sputtering or precise etching processes. Moreover, magnetic part and spiral structure are often different pieces glued together limiting the volume available for magnetic moment generation. In this paper, we propose an innovative and low cost MMM manufacturing process, based on moulding of a Sm-Co powder and acrylic (or polyurethane) resin composite gel cast in silicon moulds. Those moulds can be prepared using a metallic master such as a standard screw or any proper designed element. Elastic moulds composed of a single block allow an easy extraction and are preferable over rigid moulds, composed of two separated halves.

During the polymerization of the resin, an uniform external magnetic field is kept perpendicularly to the body's axis, aligning the Sm-Co particles along the desired direction and increasing the total magnetization as well. This magnetic field of about 0.8 T is generated by two NdFeB magnets located at two sides of the mould.

Fig. 1 shows our first prototype of a spiral-type MMM of 10.7 mm length and 2.0-mm diameter, manufactured according to the described moulding process, using a standard screw as a metallic master. As shown in the table, the percentage of the magnetic power is still pretty low, giving a magnetic moment of 1.528 emu, corresponding to a total magnetization of the order of 63 mT. Further solutions to improve the compactness of the powder and to make use of a designed screw with different threads are under development.

To explore the magnetic properties and characteristics of the motion of this MMM, we have made a series of experiments under different amplitude and frequency of an external rotating magnetic field, and under different oils of known cinematic viscosity. As reported by other authors, the MMM velocity is roughly linear on the field frequency, getting the largest value of about 9 mm/min for a field of 3.88 kA/m at 0.56 Hz in a low viscosity oil, as shown in fig. 2. Other oils with lower cinematic viscosity are plotted as well, showing as the velocity gets progressively reduced, as expected. The viscosity also controls the maximum rotational frequency (step-out frequency) over which the machine cannot longer synchronize with the external field.

Moment and velocity for this MM are still to be optimized, especially when compared to the data published of literature. For instance in [2], v/f is of the order of 0.64 mm, while we get a smaller value of about 0.27 mm. But this is not surprising especially because our MMM has not a optimized angle of the thread (which should be about 45° instead of our 13° as shown in fig. 1). We are

currently working on optimization of the MMM preparation using non-standard masters, and with different powders and resins, to get better performances. This will enable us to get working MMM with a reasonable cost and easiness of preparation.

Magnetic Tracking of Eye Motion in Small, Fast-Moving Animals.

A. Plotkin¹, E. Paperno¹, G. Vasserman², R. Segev²

1. Electrical and Computer Engineering, Ben-Gurion University of the Negev, Beer-Sheva, Israel; 2. Life Sciences, Ben-Gurion University of the Negev, Beer-Sheva, Israel

Modern magnetic tracking systems are successfully used for increasingly sophisticated applications in the fields of biomedicine, neuroscience, bionics, etc. Such systems are especially effective for eye tracking in humans and animals. No other technology, including video tracking, provides the speed and resolution required for eye movements measurements.

Conventional magnetic eye tracking systems employ a cubic transmitting frame to monitor a scleral search coil. A principal drawback of this technique is the inability to monitor the scleral search coil location. Another drawback is that the scleral search coil is unable to monitor the torsional eye movements. Finally, in many applications, the large, bulky cubic transmitting frame is inconvenient to use.

In this work we suggest a new approach and system to overcome the above drawbacks. We replace the cubic transmitting frame with an array of eight transmitting coils (see Fig. 1). The transmitting coils are arranged in a special pattern that allows unambiguous tracking of both the location and orientation of a single search coil [1].

We also replace the conventional scleral search coil with a tiny solenoid that is attached to the eye aside from its optical axis (see Fig. 1). Such a coil can accommodate a much larger number of layers, which allows us to increase the signal-to-noise ratio and the tracking resolution.

To test the efficiency of the new approach we measured the eye movements of the archer fish [2]. This fish has the capability to shoot down insects above water by spitting a jet of water from its mouth. The archer fish has an expert visual system that is expected to provide insights into the brain visual processing. We challenge our new system with an application where both the eyes and the head of an archer fish (see Fig. 2) should be monitored while the fish is shooting. Our experiments with a 60x60 cm transmitting array and a 2-mm diameter, 2-mm length search coil have shown the ability of the new system to monitor the fastest movements of the fish eyes (see Fig. 3). We have obtained the tracking resolution of 3 millidegree and 8.3 micrometer rms for a 200-Hz bandwidth at a 25-cm distance from the transmitting array center. The tracking resolution decreases down to 30 millidegree and 83 micrometer rms for a 40-cm distance.

The above results demonstrate very high system efficiency in tracking both the location and orientation. The new transmitting array and the new search coil are convenient in use and can successfully be applied to many other applications with behaving animals.

Introduction

Diffusion-weighted imaging (DWI) using magnetic resonance imaging (MRI) reflects the diffusion of water molecules in a sample. The diffusion of water molecules in biological tissues is restricted by cell membranes and other microscopic structures. If we can theoretically predict signals of diffusion MRI for samples having various microscopic structures, we can estimate the unknown diffusion parameters, such as shape and permeability through a comparison of theoretically predicted signals and experimental results¹⁾. Therefore, establishment of a method to predict the signals of DWI is important. The finite-difference method is a general numerical method for solving partial differential equations in discrete space and time²⁾, and is applicable to the diffusion equation of nuclear magnetization, but this method has computational errors due to discretization. The lengths of the spatial step Δx and time step Δt are representative conditions for calculation, and the computational errors depend on these lengths. However, the relationship between computational errors and the lengths of the spatial step Δx and time step Δt involved is not clear. The purpose of this study is to obtain the lengths of the time step and spatial step which minimize the computational errors in a finite-difference diffusion simulation. We evaluated the difference between the signals of the numerical solution and explicit solution of the diffusion equation of nuclear magnetization under the same conditions. We found combinations of the time step and spatial step which minimize this difference.

Methods

The dynamics of macroscopic magnetization in a one-dimensional diffusion of molecules was derived from the following Bloch-Torrey equation³⁾:

$$\partial(CM)/\partial t = D\partial^2(CM)/\partial x^2 + i\gamma GxCM \quad (1),$$

where C is the number of water molecules per unit volume, M is the magnetization vectors per molecule, D is the diffusion coefficient, γ is the gyromagnetic ratio and G is the intensity of the motion-probing gradient (MPG). This equation was transformed into the finite-difference equation in discrete space and time as the numerical solution of the diffusion equation. The explicit solution of the diffusion equation was obtained using the Fourier transformation and Lagrange's partial differential equations. The observed signals are the spatial integration of magnetization in MRI. For a comparison of the numerical solution and the explicit solution, we defined the initial magnetization for the explicit solution using the rectangular function having width Δx , magnitude A , and position k_0 . The signals of numerical solution S_d and explicit solution S_e were derived under the same initial conditions after a time step Δt . We defined the computational error as the difference between the signals of the numerical solution and the explicit solution:

$$E = (S_d - S_e)^2 \quad (2).$$

Results and Discussion

The Fig. shows the relationship between the optimum lengths of the time step and the resulting spatial step for the following parameters: $A=1$, $k_0=5$, $D=1.95 \times 10^{-6}$ [mm²/ms] and $G=10 \times 10^{-3}$ [mT/ms]. Optimum Δx increased as optimum Δt increased. The Fig. revealed that the lengths of the time step and spatial step which minimize computational errors depended on the value of k_0 (the distance

from the origin divided by the interval between the spatial grid points). In an actual model which had a certain range, each grid point has a different combination of optimum lengths of the time step and the spatial step. However, we have to determine one combination of lengths of the time step and spatial step for the whole model. A method to determine that combination is to substitute the number of grid points divided by 2 into k_0 . This definition of k_0 provides a practical way for optimizing the whole model and this method is efficient in bringing about a decrease of computational errors in the models.

Conclusion

A decrease in the lengths of the spatial step and time step results in an improvement of computational errors, albeit with an increase in the time for computation. Practically, we can define the time for calculations and computational errors, and we can choose the optimum combination of the lengths of the spatial step and time step based on this study.

Department of Applied Quantum Physics, Graduate School of Engineering, The Kyusyu University, Fukuoka, Japan

Introduction

The electrical activity in neurons, known as an action potential, is the direct consequence of changes in the concentration of extracellular Na (Na_e) / intracellular Na (Na_i) ions. Influx of extracellular Na_e into the cell fluid causes electric potential difference, resulting in the generation of action potential. Since Na_e / Na_i changes reflect the nerve excitation, development of Na_e / Na_i imaging potentially becomes a direct imaging method for nerve excitation. However, the detection method for Na_e / Na_i changes has not been developed sufficiently.

In the present study, measurement of Na_e / Na_i in the bullfrog sciatic nerves was performed by ^{23}Na -MRS (magnetic resonance spectroscopy) using ^{23}Na frequency shift reagent $\text{Na}_4\text{HTmDOTP}$.

Materials and Methods

< ^{23}Na chemical shift reagent >

^{23}Na chemical shift reagent $\text{Na}_4\text{HTmDOTP}$ was purchased from Macrocyclics (Dallas, USA). TmDOTP is membrane impermeable and induce frequency shifts in the extracellular cation resonances sufficient to clearly resolve them from the intracellular cation resonances [1].

< ^{23}Na -MRS of sciatic nerve>

Magnetic resonance spectroscopy (MRS) is used for noninvasively investigating metabolism and the concentration of biomolecules in biological tissues. Bullfrogs were anesthetized with eugenol and sciatic nerve was isolated surgically. The nerves were maintained in Ringer solution until the further use. Action potentials of the sciatic nerve were measured by a pair of platinum electrodes attached to the nerve bundle. The separation between the recording electrodes was 5 mm. The distance between the stimulating electrodes and the recording electrodes was approximately 40 mm.

Before acquisition of ^{23}Na -MRS, nerves were submerged into the Ringer solution containing 5.0 mM TmDOTP for 5 minutes. MRS was performed on a Varian 4.7-T magnetic resonance spectrometer. The free induction decay (FID) signals were recorded from nerves. To obtain the shift of Na_e / Na_i resonance, ^{23}Na spectra were acquired from the whole sample with TR 200 ms and 1024 averages. The spectra were obtained by a weighted Fourier transformation of the FID signals (line broadening factor = 16).

Results and Discussion

To determine the effective concentration of TmDOTP, frequency shifts in saline containing various TmDOTP conc. were performed. Fig. 1A shows the frequency shifts of ^{23}Na -MR spectra in saline containing 0.01 – 0.08 M TmDOTP. TmDOTP showed concentration-dependent frequency shift within 20 – 60 ppm (4000 – 12000 Hz). Based on this result, TmDOTP conc. was determined as 5 mM.

Since TmDOTP binds to Ca^{2+} and possibly affects nerve excitation [1], the action potential of TmDOTP solution-immersed nerve was examined. Fig. 1B shows the action potential of the nerve before acquisition of ^{23}Na -MRS. We found a single peak in the recorded action potentials generat-

ed from A α fibers (fast-conduction, responsible for motor function). TmDOTP had no effects on the generation of action potential.

Fig. 2 shows ^{23}Na -MR spectra in Ringer solution-immersed nerve and TmDOTP solution-immersed nerve. Na_e and Na_i signals were detected clearly in the spectra of TmDOTP solution-immersed nerve while single peak was detected in Ringer solution-immersed nerve.

Conclusion

The present study demonstrated the measurement of Na_e / Na_i in sciatic nerves by ^{23}Na -MRS using ^{23}Na frequency shift agent $\text{Na}_4\text{HTmDOTP}$. Na_e and Na_i signals were detected clearly in the spectra of TmDOTP solution-immersed nerve. These results suggest the potential application of Na_e / Na_i imaging for direct imaging of nerve excitation.

Detection of single Magnetic bead using Spin Valve Structure for an Array of PHR Sensor.

S. Oh, H. Tran Quang, K. Kim, C. Kim
Chung nam univ., Daejeon, South Korea

Abstract

Commercially available magnetic bead is commonly used in biological applications. We have observed signal in single magnetic bead (M-280 Streptavidin) by Planar Hall Resistance (PHR) sensor.

PHR has been measured in spin valve structure NiFe/Cu/NiFe/IrMn as a function of magnetization measured by vibrating sample magnetometry (VSM) and the PHR sensor signals are measured by four probe method. PHR sensor fabricated by lithography method with patterned size of $3 \times 3 \mu\text{m}^2$. Using this sensor, we detected the single magnetic bead.

Introduction

Recently, there is tremendous improvement into a Lab on a Chip or Micro Total Analysis Systems (μ _TAS) that has received to be growing attention by researchers [1-2]. The sensitivity of the nano scale sensors are much higher than the sensitivity of the micro scale sensors but decreasing the size of the sensor needs much time to detect the bio molecule [3] In this paper, we explain the movement and detection of micrometer sized magnetic bead. The first work based on this approach, the bead array counter (BARC) bio sensor and used $2.8 \mu\text{m}$ magnetic labels (Dynabead M-280) which are applicable for biowarfare agents [4].

Experimental Methods

Spin valve structure (NiFe/Cu/NiFe/IrMn) were fabricated by DC magnetron sputtering under working pressure of 3 mTorr and the base pressure of 3×10^{-8} Torr on SiO_2 wafer at room temperature. During sputtering process a uniform magnetic field of 300 Oe is applied in the film plane used to induce a uniaxial magnetic anisotropy. Samples with size of $3 \times 3 \mu\text{m}^2$ for PHR measurements were prepared by lithography and lift-off etch method for the junction and electrodes. We used lift-off etch method in order to get more clean surface instead of dry etch method. To make passivation layer Si_3N_4 (200 nm) / SiO_2 (20 nm) / Au (20 nm), we used the RF magnetron sputtering with working pressure 2 mTorr. The signal of the single magnetic bead was done by using the four probe method.

Results and Discussion

Fig.1 shows the spin valve structure of Ta (5 nm) / NiFe (3 nm) / Cu (1 nm) / NiFe (4 nm) / IrMn (20 nm) / Ta (5 nm). The as-sintered pinned Permalloy layer displayed an exchange bias of 639 Oe which is very high.

Fig.2 shows the SEM image of the junction with one single magnetic bead with size $2.8 \mu\text{m}$ and the clear image of the junction is shown on one side of the image.

For the pattern size of $3 \times 3 \mu\text{m}^2$, the sensor signal is shown in Fig.3 where the PHR voltage versus time was plotted. During the measurement, we applied a magnetic field of 20 Oe. The PHR Voltage changed very slowly up to 150 μV but after that there is a sudden change in the signal of 200 μV during bead drop which was clearly shown in the fig.3.

Conclusion

The present work deals with movement and detection of micrometer sized magnetic beads and we have successfully demonstrated the detection of $2.8 \mu\text{m}$ single magnetic bead. Earlier, we reported our work in which we fabricated the sensors with different junction size and different magnetic bead sizes.

Introduction

The Switched Reluctance Motor (SRM) is an electric machine that consists of a simple structure with a winding only on the stator and not on the rotor. The costs are lower than other motors due to its simple construction. It is easy to implement a high speed drive system and both the torque and efficiency of the unit volume are highly superior to all others [1]. However, the SRM has disadvantages that torque ripple and vibration/noise are big. Especially, torque ripple happens by structure of SRM, so it can confirm general characteristic of SRM through analysis considering teeth/slot structure [2]. The Linear Switched Reluctance Motor (LSRM) has the advantage of SRM stated above and structure. However, contrary to the structure of conventional SRM, the LSRM presented in this paper has structure moving stator and a long air-gap. Hence, magnetic force characteristics are analyzed to air-gap distance.

This paper deals with extraction of design parameters of LSRM based on force calculation using space harmonic analysis, 2D/3D FEM and experimental measurement. First, analytical solutions for flux density due to mover winding currents are derived in terms of magnetic vector potential and a 2D rectangular coordinate system, for the case when the mover is located at aligned and unaligned position. The analytical results are compared with those obtained from a 2D finite element method (FEM). Second, using Fourier series expansion, this paper predicts the force profile of LSRM analytically. And then, accurate results such as force measurement and 2D FEM are given to confirm the analysis. Finally, we extract design parameters such as overhang, teeth width of mover and stator based on force calculation using 3D FEM.

Analysis model of the LSRM and assumption

Fig. 1 shows the analytical model of LSRM which consists of 6-pole/concentrated winding type mover, 4-pole stator corresponding with 6-pole mover. The symbols of LSRM are as followings: "A" is positive phase and "a" is negative phase. The teeth and slot width, teeth and back-iron height and stack length of mover are w_{mp} , w_{ms} , h_{mp} , h_{my} and stm respectively. Those of stator are w_{sp} , w_{ss} , h_{sp} , h_{sy} and sts respectively. The air-gap length of LSRM is g .

Results and discussion

R. Krishnan [2] presented analytical formulas for force at aligned and unaligned position using the normal flux density. This paper calculates continuous force of LSRM according to mover position using analytical formulas for force presented in [2] and Fourier series expansion. Fig. 2(a) and 2(b) show the analytical results of normal and propulsion force according to mover position. The analytical results are compared with those obtained from 2D FEM. In our manuscript, we will present design parameters such as overhang, teeth width of mover and stator based on force calculation using 3D FEM.

Dynamic Analysis of Rotor Eccentricity in Switched Reluctance Motor with Parallel Winding.

L. Jian

Electrical Engineering, Dong-A University, Busan, South Korea

Abstract. This paper investigated the rotor eccentricity effects of switched reluctance motor and the reduction of these effects by different winding methods. The motor was simulated by using 2D transient magnetic FE analysis coupled with external circuits. The main exciting force of the vibration is the electromagnetic force in the stator that is calculated using Maxwell stress method. Serial connection and various parallel connections of windings were modeled in the external circuit. The influence of winding method counteracting unbalance forces on the rotor vibration behavior is investigated in this paper. Dynamic FEM simulation is utilized to study the current distribution in the paralleled paths under rotor eccentricity.

Keywords: rotor eccentricity, switched reluctance motor, unbalanced magnetic pull, parallel paths. In order to maximize the power density of the motor at a fixed inverter volt-ampere rating, the SRM must be designed with a sufficiently narrow air gap that at the aligned position the machine saturates at a current much less than its peak operating current [1]. The air gap of SR motors in fractional horsepower applications is usually 0.2mm-0.4mm which is much smaller than PM motors and induction motors. Also so it is more sensitive to rotor eccentricity. It is therefore essential to keep the rotor eccentricity to a minimum by using strict control of manufacturing and assembling procedures. However, for economic reasons, and especially for mass produced machines, it is not always possible to do so. The use of parallel paths in stator windings offers another way to reduce the noise introduced by rotor eccentricity.

The basic reason for using parallel paths can be explained Figure 1. (a), which shows the schematic diagram of a 12/8 SRM stator winding arrangements having concentric-type pole windings. Let us assume that the rotor is shifted downwards. The magnetic flux per pole produced by pole winding A1 with same current is less than that by winding A3 since the flux due to A1 has to pass through a larger air gap. In other words, the inductance of winding A1 is less than that of winding A3. If the windings in each phase are connected in series, e.g. A1, A2, A3 and A4 are in series and carry the same current, then the magnetic flux produced by A1 would be less than that produced by A3. The unbalance of the magnetic fluxes introduced an unbalanced magnetic pull and low pole-air force waves to cause noise and vibration. If, however, windings A1, A2, A3 and A4 are connected in parallel, as shown in Fig.2 (c)-3, the current flowing in A1 would be larger than that in A3 since the inductance voltage drop per unit current in A1 is small than that in A3. The large current in A3 will offset, to a certain extent, the unbalance in magnetic flux distribution, and hence will reduce the unbalanced magnetic pull and noise emission.

The influence of winding method counteracting unbalance forces on the rotor vibration behavior is investigated in this paper. Dynamic FEM simulation is utilized to study the current distribution in the paralleled paths under rotor eccentricity. As shown in Fig.2 (c)-3, the coil of opposite stator poles is paralleled. The inductances of paralleled paths are different due to the non-uniform air gap. The normal force on the stator poles are unequal and have the tendency to draft rotor back to its center.

More detailed explanation and results will be given in the full paper.

Comparison of 12/8 and 6/4 Switched Reluctance Motor: Noise and Vibration Aspects.

L. Jian

Electrical Engineering, Dong-A University, Busan, South Korea

The wide application of switched reluctance motors (SRM) is limited by their higher vibration and acoustic noise. It has been shown that the dominate source of the vibration and acoustic arises from the radial force acting on stator. The 12/8 SR motor have 2 times of poles as the 6/4 SR motor, thus with the same output torque the magnetic force should be half as the later one. It's widely believed in industry that the 12/8 SR motor is more quietly than 6/4 one. Two prototypes (in Fig.1) were developed during the past two years. The From load test, the spectrum of vibration was measured for these two prototypes. Note these two prototypes have the same stack length and outside diameter and test was undertaken at same conduction.

The radial force acting on one stator pole is abstracted from the FEA results and displays in Fig. 2. The force is a function of time and gets its peak value at commutation. The frequency of radial force in 12/8 is two times as that in 6/4 since there are eight rotor poles pass over the excited stator phase in one rotation in 12/8 prototype while there are only four poles in 6/4 prototype. The vibration doesn't reduce so much as radial force when we compare Fig. 2 and Fig. 3.

The vibration and magnetic excitation seems to have a complicated relationship which depends on the impedance of stator and housing [1]. An accurate determination of resonant frequencies and mode shapes of the SRM stator is therefore essential for low acoustic noise design. Based on the structural finite element method and elasticity theory, 3D vibration modes and resonant frequencies of prototypes were calculated[2].

The meshing of stator core without and with housing was shown in Fig. 4 which contains 25088 and 147209 elements respectively, thus the calculation time of the second model would take much longer time. The 8th and 11th mode shape and frequency were shown if Fig. 5.

More detailed explanation and results will be given in the full paper.

Comparison of iron losses in switched reluctance motor with different winding arrangements and switching sequences.

T. Sun, J. Hong

Department of Mechanical Engineering, Hanyang University, Seoul, South Korea

I. Introduction

Some drawbacks including low electrical utilization, acoustic noise and special drive much limit the performance and application of switched reluctance motors (SRM). In order to improve these, several different stator winding arrangements and switching sequences have been proposed [1]-[3]. Although all these methods claimed that the advantages in dynamic performance were achieved, none of them demonstrated the steady-state characteristics, especially in the aspect of losses and efficiency. Unlike the PM synchronous motors, the SRM has great changes in the flux density of the rotor. Hence, the iron losses become much significant. As well known, the iron losses consist of hysteresis loss and eddy-current loss [4]. The hysteresis loss is proportional to the frequency and amplitude of flux density, while the eddy-current loss is proportional to the square of the both. The different winding arrangements and switching sequences directly cause the different frequency and amplitude of flux density, although the dimensions of motor bodies are completely same.

This paper will compare the iron losses of SRMs with different winding arrangements and switching sequences. The non-sinusoidal driving current makes the conventional iron-loss calculation method unavailable. This paper will adopt the method which was introduced and verified in [4] to solve this problem. By using of the Fourier transform and experimental iron-loss curves, this method can evaluate iron losses with any shape and period of flux density. Finally, the iron losses in the stator and rotor, and the ratio of the total iron losses to the input power will be compared. These results can give more reference for the SRM design and the selection of drive method.

II. Analyzed SRM Models

The fundamental structure of the analyzed model is a 6/4 V-type SRM. The concentrated winding, distributed winding and toroidal winding are combined with this structure, respectively. The winding arrangements and corresponding switching sequences are shown in Fig. 1.

III. Iron-loss Calculation Method

A. finite element analysis

The finite element analysis (FEA) is used to solve the magneto static analysis. The ideal square shape currents with the same amplitude are used to excite the four models. The calculated flux density of each element then is decomposed into the normal- and tangential-direction variations.

B. harmonic analysis

After obtain the flux densities of each element, the frequency and amplitude of each harmonic component are analyzed by using Fourier transform.

C. interpolation in experimental data curve

A group of iron-loss data which is tested by Epstein is shown in Fig. 2. The total loss including hysteresis loss and eddy current loss of each element can be obtained by interpolating these data curves with the frequencies and amplitudes calculated in the last step. Finally, summing the results calculated in each element, the losses of any desired region can be evaluated.

IV. Comparison of Results and Discussion

Fig. 3 shows the final comparison results on the total iron losses and the ratio of iron losses to the input power. The results are unified by those of the model with concentrated winding. It can be seen that the model with distributed winding has the lowest iron losses. The bipolar conduction improves the iron losses significantly.

Optimum Design Criteria for Maximum Torque Density and Minimum Torque Ripple of Synchronous Reluctance Motor according to the Rated Wattage using Response Surface Methodology.

Y. Choi, S. Mun

Electrical Eng., Hanbat National University, Daejeon, South Korea

Introduction

Issues such as efficiency and torque/ampere are important in evaluating the performance of a SynRM. Such characteristics depend upon the rotor shape of the machine related to the ratio K_w of total flux barrier width to total iron sheet width and, therefore, require a numerical evaluation and design. However, it is not a fixed value that is applied to all shapes with regard to a variation of rotor in a SynRM. So, Reference [1] proposed that a design solution is found through the comparison of inductance difference and ratio according to the rotor shape variations under each rated wattage. However, Reference [1] have been performed the situations that each flux barrier width are same those for each ratio K_w , respectively, and torque ripple are not considered.

If each flux barrier is same width, it is impossible to gain a torque ripple reduction across the wide current range as well as obtain the good performance. Also, if various flux barrier width of rotor is existed in some ratio K_w , it is expected to gain another characteristics with regard to difference and ratio of inductance and torque ripples.

The RSM has been achieved to use the experimental design method in combination with Finite Element Method and well adapted to make analytical model for a complex problem considering a lot of interaction of design variables [2]-[4].

The focus of this paper is found firstly a design solution through the comparison of inductance difference and ratio and torque ripple according to rotor shape variations under each rated wattage and, Secondly, a mixed resolution rotatable central composite design (CCD) is introduced and analysis of variance (ANOVA) is conducted to determine the significance of the fitted regression model.

Design model and Procedure

The process of optimization design is shown in Fig.1.

The shape coordinates of the rotor have been drawn as a condition of ratio K_w . In Fig. 1, design variables of flux barrier width are determined to improve torque performance of a SynRM. And then, analysis data is obtained through finite element method based on central composite design mostly used in RSM, and optimum point is determined through analysis of the data. Finally, it can be obtained the maximum torque density & minimum torque ripple of Synchronous Reluctance Motor (SynRM) according to the rated wattage.

Fig. 2 shows the point variables and variation direction example for the shape change according to flux barrier width in 3 number of flux barrier. Each pair (W_1, W_8), (W_2, W_7), (W_3, W_6)... move symmetrically on the basis of q-axis. And points of P_1 - P_8 move as a condition that flux barrier widths are varied [5].

Fig. 3 shows flux plots of a optimum design example for 3HP.

More detailed results and discussion will be given in final paper. And the mathematical expressions for response surface methodology will be also given in extended version.

The Evaluation of On-line Observer System of Synchronous Reluctance Motor Using a Coupled FEM & Preisach Model.

H. Lim¹, J. Lee¹, M. Lee¹, D. Lee²

1. Electrical Engineering, Hanbat National University, Daejeon, South Korea; 2. Electrical Engineering, Hanyang University, Seoul, South Korea

Introduction

The influence of the saturation cannot be neglected since the high-speed operation and precision sensorless vector control of Synchronous Reluctance Motor (SynRM) are required. The q-axis usually shows minimal saturation in high saliency ratio, but the high performance of d-axis usually shows significant saturation when the machine is being operated at rated operations.

In the case of d-axis excitation, the saturation is the combined effect of saturation in the stator yoke, stator teeth, and rotor rib, and can reduce the L_d inductance, which has an effect on the torque density, power factor and efficiency of SynRM, by as much as 50%.

Therefore it is difficult to expect a good control response performance from SynRM without considering the above defects.

Fortunately, the advantages of finite element method (FEM) unlike voltage equation modeling are primarily their ability to model the complicated internal structure within a SynRM and ability to model magnetic saturation to high degree of accuracy.

In high speed applications, iron loss can become the major cause of power dissipation. Therefore, whereas in other kinds of machines a rough estimation of iron loss can be accepted, their importance in SynRM justifies a greater effort in calculating them more precisely. Preisach's model, which allows accurate prediction of iron losses, is adopted in the procedure to provide a nonlinear solution [1]-[3].

In this paper, a coupled finite element analysis and Preisach's modeling for SynRM are presented and is the sensorless vector control parameters estimation is performed under the effect of saturation and iron loss.

For considering the dynamic characteristics, moving mesh technique is used and vector control algorithm is combined with an analysis tool. Extensive experimental works have been conducted to verify the accuracy of the analysis.

Analysis Model

A direct convergence method, which is not diverged at any initial value and has the advantage to converge quicker than Newton-Raphson method, iterates the procedure to provide a nonlinear field solution. Indirect field-oriented control algorithm is applied to the proposed analysis model for the example of dynamic characteristics. This technique is illustrated in Fig. 1.

To verify the validity of the proposed method, the TMS320C31 DSP control unit and Power Circuits are equipped as shown in Fig. 2.

Analysis Result And Discussion

Fig. 3(a), (b) 3 phase current characteristics of each analysis in single B-H and proposed method, respectively.

It is observed that whereas current responses in the single B-H analysis of Fig. 3(a) is nearly match to sinusoidal ones, another (b) highly distorted as hysteresis phenomena is existed as shown in Fig. 3.

Fig 4(a), (b) show the i, λ phase relationships in single B-H and proposed method, respectively. The $i-\lambda$ loci, which is total hysteresis loss of a SynRM, can be investigated on the basis of proposed analysis method.

More detailed results and discussion will be given in final paper.

INTRODUCTION

This paper deals with a design and characteristic analysis of Synchronous Reluctance Motors(SynRM) using an equivalent magnetic circuit modeling. SynRM is classified into several types according to a rotor's shape such as segment-type, flux-barrier type, and axial lamination type. In this paper, a rotor's shape of an axial lamination is considered to design and characteristic analysis of SynRM using an equivalent magnetic circuit modeling.

Voltage, torque and power factors of SynRM model are defined by mathematical theories for explaining an operating principle. Inductances of d-q axis are related to determine a specification of design parameters and are determined by voltage-torque equations. These are important electric parameters to design of a rotor's shape using an equivalent magnetic circuit modeling.

In this paper, SynRM model with an axial lamination rotor is modeled using an equivalent magnetic circuit method. And this method determines design parameters such like current and inductances to satisfy a specification of SynRM model. This model is designed using an equivalent magnetic circuit modeling to consider zig-zag magnetic flux and analyzed by finite element method. The results such as current and torque variation using E.M.C.M are compared with ones by F.E.M. Moreover steady torque of SynRM model compared with the experimental ones.

THEORETICAL CONSIDERATIONS

Voltage equations of SynRM are similar to a general induction motor, but these exclude a term related to a rotor. Eq(1) and Eq(2) are d-q axis voltage and current equations of SynRM with an axial lamination rotor.

$$V_q = V\sqrt{2}\cos\delta = R_s I_q + j\omega L_d I_d, V_d = V\sqrt{2}\sin\delta = R_s I_d - j\omega L_q I_q \quad (1)$$

$$I_q = V\sqrt{2}(R_s \cos\delta - \omega L_d \sin\delta)/(R_s^2 + \omega^2 L_d L_q), I_d = V\sqrt{2}(R_s \sin\delta - \omega L_q \cos\delta)/(R_s^2 + \omega^2 L_d L_q) \quad (2)$$

PROTOTYPE MODEL

Fig. 1 shows prototype model manufactured by an equivalent magnetic circuit modeling. As seen in Fig. 1, the rotor of SynRM model consists of magnetic and non-magnetic steel layers laminated alternately. The center of the rotor consist of non-magnetic steel is filled out a plastic material.

RESULTS OF ANALYSIS AND TEST

1. Results from F.E.A

Current and torque variation by FEA is shown in Fig. 2. As seen in Fig. 2, the results of current and torque variation show good agreement with other values according to estimating methods.

2. Results from test

2.1. Alternating current test

Saturated inductances of SynRM model are measured by an alternating current standstill test. Fig. 3(a) shows electric circuit for a measurement according to d-q axis alignment of a rotor. Fig. 3(b) is inductance curves obtained from the measurement to increase the frequency from 50Hz to 500Hz.

2.2. Measurement of steady torque.

Instrument setup for measuring a steady torque consists of a handle gear, torque sensor and SynRM is shown in Fig. 4. To flow DC current of SynRM model, steady torque is measured at respective positions for a rotation.

Fig. 5 shows steady torque curves of analyzed and measurement results.

CONCLUSION

This paper presents design and characteristic analysis of synchronous reluctance motor using an equivalent magnetic circuit modeling to consider zig-zag magnetic flux. The results such as current and torque variation using E.M.C.M are compared with ones by F.E.M. And steady torque of SynRM model compared with the experimental ones.

Design Solutions To Minimize Iron Core Loss In Synchronous Reluctance Motors Using Preisach Model & Finite Elements Method(FEM).

H. Lim¹, J. Lee¹, M. Lee¹, D. Lee²

1. Hanbat National University, Daejeon, South Korea; 2. Electrical Engineering, Hanyang University, Seoul, South Korea

This paper deals with an automatic design procedure for the minimization of iron core loss in a synchronous reluctance motor (SynRM). The focus of this paper is the design relative to hysteresis loss on the basis of rotor shape of a SynRM in the same torque density. The coupled Finite Elements Analysis (FEA) & Preisach model have been used to evaluate the iron core loss with the rotor shape. The proposed procedure allows to define the rotor geometric dimensions starting from an existing motor or a preliminary design. The iron loss has been reduced with a rotor design variation.

Optimum Design of Synchronous Reluctance Motors Based on Torque/Volume Using Finite Element Method & Sequential Unconstrained Minimization Technique.

S. Mun, Y. Cho

Electrical Engineering, Hanbat National University, Daejeon, South Korea

Synchronous reluctance motor (SynRM) present many advantages if compared to induction motors that concern the simple, rugged rotor design, no rotor cage and consequently no copper losses and no rotor parameters to be identified. Issues such as efficiency and torque/ampere are important in evaluating the performance of a SynRM[1].

Such characteristics depend upon the rotor shape of the machine related to the ratio K_w of total flux barrier width to total iron sheet width and, therefore, require a numerical evaluation and design. If $K_w =$ about 0.5, it is possible to gain a high inductance difference L_d-L_q across a wide current range as well as obtain the maximum output torque[2],[3].

And a paper which is discussed the influence of the ratio K_w of total flux barrier width to total iron sheet width on a SynRM have been presented [4]. However, Reference [2] investigated the axially laminated type and reference [3] discussed the 6 flux barrier type respectively, and output powers are different. Reference [4] proposed the design of the 340W home appliance SynRM then, K_w is 1.

Therefore, it is not a fixed value that is applied to all shapes with regard to a variation of rotor in a SynRM.

So, Reference [5] proposed that a design solution is found through the comparison of inductance difference and ratio according to the rotor shape variations under each rated wattage.

And Starting from an existing design, the best design solution is selected, and we could be seen that the flux barrier number, K_w can be a fixed value related to the rotor diameter (3HP, 3.5HP, 4.5HP, 5.5HP, 6HP, 7HP, 8HP, each stack length are different.).

In this paper the ratio K_w of total flux barrier width to total iron sheet width and flux barrier numbers and additional rotor diameters of a SynRM is defined as design parameter.

Results and Discussion

Fig. 3 shows an example of zandel functions and design solution of 1HP machines(rotor diameter: 66.822mm).

And Fig. 4 shows the rotor optimum design function characteristics according to increasing rotor diameter at each rated current. One should notice that the design solutions should be related to the rotor diameter and it will be the important data in motor design of similar specifications.

The more detailed optimum design procedure and discusses will be represented in next extended version.

More detailed optimization process, results and discussion will be given in final paper. And the mathematical expressions for Sequential Unconstrained Minimization Technique will be also given in extended version.

Reduced windage loss rotor of SRM using magnetic saturation for high speed application.

S. Won, J. Lee

Electrical Eng., Hanyang University, Seoul, South Korea

1.Introduction

The increasing popularity of the switched reluctance motor is mainly due to the simple rotor structure and the fact that its speed-torque characteristics can be tailored to suit the desired application. Especially, for high speed applications like vacuum cleaners, the motor speed is up to 40000 rpm, where the windage losses by rotor shapes are considerably higher than for an equivalent cylindrical rotor of the same diameter [1].

This paper presents a novel switched reluctance motor rotor shape which has ribs between the rotor salient poles on the rotor outer surface. Fig. 1 shows the conventional switched reluctance motor and the proposed rotor shape which is an aerodynamically cylindrical rotor but magnetically same as a conventional rotor.

2.Parametric Simulation

Because the proposed rotor has ribs between the salient poles of the rotor, these ribs must be saturated while the stator poles overlap the ribs, for the rotor gets reluctance torques. Thus, the proposed rotor can not produce sufficient torque until the ribs are saturated and the resultant torque of proposed rotor is slightly less than the conventional rotor. But because the windage loss at high speed is overwhelming this torque discrepancy, the total power need to rotate the shaft is much less than conventional switched reluctance motor. Fig. 2 shows the flux density distribution of the proposed rotor ribs that is saturated.

Because the instantaneous torque of the SRM is proportional to the variation of inductance, we need to know the inductance variations according to angles and current values. The parametric finite element analyses are performed to get these inductance variations. Fig. 3 show inductance profile maps of the conventional rotor and the proposed rotor. Compared to the conventional rotor, the proposed rotor has high inductance values and relatively not so steep inductance variation slope according to angle at low current(below 2~3 A) because the ribs are not saturated while current values are low. Eventually, the motor torque is not enough while current values are below 2~3 A, but above 3A, the motor can produce sufficient torque.

3.Motor performance calculation

To predict the dynamic performance of SRM, it is needed to solve differential equations for the appropriate switched conditions including the mechanical equations. In order to know the load torque which includes windage loss, several experiments were performed. Using this inductance profile and load torque curve, the authors can perform the dynamic characteristics analysis without performing a transient finite element analysis which is burden job in simulation time aspect. The simulation is performed at speed of 35000rpm, where the motor has quite large windage loss. From the results of this simulation, we can find out that the proposed rotor shape is very useful at high speed. The extended paper will contain detailed comparison graph.

4.Conclusion

The proposed rotor has higher efficiency at high speed. The novel rotor shape does not compromise simple rotor structure of conventional switched reluctance motor and has higher efficiency at high speed by reducing the windage loss. The new rotor shape can be produced from the existing facilities. The rib structure which makes the proposed rotor reduce windage losses can be easily obtained without an additional manufacturing process. This study will be very useful not only for

researchers who study on electric machines, but also for engineers who have been engaged in manufacturing field for electrical home appliance machines.

1. University of Maribor, FE&CS, Maribor, Slovenia; 2. TECES, Maribor, Slovenia

Introduction

The paper proposes a new method for determining force characteristics of an electromechanical system by using co-energy considering only the main flux linkage. An electromagnetic brake (EMB) was used as the tested electromechanical system. The co-energy is calculated by integrating the flux linkages in terms of exciting currents. The flux linkage depends on the exciting current and on the variable air-gap thickness. The characteristics of flux linkages can be determined numerically using finite element method (FEM). Using flux linkage characteristics the current and air-gap thickness dependant co-energy characteristics can be determined in the entire range of operation. Considering the co-energy variation caused by the air-gap thickness variation, the attractive force characteristics can be obtained.

Numerous papers have been published dealing with the determination of magnetically nonlinear characteristics of flux linkages in different electromagnetic devices [4-5]. Paper [6] deals with determining force characteristics using co-energy caused by the total flux linkage ψ of the actuator. The co-energy determined in this way contains also the leakage flux which does not close through the armature and can therefore not contribute to force generation.

The procedure for determining force characteristics of an EMB using co-energy considering only the main flux of an EMB has not been described yet.

The results presented in this paper are used as a part of the EMB magnetically nonlinear dynamic model which is used for prediction of reaction times.

Electromagnetic brakes

Electromagnetic brakes (EMBs) are often used for breaking (or locking) rotors of electrical machines. The EMB consists of a magnetically nonlinear yoke and armature, winding, rotating disc, friction brake pad and steel springs (Fig. 1). The current carrying winding excites the magnetic circuit of the EMB with the total flux linkage ψ . The main part of aforementioned flux, the main flux linkage ψ_m , couples the electrical and the mechanical subsystem of the EMB and passes through the air-gap, yoke and armature. The attractive force between the yoke and the armature depends exclusively on the main flux linkage ψ_m . The difference between the total flux linkage ψ and the main flux linkage ψ_m is the leakage flux linkage ψ_σ , which does not pass through the air-gap.

Comparison of results obtained by FEM and measurements

The comparison of results obtained by FEM and measurements is presented in Fig. 2. It shows that electromagnetic forces calculated with the total flux linkages (F) exhibit the largest discrepancies from measurements. The electromagnetic force characteristics calculated via co-energy determined with the main flux linkages (F_m) and by Maxwell stress tensor method using FEM (F_{Maxw}) are closer to the measured (F_{meas}) electromagnetic forces.

The comparison of results obtained by FEM and measurements for whole operating range (different air-gap and current excitations) will be presented in full version of this paper.

Conclusion

The paper will show that the electromagnetic forces have to be calculated considering the main flux (linkage) when using co-energy, because only the main flux linkage couples the electrical and mechanical subsystems. The leakage flux linkage is not negligible and has to be taken into account.

The consideration of leakage flux linkage is important for predicting the dynamic response characteristics using dynamical model of the EMB.

The results presented agree very well, which confirms the quality of the proposed method. As far as the authors of this paper are aware, this is the first work that describes the determination of current and air-gap thickness dependant force characteristics using co-energy.

Comparison of electromagnetic forces for rated air gap thickness

Exchange bias in surface-crystalline FeNbB ribbons.

L. Kraus¹, O. Zivotský², K. Postava², P. Švec³, D. Janičkovič³

1. Institute of Physics v.v.i., Academy of Sciences of the Czech Republic, Prague, Czech Republic;

2. Department of Physics, Technical University of Ostrava, Ostrava, Czech Republic; 3. Institute of Physics, Slovak Academy of Sciences, Bratislava, Slovakia

Exchange bias in magnetic multilayers is of great importance for practical applications. The characteristic feature of exchange bias is the shift of the hysteresis loop from its normal position at $H = 0$ to the value $H_b \neq 0$, called the bias field. Similar behavior has been observed in surface crystallized Co-based amorphous ribbons [1,2]. Recently a surface crystallinity was found in as-quenched FeNbB ribbons [3]. The investigation of exchange bias in these materials is reported here. Fe_{80.5}Nb_{6.9}B_{12.6} ribbons, 28 μm thick and 10 mm wide, were prepared by the flow-casting method. The as-quenched ribbons exhibit partial crystallinity on both surfaces while the bulk of ribbon is amorphous. The X-ray diffractions taken from both sides of ribbon (Fig.1) indicate the presence of α -Fe. The coexistence of amorphous phase and crystalline α -Fe on the ribbon surfaces has also been confirmed by the conversion electron Mössbauer spectroscopy (CEMS) and magneto-optical Kerr effect (MOKE) [3]. The crystalline phase can be removed by a short etching of ribbon in a diluted nitric acid. The properties of the two surfaces are different. A high texture of the crystallites and their concentration in a very thin layer (about 2 nm thick) is typical for the wheel side. On the shiny side the crystallites are more or less randomly oriented and they extend deeper into the ribbon interior. The effective thickness of the surface layer on the shiny side is more than 30 nm. The coercive forces of the surface layers, measured by MOKE, are 0.8 kA/m and 3.2 kA/m for the wheel and shiny side, respectively [3].

The bulk magnetic properties of the ribbon are investigated by a DC hysteresis-loop tracer. The unstrained ribbon shows the hysteresis loop with low coercivity ($H_c \approx 3.5$ A/m), low remanence ($J_r/J_s \approx 0.04$) and saturation field about 600 A/m, which is typical for amorphous magnetostrictive alloys with random internal stresses. When tensile stress is applied to the ribbon the remanence steeply increases because of positive magnetostriction. The shape and position of low-field hysteresis loop now depends on the magnetic history of sample. Three hysteresis loops, measured with applied stress of 600 MPa, are shown in Fig.2. After demagnetization of sample, by decreasing alternating magnetic field, the usual symmetric hysteresis loop is observed (full line). If, however, the sample is saturated in a strong magnetic field H_{pre} , before the measurement, the low-field hysteresis loop substantially changes. It can be decomposed into two parts: (a) a small symmetric loop, which is responsible for about 10% of the magnetization reversal, (b) a larger loop with smaller H_c and the center shifted in the direction of the premagnetizing field. The small, symmetric, loop can be attributed to that part of ribbon, which is not affected by the hard magnetic surface layers. On the other hand, the behavior of larger loop can be explained by an exchange coupling between the Fe grains and the bulk amorphous phase.

For applied tensile stress σ , between 100 and 600 MPa, both the bias field H_b and the coercive force H_c linearly increase with σ . It may be explained by an increase of remanent magnetization of hard magnetic layers due to the stress induced magnetic anisotropy. Such behavior, however, seems to be in contradiction with the expected properties of polycrystalline iron, which should behave (in average) as a medium with negative magnetostriction. Experience, however, shows that exceptions from this rule are possible (e.g. [4]).

Similar behavior as in the ribbon under tensile stress can be observed when the ribbon is wound into a toroid. In this case, however, the outer half of ribbon is extended while the inner one is com-

pressed. Thus practically only the outer half of ribbon contributes to the low-field hysteresis loops. It is observed, as expected, that the bias field is proportional to the curvature of toroid. Differences are, however, observed if the toroid is wound with the shiny side out or in. For the ribbon wound with the wheel side out the bias field is about four times smaller than for the toroid with the shiny side out. This indicates that mainly the harder surface layer on the shiny side ($H_c \approx 3.2$ kA/m) is responsible for the exchange bias.

In this paper the surface magnetic properties of as-quenched (AQ) Fe_{80.5}Nb_{6.9}B_{12.6} ribbons are investigated using longitudinal magneto-optical Kerr effect (MOKE). These materials belong to the NANOPERM-type magnetic alloys, which are often applied in the area of nanocrystalline soft magnetic materials and magnetic sensors. It was shown [1] that preparation process of these materials causes the origin of very thin crystalline layer on the surface and its depth can be increased by postpreparation heat treatment (annealing). Hence there is a need to study the magnetic properties and the depth profile in the near-surface region of the alloys.

10 mm wide and 28 µm thick ribbons were prepared by conventional planar flow casting method and additionally spark-cut to the 9 mm discs to eliminate the in-plane shape anisotropy. MOKE methods are very sensitive to the ultra thin films and surfaces and enabled us to obtain the magnetic information from the ribbon surface depth up to 30 nm. MOKE experimental setup based on differential intensity method is used to obtain the magneto-optical (MO) angles of Kerr rotation $\theta_{Ks,p}$ and ellipticity $\epsilon_{Ks,p}$ for s- and p-polarized light at different incident angles. The longitudinal hysteresis loops detecting the magnetization component in the sample plane and in the plane of incidence are obtained. We did not observe any polar (out of plane) component of magnetization.

Figures 1a, b and 1c, d show the magneto-optical Kerr angles of θ_{Ks} and ϵ_{Ks} from wheel and shiny ribbon side at the incident angle of 80°. External magnetic field H is applied along the original ribbon axis. Shape differences in the case of wheel and shiny loops from Fig. 1 confirm different magnetic properties at both ribbon sides with the coercive fields of 10 Oe (wheel side) and 40 Oe (shiny side).

A. Wheel ribbon side

Magneto-optical angles measured on wheel side show different shapes of loops not only in the case of s-polarized light (Figs. 1a, b), but also for p-polarized light (not shown here). From this fact one can imply that the near-surface region on the wheel side is inhomogeneous and MOKE detects the contributions of two phases, crystalline and amorphous ones. Partial surface nanocrystallization with strong texture was confirmed also by the conversion electron Mössbauer spectroscopy (CEMS) and X-ray diffraction (XRD) measurements, which determine 14% of crystalline phase in the near surface region of thickness of about 200-300 nm (CEMS sensitivity).

Existence of crystalline phase in thin surface layer was checked in two ways: i) electrochemical surface polishing ii) etching of surface in diluted HNO₃. After short polishing and etching, the surface crystalline layer was removed, because measured MOKE angles have the same shape for both polarizations and coercive field decreased to 3 Oe (see subplots e, f of Fig. 1). Optical and magneto-optical parameters of remaining amorphous phase can be established by comparing the measured data in the range of incident angles from 20° to 80° with the theoretical model based on the light propagation in layered anisotropic media. Refractive index n_a and Voight constant Q_a of amorphous phase were calculated as: $n_a = 3.02 - i4.18$; $Q_a = 0.0156 + i0.0025$.

Knowing the MO parameters of amorphous phase we can now analyze MOKE of the as-quenched non-polished and non-etched ribbon. We assume that the near-surface region of AQ sample consists of an upper hard crystalline layer and the soft amorphous bulk with the parameters established in the previous step. To complete the ribbon depth profile from the wheel side we fitted all measured data with the two-layer model and found the parameters of the crystalline phase $n_c = 2.92 - i3.07$;

$Q_c = 0.0256 + i0.0024$ with the thickness $d_c = 2$ nm. The refractive index n_c is very close to the pure iron ($n_{Fe} = 2.90 - i3.07$), which confirms the CEMS and XRD results.

B. Shiny ribbon side

We can see that θ_{Ks} and ϵ_{Ks} hysteresis loops (subplots 1c, d) obtained from shiny side have the same shapes. In contrast to the wheel side this behaviour can be explained by a single-layer model with an effective optical medium composed of crystalline and amorphous phases of the thickness, which is larger than the penetration depth of light. Higher value of coercive field indicates that the surface crystalline layer is harder than that on the wheel side. Moreover, the existence of crystalline layer from shiny side was confirmed also by CEMS. Calculated effective optical and magneto-optical parameters ($n_s = 2.87 - i3.46$; $Q_s = 0.0196 + i0.0044$) of detected layer can be also compared to pure iron.

Bulk amorphous alloys are multicomponent systems and may be prepared at the quenching rate $1-10^2$ K/s. The relatively low quenching rate enables to obtain them in the form of rods and tubes by solidification of molten material in a copper mould or thick ribbons using a melt spinning method. These alloys are a new group of materials and exhibit many interesting properties.

In this paper we present the results of microstructure, and low and high magnetic field properties studies of the bulk amorphous $(\text{Fe}_{0.61}\text{Co}_{0.10}\text{Zr}_{0.025}\text{Hf}_{0.025}\text{Ti}_{0.02}\text{W}_{0.02}\text{B}_{0.20})_{100-x}\text{Y}_x$ ($x = 0$ or 2) alloys in the as-quenched state and after annealing below the crystallization temperature. Ingots were prepared from high purity components by arc melting in argon atmosphere. Amorphous samples in the form of rods 2 cm long and 1 or 2 mm in diameter were obtained by a suction casting method. The amorphicity of the samples in the form of rods and after powdering was checked by X-ray diffraction. The microstructure of the samples was studied by Mössbauer spectroscopy. The Curie and crystallization temperatures were determined by means of a force magnetometer. Low field magnetic properties, i.e. initial magnetic susceptibility (χ_0), its disaccommodation ($\Delta(1/\chi) = 1/\chi_2 - 1/\chi_1$, where χ_1 and χ_2 are the susceptibilities measured at $t_1 = 2$ s and $t_2 = 120$ s after demagnetization of the sample, respectively), maximum susceptibility (χ_m) and core losses (P), were measured by a completely automated set-up. Using a vibrating sample magnetometer (VSM Lake shore type) the approach to the ferromagnetic saturation was also studied. All investigations were carried out for the samples in the as-quenched state and after annealing at 720 K for 15 min.

All samples in the as-quenched state were fully amorphous. In the X-ray diffraction patterns one could see only a broad maximum which is characteristic of an amorphous state.

The as-quenched alloys show relatively high initial magnetic susceptibility. Moreover, these alloys show good thermal stability of the initial magnetic susceptibility (Fig. 1, curves a and b). In the temperature range from 130 K to 475 K only a slight increase of χ_0 is observed. At higher temperature (near the Curie temperature) the initial magnetic susceptibility rapidly drops. From this figure it is also seen that the addition of 2 at.% of yttrium to the $\text{Fe}_{61}\text{Co}_{10}\text{Zr}_{2.5}\text{Hf}_{2.5}\text{Ti}_2\text{W}_2\text{B}_{20}$ master alloy causes only a slight decrease of χ_0 and Curie temperature. It is worth noticing that this addition causes about four-folded decrease of the maximum of magnetic susceptibility disaccommodation (Fig. 1, curves c and d) which is very important feature from application point of view.

Assuming a gaussian distribution of relaxation times the isochronal disaccommodation curves $\Delta(1/\chi) = f(T)$ were decomposed into three elementary processes and their mean activation energies were found. From results obtained we can state that the observed phenomenon is connected with ordering of atomic pairs near the free volumes, which play the similar role as point defects in crystalline materials. After the annealing of the samples at 720 K for 15 min the intensity of disaccommodation distinctly decreases which is connected with the annealing out of some free volumes. It is worth adding that disaccommodation intensity in the bulk amorphous alloys is lower than in classical amorphous ribbons due to lower quenching rate. It is connected with the increase of the atom packing density because of irreversible relaxation processes occurring during the sample preparation.

The studied alloys are the soft ferromagnets and the core losses measured for them are of the same order as observed in the classical silicon – iron alloys. Magnetic softness of these alloys was also manifested during investigations of the approach to the ferromagnetic saturation. The saturation magnetic polarization is equal to 1.08 T and 1.04 T for the alloy without yttrium and containing 2 at.% of Y, respectively. From the analysis of the magnetization curves in high magnetic fields we have evaluated the width of quasi-dislocation dipoles present in the samples which is equal to 3.16 nm and 2.95 nm for the $\text{Fe}_{61}\text{Co}_{10}\text{Zr}_{2.5}\text{Hf}_{2.5}\text{Ti}_2\text{W}_2\text{B}_{20}$ and $(\text{Fe}_{0.61}\text{Co}_{0.10}\text{Zr}_{0.025}\text{Hf}_{0.025}\text{Ti}_{0.02}\text{W}_{0.02}\text{B}_{0.20})_{98}\text{Y}_2$ bulk amorphous alloys in the as-quenched state, respectively. Reassuring, the addition of 2 at.% of yttrium to the $\text{Fe}_{61}\text{Co}_{10}\text{Zr}_{2.5}\text{Hf}_{2.5}\text{Ti}_2\text{W}_2\text{B}_{20}$ alloy causes the distinct decrease of disaccommodation intensity without drastic drop of initial susceptibility and the saturation magnetic polarization.

Initial magnetic susceptibility (a, b) and isochronal disaccommodation curves (c, d) of the $(\text{Fe}_{0.61}\text{Co}_{0.10}\text{Zr}_{0.025}\text{Hf}_{0.025}\text{Ti}_{0.02}\text{W}_{0.02}\text{B}_{0.20})_{100-x}\text{Y}_x$ in the as-received state: $x = 0$ (a, c), $x = 2$ (b, d).

Magnetic properties of as - quenched Fe87-xZr3.5Nb3.5B6Cux nanocrystalline ribbons.

Soft magnetic Fe-M-B (M=Zr, Nb and Hf) nanocrystalline ribbons are of potential applications in many fields. Nanocrystalline Fe-M-B ribbons were usually fabricated by crystallization of amorphous ribbons through annealing processes. The good soft magnetic properties of those annealed ribbons mainly originate from the microstructure consisting α -Fe nanograins with sizes of 8-20 nm. Recently, we reported that nanocrystalline ribbons Fe-Cu-Nb-Si-B and Fe-Zr-B-Cu with high Cu contents with good soft magnetic properties can be fabricated by melt-spinning technique without additional annealing [1]. In the present work, we prepared as quenched ribbons Fe87-xZr3.5Nb3.5B6Cux with wheel speed $V=35$ m/s. Nanostructure was obtained in Fe87-xZr3.5Nb3.5B6Cux as quenched ribbons. The permeability and giant magnetoimpedance were investigated.

As quenched ribbons with low Cu content are mainly amorphous. With addition of Cu content, nanostructure α -Fe appears. An appropriate addition of Cu enhances the nucleation of α -Fe in as quenched ribbons (see Fig.1). Cu clusters induces significant fluctuation in Fe concentration, causing high density of nucleation sites for primary crystallization. Based on Scherrer's equation, the grain size D of α -Fe for as quenched ribbon $x=3$ was estimated as 13 nm. It seems that the amount of amorphous may enhance again with addition of high Cu content ($x \geq 3.5$), which may be due to the reduction of effective number density of Cu enriched cluster accompanying the coarsening of the Cu cluster. The Cu content dependence of permeability μ' was shown in Fig.2. The μ' value with amorphous $x=0$ is only 2100. With increasing Cu content, the μ' increases, experiences a maximum of about 24090 at $x=3$, and finally drops. We also investigated the GMI effect of as quenched Fe87-xZr3.5Nb3.5B6Cux ribbons (Fig.3 and 4). The strongest magnetoimpedance $\Delta Z/Z_0$ among $x=0-5$ also occurs at $x=3$, consistent with permeability dependence. The value $\Delta Z/Z_0$ (under $H=90$ Oe) at $x=3$ is 37.55 %. The drop of magnetoimpedance and permeability at high Cu content ($x \geq 3.5$) may be correlated with the reduction of effective number density of Cu clusters.

The presence of magnetic inhomogeneities is a leitmotiv in systems with magneto- and/or bio-electronic applications, the latter pursued over these days [1, 2]. One of such curious systems is that constituted by Fe-Al alloys [3, 4]. In the rich Fe-side, there is an intriguing change of lattice around Fe₇₅Al₂₅, from a B2 to a DO₃ structure. Recent reports reveal that disordered Fe₇₀Al₃₀ alloys become structurally modified in two steps (above RT); these structural variations result in changes of the magnetization [5]. This points out that the alloying of Fe and Al is extremely influenced by tiny changes in the structure, resulting in crucial implications in the magnetic behavior, as confirmed theoretically [6]. In the surroundings of the Fe₇₀Al₃₀, ferromagnetism, which evolves to a spin glass (SG) state, is present. To understand such phenomenologies, the presence of magnetic clusters should be taken into account. In this sense, SANS measurements showed their presence, which was also studied in through the modification of the spin excitations [7]. Ferromagnetic resonance in four alloys of Fe-Al showed significant variations of the resonant field. The interpretation was based in the presence of magnetic clusters [8].

In this paper, we have selected Fe₇₀Al₃₀ and Fe₇₁Al₂₉ and analyzed the SG transitions. The alloys were prepared by induction and were object of a powdering process by mechanical milling and subsequently annealed. To analyze the dynamic response of the magnetic clusters, the AC-susceptibility was measured. The applied oscillating field $h = 0.1$ Oe and seven frequency ($100 \leq \nu \leq 7$ kHz) values were selected. The Figure shows the thermal variation of the real $\chi'(\nu, T)$ and complex $\chi''(\nu, T)$ components in Fe71. The real component presents a slow decrease with decreasing temperature until approximately 100 K are reached, with a sudden drop of the value. This variation is similar to that obtained in zero-field-cooled magnetization. The behaviour for Fe71 resembles that of a reentrant spin glass. The complex component displays a peak around 60 K. For the Fe70 the behaviour is similar but reveals two transitions.

In addition, there is a shift to higher transition temperatures whenever the frequency is increased. The analysis of the results will be developed in three different steps, as reported in heterogeneous amorphous (FeZrB) or crystalline (CeNiCu) metallic alloys. We will initially apply the process for the lowest transition, which marks a drastic reduction [9]. The first step is to quantify the frequency-shift (δ); $\delta = 0.078(5)$ in Fe70 and $\delta = 0.066(9)$. These values are comparable to reentrant FeZrB glasses [9]. In a second step, it is necessary to extract the $z\nu$ dynamic exponent. Our fits result in $z\nu = 7.2(1)$ in Fe70 and $9.8(1)$ for Fe71. These lie inside the fragile regime giving an indication of a SG transition. The β -coefficients of the transition are $\beta = 1.0(1)$ (Fe70) and $1.1(1)$ (Fe71), which are larger than expected. A discussion of their physical meaning in connection with the clustered magnetic environment will be presented.

Metastable alloys of nominal composition (Fe_{0.5}Cu_{0.5})_{100-x}Zr_x (x=0-20 at%) have been synthesized by high energy ball milling (HEBM) in a planetary mill with hardened steel vials. To avoid oxidation of the powder upon the milling process the vials were sealed under nitrogen atmosphere prior to the milling. The starting materials were Fe, Cu and Zr in powder form, with a purity of 99.9 %. The final milling time was 120 h. The final composition of the powder was determined by using scanning electron microscopy (SEM) equipped with an energy dispersive x-ray analysis (EDX). A maximum value of 2 at.% of additional Fe has been determined through this analysis, although no traces of Ni or Cr coming from the milling media have been detected.

In spite of the high and positive enthalpy of mixing between Fe and Cu for equiatomic composition, nanocrystalline (with a face cubic centered structure) or amorphous alloys have been obtained depending on the Zr content.

The alloy formation is confirmed by Mössbauer spectroscopy and by means of X-Ray Absorption Fine Spectra (XAFS). The later is a powerful technique for studying nearest neighbour distances in these type of alloys for the different elements, since the energy of the radiation can be tuned for studying a particular element [1]. XAFS studies point out a drastic decrease of peak intensity as well as in the nearest neighbour distances for Zr contents above 13 at% that indicates a transition to an amorphous structure. Magnetic measurements show that both, the Fe magnetic moment and the ordering temperature of the alloys drop substantially when compared with equiatomic FeCu solid solutions [2]. The Curie temperature for equiatomic Fe_{0.5}Cu_{0.5} is around 500K, while for (Fe_{0.5}Cu_{0.5})_{100-x}Zr_x alloys, values below 285K are obtained. The later values are similar to that observed in Fe-rich Zr alloys, in spite of the much higher Fe content. The origin of the complex magnetic properties of iron rich metallic glasses containing low concentrations of early transition metals (Zr, Sc, Hf, Y) have attracted considerable interest during more than two decades, giving rise to several controversial microscopic interpretations [3,4].

In addition, (Fe_{0.5}Cu_{0.5})_{100-x}Zr_x alloys exhibit an anomalous temperature dependence of the thermoremanence, as an example figure 1 illustrates this behavior for an alloy with x=13 at%. Thermoremanence (TRM) measurements are performed by cooling the sample under the presence of an applied magnetic field down to 5K. Then, the field is removed and the remanent magnetization is measured while heating up the sample. TRM decreases with increasing temperature until it reaches a minimum value for temperatures close to Curie temperature (T_c), as expected. However, further increase in temperature promotes a spontaneous increase of the magnetization that is observed up to 350K, which is maximum temperature that can be reached in our system. This behaviour is reversible, meaning that no irreversible structural changes take place in the alloys. More likely, this anomaly seems to be related with changes in the interatomic distances with temperature, as occurs in invar alloys [5].

Preliminary XAFS measurements of the nearest neighbour distances have been performed at different temperatures. Figure 1 compares the evolution of the nearest-neighbour (D_{nn}) distances of iron atoms with that of the TRM measured after cooling the sample under an applied magnetic field of 10000 Oe. It should be remarked that the D_{nn} distances are nearly temperature invariant for tem-

peratures below T_c, as corresponding to the proposed invar effect. On the other hand, at temperatures over T_c the normal thermal expansion is evident. This thermal expansion is accompanied by an increase of the magnetic signal on the TRM. The increase of first near-neighbours distances with temperature produced by thermal expansion, can yield to an enhancement of the density of the states at Fermi level that could promote, at least locally, the ordering of the magnetic moments above T_c [2]

The alloys of the system (Fe₆₀Al₄₀)_{100-x}Nbx ($x=0, 5, 10, 15$ and 20) were synthesized from elemental powders in a planetary high-energy ball mill during 12, 24 and 36 hours. X-ray diffraction (XRD), magnetic measurements and Mössbauer spectrometry were used to study the structural, magnetic and hyperfine properties of the system. We studied the influence of Nb content and of different milling times on the structural and magnetic properties. When Nb content increases it appear two phases the hcp (Fe,Al)₂Nb and bcc (Fe,Al) and when the milling time increases the peaks due to the Nb phase disappear while those attributed to the bcc Fe-Al phase are broadened given evidence for the highly disordered structure of the powders.

Results and discussion

Mechanical alloying was carried out in a planetary high-energy ball mill (Fritsch Pulverisette 7) starting from pure element powders (>99.8%). The nominal composition of the alloyed powders were (Fe₆₀Al₄₀)_{100-x}Nbx ($x=0, 5, 10, 15$ and 20) and all samples were milled under the same milling conditions with a powder mass to ball mass ratio fixed at 1:15 and for 12, 24 and 36 h. The structure of the samples, their lattice parameters and the grain sizes were determined by the Rietveld refinement of the X-ray diffraction (XRD) patterns using the MAUD program. Transmission Mössbauer spectra (MS) were collected by using a conventional spectrometer working at different temperatures and using a 925 MBq source of ⁵⁷Co in Rh matrix. The MS were fitted by using the MOSFIT program.

The formation of the nanocrystalline structure during MA was followed by X-ray diffraction and the obtained crystallite sizes were less than 30 nm for all samples. Figure 1 shows the XRD patterns of the system (Fe₆₀Al₄₀)_{100-x}Nbx ($x=0, 5, 10, 15$ and 20) for 12 hours of milling. After $x=10$ they were refined by means of 2 components ascribed to a bcc (Fe,Al) phase and a hexagonal (Fe,Al)₂Nb phase while those of samples with $x=0$ and 5 only with the bcc (Fe,Al) phase. The obtained lattice parameters of the bcc Fe-Al phase increase from 0.2912 nm for $x=0$ up to 0.2986 nm for $x=20$. For $x=10$ the hcp (Fe, Al)₂Nb the lattice parameters are $a=0.4894$ nm and $c=0.7893$ nm and for $x=20$ they are $a=0.4876$ nm and $c=0.7906$ nm.

Figure 2 shows the room temperature (RT) Mössbauer spectra (MS) of the system (Fe₆₀Al₄₀)_{100-x}Nbx ($x=0, 5, 10, 15$ and 20) for 12 hours of milling. The spectra for $x=0$ and $x=5$ were fitting using a magnetic distribution and a singlet, showing the existence of magnetic and paramagnetic sites and the ferromagnetic character of these sample at RT. After $x=10$ the samples present broad asymmetrical quadrupolar doublets, which allow to conclude that these samples are paramagnetic at RT.

As the milling time increases, for $x=0$ and 5 only bcc (Fe,Al) phase was found and after $x=10$ the peaks due to the Nb phase disappear while those attributed to the bcc Fe-Al phase are broadened and their intensities increase given evidence of the highly disordered structure of the powders.

For $x=20$ they show a larger degree of disorder which occurs faster due the larger Nb content. From the refinement which has been performed in the same conditions as above, one observes an extremely large lattice parameter (near 3.47 nm) and a very small grain size (2 nm). Such a rough description allows concluding a priori that the 36 milled powders also results from a random packing of FeAl cubic clusters.

The XRD patterns of the $x=20$ samples milled during 12, 24 y 36 hours(a) are very similar to the last showed in Fig. 1, showing their disordered character. RT MS of these samples, consist of asymmetrical quadrupolar doublets with broadened lines. Its asymmetry changes sign going from the 12 to the 36 hours sample. The best fits of the spectra were conducted by means of only QD, allowing to conclude that all samples are P at RT. Differently for the compositions $x=0$ and $x=5$, when the milling time increase the magnetic behaviour increase.

Increasing both, milling time and Nb content, give rise to an increasing degree of disorder with a tendency to amorphization, with crystallite size changing from 13 to 1 nm. Mössbauer measurements permitted us to prove that for samples with $x=0$ and $x=5$ at RT a change from F to P phase is present and for $x=10$ or more they are P, and in this case the F phase disappears as a consequence of the bigger content of Nb.

Samples of Fe₅₀Co₅₀ produced by mechanical alloying (MA) during 0.5, 2, 4, 8, 12, 24 and 48 h were characterized by x-rays diffraction (XRD), Mössbauer spectrometry (MS) and x-ray photoelectron spectroscopy (XPS). The XRD results showed that up to 8 h the α -Fe and Co-HCP phases coexist and that for 12 h and higher milling times only the peaks of a BCC phase were detected. The Mössbauer spectra at room temperature (RT) of the samples between 0.5 and 4 h showed only a sextet which nearly corresponds to that of the α -Fe, and those after 4 h two sextets, which correspond to sites of α -Fe and of Fe surrounded by Co atoms. The fit of the spectra with a hyperfine field distribution confirms the previous interpretation. The mean hyperfine field was 33 T for samples milled between 0.5 and 4 h, then continuously increases up to 35.1 T for 12 h and then change up to 35.2 for 24 and 48 h. The XPS measurements shown the presence of a superficial shell formed by carbides and oxides of Fe and Co and that for 12 h metallic Fe and Co are yet present. Then the BCC FeCo disordered alloy is completely formed after 12 h.

Experimental procedure and results

Fe and Co powders with purity bigger than 99.9% were mixture at the equiatomic Fe₅₀Co₅₀ composition and MA during 0.5, 2, 4, 8, 12, 24 and 48 h, using a ball mass to powder mass ratio of 15:1. The prepared samples were characterized by XRD, MS and XPS at room temperature (RT). The XRD patterns were refined by the Rietveld method using the GSAS program and the Mössbauer spectra were fitted by using the MOSFIT program. The calibration samples were Si and α -Fe for XRD and MS, respectively.

The XRD patterns obtained for samples with 0.5 to 8 h show the sequence peaks of the HCP Co and those of the BCC Fe, and only the peaks of a BCC phase for samples with 12 h and more. The obtained lattice parameters of the HCP phase were $a=0.251$ and $c=0.411$ nm independent of the milling time, and that of the BCC phase is nearly 0.2867 nm between 0.5 and 4 h, and then gradually decreases up to 0.2856 nm for 48 h. This decrease is due to the continuous substitution of Fe by Co atoms in the BCC lattice of Fe.

The obtained mean grain size of the BCC phase decreases from 50 nm for 0.5 h to 12 nm for 8 h and then remains nearly constant. They present a spherical shape. The grains of the HCP phase change from a prolate (with dimensions of 30x7nm) to an oblate shape (with dimensions 2x20nm) when the milling time increase passing by a spherical shape at 4 h (with 20 nm).

Figure 1 shows the Mössbauer spectra at RT of the prepared samples. The fit was with one sextet for samples milled from 0.5 up to 4 h, and two sextets for the other samples. For the samples with 24 and 48 h it was necessary to add a broad doublet in order to obtain the best fit, whose Mössbauer parameters were $\delta \sim 0.54$ mm/s and $\Delta Q \sim 1.54$ mm/s. It was not possible to associate these parameters to an knowledge phase. The spectral area of this doublet is less than 4 % and due this it was not detected by XRD. The Mössbauer parameters of the sextet used to fit the spectra of samples with 0.5, 2 and 4 h nearly correspond to that of pure Fe.

One of the two sextets obtained from the fitting of samples with 8 h ore more nearly corresponds to that of the pure Fe and the other (a broader one) presents a hyperfine magnetic field of about 36 T. After 4 h of milling the spectral area of Fe decreases and that of the BCC FeCo phase increases. These results are in accordance with those obtained by XRD and can be interpreted in the following way: between 0.5 up to 4 h of milling the grain size of the α -Fe and Co present changes but it was not detected diffusion each other. For bigger milling times Co begins to diffuse inside the BCC Fe lattice and two types of Fe sites can be detected, one similar to that of pure Fe with $B \sim 33$ T and other with Co substituting Fe with $B \sim 36$ T. This substitution continues and the number of pure Fe sites decreases and that of Fe with Co increases.

A second fit of the spectra where made with a hyperfine field distribution showing a narrow peak around 33 T for the samples with 0.5, 2 and 4 h, and two peaks around 33 T and 36 T, respectively, for the samples with 8 h ore more. The peak around 33 T decreases with the milling time and that at 36 T increases. The mean hyperfine field increases from 33 to 35.1 T when the milling time increases up to 12 h, and then increase up to 35.2 T for 24 and 48 h. Our study did not detect Fe sites with $B < 33$ T which can be attributed to Fe atoms diffused into the Co matrix.

Finally, the XPS studies conducted on as-prepared samples with 12 and 24 h showed that they present a shell composed by Fe and Co carbides and oxides. When these samples were cleaned by bombarding with Ar, metallic and alloyed Fe and Co peaks were detected in the 12 h sample whereas only alloyed Fe and Co peaks were detected in the 24 h samples. These results permit to conclude that the disordered Fe₅₀Co₅₀ alloy is formed between 12 and 24 h.

1. Institute of Metal Physics, Ural Division, Russian Academy of Sciences, Yekaterinburg, Russian Federation; 2. St.-Petersburg Institute of Nuclear Physics, Russian Academy of Sciences, Gatchina, Russian Federation

Soft-magnetic Fe-based alloys have an essential and useful property: upon annealing in a magnetic field or under stretch loading in these alloys a magnetic anisotropy is easily induced. An investigation of the nature of magnetic anisotropy in crystalline Fe-rich α -FeSi alloys have revealed an ordered arrangement of the Si atoms preferentially oriented in the direction parallel to the axis of the magnetic anisotropy induced during field or stress annealing [1,2]. The effect of annealing under stretch loading on the anisotropy of magnetic properties of a nanocrystalline alloy of Fe–Si–B–Nb–Cu system (finemet) for the first time was studied in [3] and it was shown that an anisotropy of easy plane type perpendicular to the stretching axis is formed. This is why we undertook the present investigation of the structure of these alloys in order to reveal its fine details that could provide a reason for the appearance of a transverse magnetic anisotropy after annealing under load.

Three series of samples of the alloy $\text{Fe}_{87-X}\text{Si}_X\text{B}_9\text{Nb}_3\text{Cu}_1$ were investigated where silicium is introduced at the expense of ferrum, in concentrations from 0 to 13.5 at.% ($X = 0 - 13.5$). A first series was prepared in the form of thin tapes via high-rate quenching from the melt on the rotating copper disk. To obtain a second series of samples, the initial tapes were annealed at the temperature of nanocrystallization (520°C, 120 minutes). Samples of a third series were also obtained from the initial tapes with the help of a thermomechanical treatment that consisted in their annealing and subsequent cooling under stretch loading (520°C, 120 min; a load of 440 MPa).

X-ray diffraction measurements were performed in the transmission geometry with the use of a monochromatized radiation K_α Mo and the laboratory diffractometer equipped with a four-circle goniometer. The Bragg and superstructure reflections were registered in conditions when the scattering vector lied in the plane of samples. From the position of these reflections the corresponding spacings between the planes in the FeSi phases were estimated via measurements along and transverse to the tape axis, parallel and perpendicular to the tensile stress direction (TSD). For the first time such an investigation of the samples of finemet with the silicium content $X = 15.5$ subjected to annealing under a load of different value were performed by Ohnuma et al [4]. However, in [4] the position of only one reflection was under study, which did not completely clarify the character of lattice residual deformations.

In the initial state, i.e., immediately after quenching, all the alloys are in condition of ultrafine grain (an average grain size is approximately of 2 nm in diameter). Their structure is independent of a direction and the silicium content. After an annealing that provides for nanocrystallization, a distribution of interplanar spacings remains isotropic but with a large size of crystallites – up to 10–12 nm. The lattice parameter with increasing X decreases somewhat rapidly than that typical of bulk samples of FeSi alloy. At a silicium content of 13.5%, the superstructure peaks (111) and (200) from the Fe_3Si phase were registered as most intense.

After annealing under stretching load, the interplanar spacings in TSD increase. But the lattice of nanocrystals is deformed not isotropically. It turns out that the value of a change in the spacing Δd_{hkl} between the planes (hkl) depends on the angle between the direction of the wave vector [hkl], when it is parallel to TSD, and the nearest axis $\langle 111 \rangle$. The greater this angle, the larger the deformation.

For the direction [111], Δd_{111} has a minimum value; in the direction of easy magnetization [100], Δd_{100} is maximum. This is why the lattice deformation is of tetragonal character when an increase in the interplanar spacing in the direction of the $\langle 100 \rangle$ axis the nearest to TDS is the largest. At $X = 13.5$, more than half the volume of the FeSi phase is occupied by the phase Fe_3Si , whose crystal lattice after annealing under stretch loading has the same character of deformation. After cooling, a deformed structure of nanocrystals, which has formed upon annealing under stretch loading, remains unaltered due to high strength characteristics of the amorphous matrix. Since the nanocrystals with a constituent composition close to stoichiometry (Fe_3Si) have a negative value of magnetostriction, then at tetragonal deformation – as a result of stretch loading along the axis [100] which makes a minimum angle with TSD, – a magnetization is induced in the plane normal to the axis of loading, namely, along one of the easy axes [010] or [001]. Since the number of crystallites is very high and their distribution reveals no effect of texture, then a great deal of the crystallites stretched along the tape contribute to a transverse distribution of magnetization and bring about the appearance of the magnetic anisotropy of easy plane type which is transverse to TSD.

Magnetic properties and reaction kinetics of synthesized Fe-Ni-Co alloy during H₂ reduction of Ni_{0.5}Co_{0.5}Fe₂O₄.

M. Bahgat, M. Paek, J. Pak

Metallurgical and material engineering, Hanyang university, Ansan, South Korea

There is considerable technological and theoretical interest in magnetic nanoparticles due to the characterized enhancement in its magnetic recording density, recording speed, the noise suppression, and the material lifetime with the decrease in magnetic particle size [1,2]. Fe-Co-Ni alloys have been demonstrated to have a low coercivity and high-saturation magnetization [3, 4]. In the present work, double sintering ceramic technique was applied for the synthesis of Ni_{0.5}Co_{0.5}Fe₂O₄ at 1100 and 1200 °C. The reduction kinetics and magnetic properties of the synthesized Fe-Ni-Co alloy nanoparticles was thoroughly investigated.

Ni_{0.5}Co_{0.5}Fe₂O₄ compacts were reduced at 800, 900, 1000 and 1100 °C in constant flowing hydrogen gas atmosphere (100% H₂). The course of reduction was followed up thermogravimetrically. The synthesized nickel cobalt ferrite powder and the reduced products were characterized by XRD, porosity measurements, FE-SEM, optical microscope and VSM.

Ni_{0.5}Co_{0.5}Fe₂O₄ was synthesized successfully with average crystallite size about 52.1 nm.

The pore size measurements show that the synthesized ferrite compacts at 1100 °C have higher total porosity (44.04%) relative to that at 1200 °C (30.98%). The SEM micrograph of the synthesized ferrite powder at 1100 °C is shown in Fig. 2. Dense grains of Ni_{0.5}Co_{0.5}Fe₂O₄ are formed in a very well regular crystalline shape with presence of large number of micro-pores.

It can be seen that for each reduction curves, the rate of reduction was highest at early stage and gradually decreased with time till the end of experiment. The reduction rate increased as the reduction temperature increased either in the initial or final reaction stages.

Complete reduction was achieved with synthesis of Fe-Ni-Co alloy of average crystallite size about 18-20 nm. To illustrate the rate controlling mechanism the apparent activation energy (*E_a*) of reduction was calculated and it was found that the initial reduction stages are controlled by the combined gas diffusion and interfacial chemical reaction mechanisms with more contribution for the gas diffusion mechanism while the final reduction stages are controlled by the interfacial chemical reaction mechanism.

The magnetic measurements indicated a significant decrease in coercivity (*H_c*) with increasing the reduction temperature while reversely the saturation magnetization (*B_s*) shows sharp increase with increasing reduction temperature as shown in Fig. 2. Namely the *H_c* values decreased from 328.2, 95 to 52.5 Oe while the *M_s* values increased from 54.8, 241.7 to 277.2 emu/g for fired, 900 and 1100 °C reduced samples respectively.

The significant decrease in coercivity (*H_c*) is correlated to grain growth and sintering effect with increasing the reduction temperature that leads to a great continuity of grain domains. However the sharp increases in saturation magnetization (*M_s*) are explained by the formation of metallic alloying elements Fe, Ni, Co as products of reduction process whereas Fe-Co-Ni alloys have been demonstrated to have a low coercivity and high-saturation magnetization [3,4]. So the micro-structural development of the synthesized Fe/Ni/Co alloy with the increase of reduction temperature could be responsible for the promotion in its magnetic behavior.

Magnetocaloric effect in the FeCrCuNbSiB amorphous materials.

A. Kolano-Burian¹, M. Kowalczyk², R. Kolano¹, R. Szymczak³, H. Szymczak³, T. Kulik², J. Szynowski¹

1. Institute of Non-Ferrous Metals, Gliwice, Poland; 2. Faculty of Materials Science and Engineering, Warsaw University of Technology, Warsaw, Poland; 3. Institute of Physics, Polish Academy of Sciences, Warsaw, Poland

Considerable advances have been made recently in developing new types of magnetic materials exhibiting large magnetic entropy change, which can be used in magnetic refrigeration near room temperature [1-3]. The aim of this work was to analyse magnetic properties of the FeCuNbSiB amorphous alloys modified with Cr from a point of view of their potential application for magnetic refrigeration at a room temperature.

The amorphous soft magnetic ribbons from the $\text{Fe}_{78-x}\text{Cr}_x\text{Cu}_1\text{Nb}_5\text{Si}_4\text{B}_{12}$ alloy ($x = 0, 5$ and 8) were fabricated by melt-spinning technique. The SQUID magnetometer was used to measure magnetisation of all studied samples at different temperatures. Fig. 1 shows $M(T)$ dependence for the $\text{Fe}_{70}\text{Cr}_8\text{Cu}_1\text{Nb}_5\text{Si}_4\text{B}_{12}$ sample measured at different applied magnetic fields up to 50 kOe. From the $M(T)$ dependence, measured at 2 kOe, the T_c was determined by differentiation ($\partial M/\partial T$). It was found that with the increase of Cr content in the alloy, the T_c considerably decreases reaching the values of 170°C, 90°C and 20°C for the alloys containing 0, 5 and 8 at. % Cr, respectively.

The ferromagnetic-to-paramagnetic transition in these alloys is not as sharp as in perovskite type materials, which are considered as suitable for application in magnetic refrigerators. However, in the alloy containing 8 at. % Cr this transition occurs close to the room temperature, which is illustrated in Fig. 2 showing $B(H)$ curves for the $\text{Fe}_{70}\text{Cr}_8\text{Cu}_1\text{Nb}_5\text{Si}_4\text{B}_{12}$ alloy measured within a temperature range from 200 to 400 K using VSM. For the comparison, Fig. 3 shows $B(H)$ curves for the $\text{Fe}_{78-x}\text{Cr}_x\text{Cu}_1\text{Nb}_5\text{Si}_4\text{B}_{12}$ alloys containing 5 and 8 at. % Cr measured at the temperature of 300K. Under this work, calculations of the magnetic entropy changes (ΔS_H) resulting from spin ordering were made for all alloys examined. For the isothermal processes, the ΔS_H of the magnetic system due to the application of a magnetic field H is [4]:

$$\Delta S_H(T, H) = \int_0^H (\partial M / \partial T)_H dH$$

Fig. 4 shows temperature dependence of the magnetic entropy changes at different applied magnetic fields for the $\text{Fe}_{70}\text{Cr}_8\text{Cu}_1\text{Nb}_5\text{Si}_4\text{B}_{12}$ alloy.

It has been concluded under this work that an increase in Cr content in the $\text{Fe}_{78-x}\text{Cr}_x\text{Cu}_1\text{Nb}_5\text{Si}_4\text{B}_{12}$ alloy from 5 at. % to 8 at. % Cr results in a decrease in magnetic entropy changes at the magnetic field of 20 kOe from 2.5 $\text{J kg}^{-1}\text{K}^{-1}$ to 1 $\text{J kg}^{-1}\text{K}^{-1}$, respectively.

Thermal and magnetic field-induced martensite-austenite transformation in melt spun Mn₅₀Ni₄₀In₁₀ ribbons.

J. L. Sanchez Llamazares¹, B. Hernando¹, J. D. Santos¹, M. J. Pérez¹, C. García², J. González², R. Varga³

1. Departamento de Física, Universidad de Oviedo, Oviedo, Spain; 2. Departamento de Física de Materiales, Universidad del País Vasco, San Sebastián, Spain; 3. Institute of Physics, UPJS, Kosice, Slovakia

Recently, it has been shown that melt spun ribbons of the alloy Mn₅₀Ni₄₀In₁₀, show martensite-austenite transformation with both phases exhibiting ferromagnetic ordering [1]. Its valence electronic concentration per atom, e/a , is 7.801, and martensite shows a lower saturation magnetization than austenite. The alloy is therefore of significant prospective importance for applications in both, magnetically driven actuators due to magnetic shape memory effect, and as working substance in magnetic refrigeration technology. In the present contribution, we report results of dc magnetization measurements as a function of temperature under different applied magnetic fields and $M(H)$ curves at selected temperatures, in order to reveal the distinctive features of the thermal and field-induced martensite-austenite transition in this alloy. A complementary characterization of its chemical composition, structure of the phases formed and sample microstructure was carried out by means of energy dispersive X-ray microanalysis (EDS), scanning electron microscopy (SEM), and X-ray diffraction (XRD) at different temperatures. After a carefully study by EDS microanalysis on the cross section and both ribbon surfaces we concluded that chemical elements are homogeneously distributed in the alloy that shows the average composition Mn_{49.5}Ni_{40.4}In_{10.1}. Zero-field cooling (ZFC), field cooling (FC), and field heating (FH) thermomagnetic curves recorded at 50 kOe are shown in Figure 1. The curves revealed the occurrence of a large thermal hysteresis of the structural martensitic transformation of 38 K, as well as a splitting between ZFC, and FC or FH curves in the martensitic region. The latter is attributed to a field-induced partial freezing of austenite phase into martensite upon cooling. The characteristic temperatures of the respective martensite-austenite phase transformation were $M_S = 213$ K, $M_f = 173$ K, $A_S = 222$ K, and $A_f = 243$ K. Low- and high-field heating and cooling $dM/dT(T)$ curves showed that the phase transition occurs in a broad temperature interval. XRD diffractograms recorded at temperatures below and above the transformation confirmed the single phase character of ribbons. Austenite phase crystallizes in a bcc L21-type crystal structure (Curie point of 311 K), transforming into a modulated fourteen-layered (14M) monoclinic martensite. The effect of magnetic field on reverse transformation was studied by measuring magnetization isotherms, under increasing and decreasing the field, in the transformation temperature range. The results are shown in Figure 2. $M(H,T)$ curves have the signature of metamagnetism owing to the effect of the magnetic field on the transformation. From relatively low magnetic field values a progressive magnetic field induced transformation from martensite to austenite is observed. Consequently, a large hysteresis between field-up and field-down curves is observed. As temperature approaches to pure austenitic or martensitic phase existence regions, these effects vanish. A field over 50 kOe is required for a complete reverse transformation.

Research on the magnetocaloric properties of materials has been revitalized since the feasibility of developing near room temperature magnetic refrigerators was demonstrated and the coetaneous discovery of the giant magnetocaloric effect (GMCE) in the last decade of the previous century. In an era of increasing energy costs and of concerns about the actual influence of human activity on the environment, magnetic refrigerators constitute a promising technology, as they are energetically more efficient than those based on conventional gas compression-expansion, and are more environment-friendly, as neither ozone-depleting nor global-warming volatile refrigerants are required. However, due to the thermal and magnetic hysteresis and reduced frequency response of GMCE materials, with a coupled magneto-structural phase transition, current refrigerator prototypes mainly use materials with a second order magnetic phase transition. Among them, there is an increasing interest in amorphous alloys, as their reduced magnetic hysteresis (virtually negligible), the high electrical resistivity (which would decrease eddy current losses), tunable Curie temperature and, in the case of bulk amorphous alloys, outstanding mechanical properties are beneficial characteristics for a successful application of the material.

However, tuning the temperature at which the peak magnetic entropy change takes place, to make it closer to room temperature, usually comes along with a reduction in the magnetocaloric response of the alloy. Recently, it has been shown that the change of the Fe/B ratio in a Nanoperm type alloy allowed to displace the optimal working temperature of the material without altering the magnitude of the peak entropy change. The aim of this work is to analyze if this compositional effect can be extended to other series of alloys. For that purpose, $\text{Fe}_{92-x}\text{Cr}_8\text{B}_x$ ($x=12, 15$) amorphous alloys have been studied. It will be shown that reducing the B content of the alloy produces a decrease in the Curie temperature of the sample (and therefore, of the temperature of the peak), but at the expense of a reduction in its magnitude (for a maximum applied field of 50 kOe, the peak entropy change is $2.6 \text{ J kg}^{-1} \text{ K}^{-1}$ and $3.0 \text{ J kg}^{-1} \text{ K}^{-1}$ for the alloys with 12 and 15 at. % B, respectively). The field dependence of the magnetocaloric response of these alloys will be studied on the basis of the recently proposed universal curve for the magnetic entropy change in materials with a second order magnetic phase transition.

XMCD-PEEM imaging of the micromagnetic structure of Co_2FeSi Heusler compound.

A. Gloskovskii¹, C. Blum¹, J. Barth¹, G. Fecher¹, P. Nagel², S. Schuppler², G. Schönhense³, C. Felser¹

The Heusler compound Co_2FeSi is a promising material for magnetoelectronic devices. With a Curie temperature of 1100 K, a saturation magnetisation of 6 Bohr magnetons and a high spin polarisation at the Fermi edge it fulfills the essential requirements for magnetic sensors or spin valves [1]. An essential feature for such devices is the micro-magnetic domain structure. X-ray magnetic circular dichroism-photoemission electron microscopy has been used for a direct observation of the domain structure of single- and polycrystalline samples.

Polycrystalline Co_2FeSi samples were etched with a solution of 0,2 mol/L in 9,25% HCl and cut along the crystallites. The crystallites are about 1 mm thick and extend along the sample surface. The samples were mechanically polished before the measurements. The (110) surface of as-grown single crystal was polished with an orientation better than 0.1° (MATECK). The freshly built-in single crystal exhibited oxidation of the surface. The magnetic contrast was strongly suppressed by the magnetically dead oxide layers. In a first step, the single crystal was cleaned by ion-bombardment (Ar^+ , 500 eV) for 120 min to remove organic impurities that remained from the cleaning process after polishing. This sample is termed “mildly sputtered”. Afterwards, it was sputtered with increased energy (1 keV). For healing and to allow for reordering of the surface, a heating at 620 K for 10 min followed the sputtering. The sputtering-heating cycle was repeated 3 times. This sample is termed “massively sputtered”. Before the third measurement the sample was polished again using the same method as for the polycrystalline sample. Immediately after polishing process the “re-polished” sample was transferred into the vacuum to prevent oxidation of the surface. The experiments were done at WERA beamline of ANKA (Karlsruhe) and UE56-SGM beamline of BESSY (Berlin). All measurements reported below were performed for non-magnetised samples. In full-field imaging photoemission electron microscopy (PEEM) combined with XMCD (X-ray magnetic circular dichroism) the magnetic contrast is very high and provides element selectivity. All XMCD-PEEM images were recorded at Fe L_3 edge.

The micromagnetic structure of two crystallites in the polycrystalline sample is shown in Fig. 1a. The crystallite at the bottom exhibits the ripple structure characteristic to polycrystalline samples studied earlier by us [2]. The upper crystallite consists of larger magnetic domains. The “mildly sputtered” sample shows the weak magnetic contrast and randomly distributed small magnetic domains (not shown). Large magnetic domains with sizes up to 100 μm appear after 3 sputtering-annealing cycles (Fig. 1b). It cannot be excluded that the crystal stoichiometry at the surface may have been altered by selective sputtering (in our case of silicon). In this case, a strong magnetic coupling of the underlying stoichiometric Co_2FeSi with the thin “Si-poor” surface layer may be responsible for the observed magnetic contrast. An attempt to recover the initial stoichiometry of the crystal surface by polishing led to the much weaker magnetic contrast shown in Fig. 1c. The size of magnetic domains was reduced to less than 10 μm .

Important information about the magnetic structure and chemical composition can be extracted from laterally resolved X-ray absorption spectroscopy. Local absorption spectra from the surface of the Co_2FeSi single crystal prepared in three different ways were taken at the Co L-edges (not shown here). The shoulder that appears at about 4 eV above the Co L_3 absorption edge is an indi-

cation of the Heusler type $L2_1$ structure. It is present for the “mildly sputtered” sample but vanishes in the “massively sputtered” single crystal. The $L2_1$ structure of the sample surface was partially recovered by re-polishing the single crystal.

To conclude, we have prepared the surface of Co_2FeSi by different methods and studied its micro-magnetic structure by means of XMCD-PEEM. Magnetic domain patterns and magnetic contrast are strongly influenced by how the surfaces are prepared.

The authors acknowledge financial support by the Deutsche Forschungsgemeinschaft (project TP7 in research unit FG 559) and as well as by BESSY (BMBF 05 ES3XBA/5).

Recent scientific and engineering efforts are directed towards thermomagnetic cooling, since it is considered environmental friendly as it eliminates the use of the traditional chlorofluorocarbons (CFCs). Conventional vapour-cycle refrigeration achieves cooling efficiencies approaching 40% of the theoretical Carnot limit. The thermomagnetic cooling (magnetorefrigeration) achieves a cooling efficiency of 60%.

The research on magnetic materials for refrigeration is increasing, with $\text{Gd}_5\text{Si}_2\text{Ge}_2$ compound being one of the best candidates for this technological application due to the giant MCE observed near room temperature (RT) [1, 2]. Since this interesting discovery, the 5:4 rare-earth compounds $[\text{R}_5(\text{Si}_x\text{Ge}_{1-x})_4]$ with $\text{R}=\text{rare-earth}$ are being object of extensive studies, not only due to the MCE that some of these compounds present, but also to their peculiar physical and chemical properties, namely strong magnetoelastic effects [3], giant magnetoresistance [4], exotic transport phenomena [5] and more recently a new magnetic regime in the PM phase attributed to a Griffiths-like phase [6]. These unexpected and unusual properties occur due to the strong interplay between the structure and magnetic properties characteristic of this family of compounds [7]. The compound here studied is the $\text{Nd}_5\text{Si}_{1.45}\text{Ge}_{2.55}$ that crystallizes on a Monoclinic (M) structural phase (P1121/a) stable down to 4 K [8, 9] and presents a purely magnetic transition (PM-FM) at $T_C \sim 57$ K. We study in detail the transport and magnetic properties of this light rare-earth compound as a function of temperature, in the range 10-300 K, namely the electrical resistance $R(T)$, thermopower $S(T)$ and magnetization $M(T)$. From $R(T)$ (see Fig.1) and its temperature derivative (obtained numerically), we observe a change on the $R(T)$ behavior around $T_C \sim 56$ K due to a magnetic transition without any thermal hysteresis, establishing the second order nature of the transition. On cooling, a spin reorientation transition is observed at $T^* \sim 37$ K with the appearance of an additional T^2 term. Above T_C , an almost linear thermal dependence is observed on $R(T)$ due to the electron-phonon interaction characteristic of metallic systems in the PM state. The $S(T)$ results (see Fig.2), are in full agreement with the $R(T)$ ones. Our magnetization data confirm previous results [9] with a second order ferromagnetic transition at $T_C = 57$ K and absence of any structural transition. In the reciprocal susceptibility an anomalous behavior is observed at $T^* \sim 115$ K, attributed to a small amount of a 5:3 secondary phase [10].

Magnetism and phase transformation in Fe / Fe oxide milled nanopowders.

O. Crisan¹, R. Nicula², I. Skorvanek³

1. National Institute for Materials Physics, Bucharest-Magurele, Romania; 2. Institute of Physics, Rostock University, Rostock, Germany; 3. Institute of Experimental Physics, Slovak Academy of Sciences, Kosice, Slovakia

The exchange bias effect has been shown to occur in granular ball-milled Fe / Fe oxide nanopowders. On the other hand, ball milling of mixtures of Fe and magnetite was shown to result in formation of wüstite (FeO) via a chemical reduction reaction occurring during the ball milling. The evolution of phase composition in such mixtures has a strong influence on the magnetic properties and the exchange bias effect, in particular.

We report in the present paper the structural and magnetic properties of mixed Fe / Fe₃O₄ nanopowders obtained by ball milling and submitted to annealing treatments.

The nanopowder system made of Fe / Fe₃O₄ with a 2:8 wt.% ratio has been milled for 50 h in a Retsch PM 400 planetary ball mill. The sun wheel frequency was 200 rpm and sun wheel / vial frequency ratio was 1.5. We used 8 tungsten carbide balls with 20 mm diameter. The powder and balls were sealed in hexane to avoid oxidation. The temperature-dependent in-situ X-ray diffraction of the synchrotron radiation was done in energy-dispersive mode at DESY-HASYLAB, Hamburg at Max 80 F2.1 beamline with $\lambda = 1.2 \text{ \AA}$. The magnetic measurements have been performed with a vibrating sample magnetometer (VSM) in a temperature range between 4.2 K and 300 K. The hysteresis loops were recorded as follows: (i) cooling to 4.2 K without the presence of external field and first loop (ZFC at 4.2 K) was measured; (ii) heated up and recording the loop at 280 K; (iii) again, cooling to 4.2 K in 5 T applied field (FC) and the loop was measured.

The XRD spectra of the as-milled sample taken at 25°C, 250°C and 400°C are presented in Fig. 1. The XRD spectrum at 25°C shows broad lines, typical for topologically disordered, nanostructured materials, as obtained after ball milling. The main Bragg reflections of the body-centered-cubic α -Fe, cubic FeO (S.G. Fm3m) and cubic Fe₃O₄ (S.G. Fd3m) are indexed in the spectrum. The occurrence of the wüstite is due to an incomplete reduction reaction $\text{Fe} + \text{Fe}_3\text{O}_4 = 4 \text{ FeO}$, activated by the high deformation energies developed during the milling. The reaction is incomplete because the Bragg reflections of initial Fe and Fe₃O₄ powders are also present in the sample. With increasing the temperature, as expected, the Bragg reflections are narrower due to the increase of the grain size. For the sample annealed at 200°C we observe the gradual decrease of the relative intensity of the main Bragg peaks of the wüstite. Meanwhile the α -Fe and Fe₃O₄ Bragg reflections increase compared to the 25°C spectrum.

At 450°C, sharp and intense Bragg lines are observed for the α -Fe and Fe₃O₄ phases at the expenses of FeO whose relative intensity reaches only about 7% of Fe₃O₄ phase. The strong reduction of the FeO content proves that the redox reaction that produced the wüstite is reversible and with increasing the annealing temperature up to 450°C, iron and magnetite become the predominant phases.

Hysteresis loop FC@5T at 4.2 K for the as-milled sample (Figure 2) exhibits a shift of the coercive field towards negative values, compared to the loops ZFC at 4.2 K and at 280 K. Coercivity increases from 41 mT at 280 K to 80 mT at 4.2 K and reaches 138 mT for the FC@5T loop. The exchange bias field calculated in the as-milled state is about 45 mT. The hysteresis loops FC@5T at 4.2 K for the samples annealed at 250°C and 400°C present a less pronounced shift towards negative values. The exchange bias field decreases with increasing the annealing temperature (inset of Fig. 2) down to 8 mT for the sample annealed at 450°C. Since the wüstite content decreases also with

increasing the annealing temperature, it seems that the exchange bias field observed in the Fe / Fe₃O₄ mixed nanopowders is mainly due to the high fraction of FeO formed during milling. Also, the high degree of disorder and important number of FM / AFM and FM / FI interfacial regions may account for the observed exchange bias in the ball milled mixed Fe / Fe oxide nanopowders.

Fig. 1 X-ray diffraction spectra taken at 25°C, 200°C and 450°C for the Fe / Fe₃O₄ as-milled sample. The spectra are given in units of reticular distance d .

Magnetic properties of high Bs Fe-based amorphous powders produced by Spinning Water Atomization Process (SWAP).

I. Otsuka¹, K. Wada¹, Y. Maeta¹, T. Kadamura¹, M. Yagi²

1. EPSON AT MIX CORPORATION, Hachinohe-shi, Aomori-ken, Japan; 2. Sojo University, Kumamoto, Japan

The authors have successfully developed Fe-based amorphous powders by our original atomization process “Spinning Water Atomization Process (SWAP)” [1]. Today, the very low loss consolidated cores made of Fe76 system amorphous powders with good magnetic-softness are widely used for switching power sources of electronic equipment. For further development, in order to deal with the recent progress of miniaturization and high output current of power supplies, amorphous powder cores with high magnetic induction Bs are essential.

In the present work, high Bs Fe-based amorphous powders were produced by a newly improved SWAP having extremely high-cooling rate over 10^6 K/s [2].

The composition of alloy powders were $\text{Fe}_x(\text{Si}_{0.7}\text{B}_{0.3})_{98-x}\text{C}_2$ $\{x = 78, 79, 80, 81, 83, 84 \text{ at}\%\}$. The particle sizes of powder used for magnetic property measurements were below 150 micrometers in diameter. Annealing of the powders was carried out at 578-728K for 3.6Ks in a nitrogen atmosphere. Examination of structure and morphology were carried out by using X-ray diffractometry (XRD) and scanning electron microscopy (SEM), respectively. The specific gravity of powder was measured by gas pycnometer. The magnetic properties were measured by vibrating sample magnetometer (VSM) with maximum applied field of 20 kOe.

The morphology of powder observed by SEM is shown in Fig.1. Smaller particles were spherical, and larger particles were rather flat with round edges. Fig.2 shows the result of XRD of Fe-Si-B-C alloy powders. In the powder particle size -150 micrometers, the broad peak providing to be in the amorphous state was retained for up to the $\text{Fe}_{83}(\text{Si}_{0.7}\text{B}_{0.3})_{15}\text{C}_2$ powder, where as a peak was slightly observed for the $\text{Fe}_{84}(\text{Si}_{0.7}\text{B}_{0.3})_{14}\text{C}_2$ powder. Fig.3 shows the saturation flux density (Bs) and coercive force (Hc) of the powders. The saturation flux density Bs of powders increased with increasing iron content. The Bs value for the $\text{Fe}_{83}(\text{Si}_{0.7}\text{B}_{0.3})_{15}\text{C}_2$ powder was 1.64 T, which was 31% higher than that of our previously developed Fe76 system amorphous powder [3], and comparable to a newly developed high Bs Fe-based amorphous ribbon [4]. On the other hand, although the coercive force was also increased with increasing iron content, a fairly low level of about 0.50 – 0.90 Oe was kept for up to the Fe83 system powder. The considerable increase of coercive force for the Fe84 system was thought to be closely related to the crystallization, as shown in Fig. 2.

The high Bs amorphous powders obtained in this study are expected to be markedly available for downsizing of magnetic cores.

1. Dept. of Electrical and Communication Engineering, Tohoku University, Sendai, Japan; 2. IMRAM, Tohoku Univ., Sendai, Japan

Particulate materials with high permeability are currently of practical use at high frequencies because they have high resistivity which suppresses eddy current loss. Recently we reported composites(1) which include 70nm Permalloy particles and 1 micron Fe particles exhibiting enhanced permeability for a certain volume ratio maintaining the high resistivity feature. For further improvement a method to synthesize submicron particles with a good soft magnetic property at a higher production rate must be developed. From this standpoint we performed an investigation of Permalloy nanoparticles synthesized by a conventional polyol method(CPM) in comparison with a microwave-assisted polyol method(MWPM) which was reported to accelerate a chemical reaction. The particle morphology, crystal structure, magnetization characteristics, high frequency permeability and variation by heat treatment are studied. The chemical process for synthesizing nanoparticles is similar to that reported by Viau et.al.(2). Chlorides of Ni and Fe were dissolved into ethylene glycol with Ni/Fe ratio 50/50 and concentration of 0.2M per liter. The solvent was kept at 155 degrees for 15min. either by a heater or in a microwave reactor and cooled to RT. Particle size was controlled by adding an appropriate amount of K₂PtCl₄ solution. Annealing was made at 250 and 350 degrees for 1 hour in Ar+H₂ atmosphere. Firstly it was confirmed that XRD peaks for all particle sizes can be identified as those from Ni₈₀Fe₂₀ alloy except for small-angle broad peaks which indicate inorganic residuals and another small-angle weak peak suggesting iron oxide that is often found for MWPM. It should be stressed that composition close to Ni₈₀Fe₂₀, saturation magnetization of about 80emu/g and coercivity of about 40 Oe are obtained for all samples regardless of particle size variation from 70 to 500nm. An example is shown in Figure 1. From the width of (111) peaks the crystal size in the particles is estimated to be 4-6 nm and again changes little regardless of large variation of the particle size. As was discussed in Ref.2, this suggests that the particles are assembly of nanocrystals of Ni₈₀Fe₂₀. These nanocrystals are responsible for the basic properties described above. As seen in Figure 2 the nanocrystals by MWPM grow faster than CPM by heat treatment up to 350 degrees, while the lattice spacing of (111) exhibits no significant change. The saturation magnetization increases up to 90-95emu/g which is close to the bulk value. Coercivity tends to decrease faster for MWPM than for CPM. For example, coercivity for the samples in Figure 2 decreases to 18 Oe for MWPM and to 30 Oe for PCM after heat treatment at 350 degrees. From SEM images it was found that the morphology of particles by CPM changes little by heat treatment while aggregation of the particles occurs for MWPM as seen in Figure 3.

In conclusion the magnetic properties of Ni₈₀Fe₂₀ particles by the polyol method are determined by nanocrystals in the particles and their magnetic properties vary little against large size difference. The nanocrystals tend to grow and improve their magnetic softness by heat treatment, but particle aggregation hinders higher temperature heat treatment. The MWPM has a higher potential to provide a high speed process for magnetically soft particles. Nanoparticle annealing in NaCl(3) which is effective to suppress particle aggregation is in preparation to establish a method to produce magnetically soft submicron particles.

Synthesis, Phase Transfer and Magnetic Properties of Monodisperse Magnetite Nanocubes.

H. Yang¹, D. Hasegawa², M. Takahashi¹, T. Ogawa^{2,3}

1. Niche, Tohoku University, Sendai, Japan; 2. Dep. of Electronics Engineering, Tohoku University, Sendai, Japan; 3. Cress, Tohoku University, Sendai, Japan

Magnetite (Fe₃O₄) is not only a common magnetic material but also an important class of half-metallic materials. The synthesis of Fe₃O₄ nanoparticles has long been of keen interest in magnetic data storage, biological application, and ferrofluids. [1, 2] Different shapes of particles can introduce electronic, optical, and magnetic properties that are different from those of their spherical counterparts. Hence, the effective control of the shape of magnetic nanoparticles is an emerging research topic.

In this work, we present a one-pot synthesis of monodisperse Fe₃O₄ nanocubes with controllable size from 6.0 to 30.0 nm. Using α -cyclodextrin (CD), Fe₃O₄ nanocubes were successfully “pulled” into water from hexane. The magnetic properties of Fe₃O₄ nanocubes with different size have been investigated.

Fe₃O₄ nanocubes were synthesized by a modified polyol process in organic phase. Fe(acac)₃ and 1,2-hexadecandiol were dissolved in benzyl ether with oleic acid and oleyl amine and then refluxed. The phase transfer was conducted by vigorously stirring the mixtures of hexane suspensions of Fe₃O₄ nanocubes and equal volume of α -CD aqueous solution. TEM was employed to determine the morphology and size of Fe₃O₄ nanocubes. Magnetic measurements were conducted using a SQUID with fields up to 5 T and temperatures from 5 to 300 K.

Our approach enables the control of the reactivity of the carboxylic group of oleic acid and as a result the nucleation and growth dynamics of the particles. By careful adjustment of the stabilizer molar amount as well as the other reaction parameters we have obtained the size-controlled monodisperse magnetite nanocubes in one-pot without a laborious multistep seed-mediated growth. Fig.1 shows the TEM images of monodisperse Fe₃O₄ nanocubes with different sizes from 6.5 nm to 30.0 nm. With a size less than 15.0 nm, the nanocubes usually have a very narrow size distribution of less than 7% and the aspect ratios close to one. However, with a size more than 25 nm, the size distribution increases greatly and the aspect ratios located between 1 and 1.5.

By the formation of surfactant bilayers with charged hydrophilic ions of α -CD, Fe₃O₄ nanocubes can irreversibly transfer from hexane into water (as shown in Fig.2). The α -CD stabilized nanocubes can be stable for long periods of time in aqueous phase under ambient atmospheric conditions.

The hysteresis loops of the Fe₃O₄ nanocubes with different sizes at 300 and 5 K are shown in Fig. 3. The saturation magnetization (M_s) at 300K of Fe₃O₄ nanocubes with a size of 6.5, 15.0, and 30.0 nm were 39.5, 80.5, and 83.0 emu/g, respectively. The Fe₃O₄ nanocubes with a size less than 25.0 nm size possess typical superparamagnetic features at room temperature. However, the 30.0 nm Fe₃O₄ nanocubes shows a ferromagnetic behavior with a high M_s close to that of the commercial magnetite powder. The field-dependent magnetizations at 5 K are presented in Fig. 3b. The Fe₃O₄ nanocubes with three different sizes show a size-dependent ferromagnetic behavior at 5K. The H_C, increased from 190 Oe for 6.5 nm, to 500 Oe for 15.0nm and 790 Oe for 30.0 nm Fe₃O₄ nanocubes. The coercivity of magnetic nanocubes is surely related to the magnetic anisotropy. The volume of nanocubes is the dominant factor in the magnetic anisotropy of Fe₃O₄ nanocubes. As a result, the coercivity of Fe₃O₄ nanocubes is clearly increased with increasing nanocubes size. In addition, the high coercivity of 30.0 nm Fe₃O₄ nanocubes maybe also result from the shape anisotropy contribution since they have an aspect ratios of more than 1.

Materials with higher saturation magnetization are required for biomedical applications such as hyperthermia and drug delivery [1,2]. Although Fe₃O₄ is commonly used for such applications due to its biocompatibility, the saturation magnetization of the nanoparticles is only around 60 emu/g. In order to overcome the drawbacks associated with low saturation magnetization and biocompatibility core-shell nanoparticles with a highly magnetic core such as Fe and biocompatible shell such as Fe₃O₄ is an alternative solution. To prolong the duration of the nanoparticles in the circulatory system, the particles are coated with a polymer such as polyethylene glycol. Materials synthesized through chemical methods have the advantage that they could be easily surface modified for biological applications. The synthesis of pure Fe through chemical methods has been so far impossible to achieve due to the highly oxidizing nature of Fe. However we have successfully demonstrated the synthesis of highly magnetic submicron sized Fe through reduction in polyols [3]. Also the synthesis of highly magnetic Fe based alloy such as FeCo by polyol process has been already achieved [4]. In this paper we present our results on the synthesis of size controlled Fe nanoparticles through polyol process and their magnetic properties.

The precursors used in the synthesis of Fe by using polyol process are FeCl₂.4H₂O and NaOH. In a typical reaction, the precursors were introduced in ethylene glycol with an [OH⁻]/Fe molar ratio as high as 40 to enable reduction. The reaction temperature and duration were 170 °C and 2 min, respectively. H₂PtCl₆ is used as the Pt precursor. The Fe particles thus synthesized were washed with alcohol and characterized using X-ray diffraction, electron microscopy and magnetic measurements.

The Fe particles synthesized using 0.1 M of FeCl₂.4H₂O in ethylene glycol are found to exhibit cubic morphology with an average size around 150 nm. Size reduction of the Fe particles was achieved by introducing very low molar concentration of Pt as a nucleating agent. Figure 1 shows the variation in the particle size and saturation magnetization with increasing Pt concentration. It is observed from the figure that with increasing Pt concentration the average particle size decreases and becomes around 15 nm with the Pt concentration of 2×10⁻⁷ M. The saturation magnetization (M_s) which is 210 emu/g (bulk 218 emu/g) for the 150 nm particles also decreases and becomes 80 emu/g for the 15 nm particles which is commonly observed due to oxidation of Fe nanoparticles [5]. The particles showed cubic morphology which is retained with sizes upto 80 nm and it becomes spherical and agglomerated with further size reduction. The cubic shape of the Fe particles suggest the crystal structure (bcc for Fe) dependent shape under thermodynamic conditions [6] upto submicron regime and the equilibrium condition is lost when the size is reduced in the nanoscale using nucleating agents. Also with increase in Pt concentration to 0.05 M, Fe₅₀Pt₅₀ nanoparticles in the size range 2-4 nm could be obtained [7].

The stability of the Fe particles were checked by annealing the Fe powders in air by wrapping in an Al foil. The XRD pattern (not shown) showed that the particles are fairly stable on annealing even at 500 °C for 30 min (M_s=190 emu/g) and prolonged annealing for 15 h is required for the disappearance of the peak corresponding to Fe. It is also observed that the asprepared particles had a thin layer of around 3 nm thick oxide shell, whose thickness increased with annealing. The thin oxide shell may be responsible for preventing rapid oxidation of the cubic asprepared particles and showed higher saturation magnetization of 210 emu/g whereas the commercial powders showed a

saturation magnetization of only 190 emu/g. The control of oxide shell thickness could be of much use in utilizing these Fe particles for biomedical applications.

The variation of particle size and saturation magnetization of Fe with Pt concentration.

Magnetic behaviour of $\text{Gd}_4(\text{Co}_{1-x}\text{Cu}_x)_3$ compounds.

T. M. Seixas^{1,2}, M. A. Salgueiro da Silva², J. M. Machado da Silva^{1,2}, H. F. Braun³, G. Eska³
 1. Instituto de Física dos Materiais da Universidade do Porto (IFIMUP), Porto, Portugal; 2. Departamento de Física da Universidade do Porto, Rua do Campo Alegre, 687, 4169-007, Porto, Portugal; 3. Physikalisches Institut, Universität Bayreuth, D – 95440, Bayreuth, Germany

In order to study the effects caused by substituting Co for Cu on the magnetic properties of $\text{Gd}_4(\text{Co}_{1-x}\text{Cu}_x)_3$ compounds with $x = 0.05, 0.1, 0.2, 0.3$, SQUID magnetisation measurements were performed on polycrystalline samples in the temperature range 5 K – 300 K using applied magnetic fields from 0 to 5 T. Details of samples preparation and characterisation methodology are described elsewhere [1].

As shown in Fig. 1, the curves of the spontaneous magnetic moment ($M_S(T)$) corresponding to $x = 0.05, 0.1$ exhibit essentially the same behaviour as that previously reported for ferrimagnetic Gd_4Co_3 [2], despite minor differences in their Curie temperatures and saturation moments ($M_S(0)$). For $x = 0.2$, however, a succession of two zero-field magnetic phases is apparent below the Curie point at $T_{C1} \equiv T_C \approx 211.3$ K: an intermediate phase, hereafter denoted FERRI I, extending from T_{C1} down to a second critical temperature T_{C2} not exceeding 170 K, with a spontaneous magnetization clearly lower than the spontaneous magnetization of compounds with $x < 0.2$ in the same temperature range; a low temperature phase, hereafter denoted FERRI, which orders below T_{C2} and shows a $M_S(T)$ curve similar to that of the compounds with $x < 0.2$ below their respective Curie temperatures. For $x = 0.3$, a single magnetic phase (FERRI) is again present with a lower Curie temperature.

The Arrot plots of the $\text{Gd}_4\text{Co}_{2.4}\text{Cu}_{0.6}$ compound at temperatures within the region of the FERRI I phase reveal the existence of two magnetic moment states (M_S , spontaneous; M_{HF} , high field) and a field-induced transition between them. At 175.0 K, the ratio of the values of the two magnetic moments is $M_S/M_{HF} \approx 0.68$. The existence of a high field metamagnetic process suggests that, within the FERRI I phase, due to a competition between anisotropy and exchange interactions, either a fraction of the Gd^{3+} magnetic moments or just a component (e. g. the basal component) of each Gd^{3+} magnetic moment is disordered. This conclusion is consistent with the low field isofield magnetisation curves.

A magnetic phase diagram based on isothermal and low field isofield magnetic measurements is shown in Fig. 2. It exhibits a particularly interesting magnetic diversity, including c-axis, canted and partially disordered ferrimagnetism.

As seen in Fig. 3, the saturation magnetic moment of Co atoms decreases exponentially with increasing Cu content. Such behaviour of $M_{Co}(x)$ may originate from the combined effect of the 3d band filling by 4s electrons from Cu atoms and a strong dependence of Co moment on the number of local Co neighbouring atoms.

Exact Calculation of The Magnetostatic Interaction in Arrays of Nanowires.

J. Velázquez

CAI Difracción Rayos X, Universidad Complutense de Madrid, Madrid, Spain

The magnetostatic interaction between nanowires is a subject of both theoretical and technological interest because of its effect on the magnetic properties of arrays of nanowires [1] and the possibility of magnetic recording for perpendicular magnetic storage media [2]. Although the magnetostatic interaction between magnetic wires is often treated as dipolar in a first approximation [3], it shows a strong non-dipolar character enhanced by the short distances between nanowires in an array [4].

The magnetostatic interaction between nanowires is due to the coupling between the field created by each nanowire due to its magnetization and the magnetization of the neighboring nanowires. The aim of this work is to develop an exact calculation of the magnetic field created by an uniformly magnetized wire.

By considering a system of reference with origin in the centre of the wire and the z-axis parallel to its axis, and taking into account the expression of the inverse of the distance (from an element of surface of the wire to any point of the space) in a series of products of Bessel's functions, the expression of the magnetic potential, V_m , is:

$$V_m = (MR/2) \int_0^\infty (d\lambda/\lambda) J_0(\lambda r) J_1(\lambda R) [\exp(-\lambda|z-(L/2)|) - \exp(-\lambda|z+(L/2)|)]$$

varying λ between 0 and ∞ and being M , L , and R the magnetization, length and radius of the wire, respectively. J_0 and J_1 are Bessel's functions and r is the radial distance to the axis of the wire. Note that the potential depends on r and z . From V_m and using partial derivatives, the radial, H_R , and axial, H_Z , components of the field created by an uniformly magnetized wire can be obtained: $H_R(r,z) = -\partial V_m(r,z)/\partial r$, $H_Z(r,z) = -\partial V_m(r,z)/\partial z$. These fields are expressed in integrals of products of Bessel's functions, and asymptotic expressions can be obtained for $(R/L) \ll 1$ then coinciding with the dipolar case (radial dependence with r^{-3}).

The attached Figure shows the dependence of H_Z and H_R with the distance from the axis of nanowire, x , where $x=(r/R)$, with $R = 15$ nm, $L = 4$ μ m ($L/R = 267$), $\mu_0 M = 1$ T, for the axial coordinate $z^* = 1.05$, being $z^* = z/(L/2)$, that is just above the end of the wire.

As can be seen, the axial field H_Z decreases with distance from the axis of the wire, while H_R shows a maximum. This maximum depends on the relation (L/R) so that the smaller it is the maximum moves towards smaller values of x and higher values of field. (see inset in the Figure). Moreover, the distance x_0 such that $H_Z(x_0, z^*) = H_R(x_0, z^*)$ only depends on L and z^* (in fact, the dependence is linear) and is independent of M and R . As for $x > x_0$ is $H_R(x, z) > H_Z(x, z)$, the process of magnetization in a nanowire is influenced by this interactive field perpendicular to the axis of the nanowire. The design of arrays of nanowires, with given distances between nanowires (and where each nanowire interact with all its neighbors), should take into consideration this fact: axial coupling for short distances and radial coupling for something greater distances, depending the limit distance on the length of the nanowire (x_0 increases linearly with L) and the axial coordinate z (x_0 decreases linearly with z^*).

Performance Analysis of Flyback Converter Based on Time-stepping FEA Incorporating Magnetic Hysteresis Effect.

J. Chen¹, Y. Guo², J. Zhu², Z. Lin²

1. College of Electromechanical Engineering, Donghua University, Shanghai, China; 2. Faculty of Engineering, University of Technology Sydney, Sydney, NSW, Australia

1. Introduction

This paper presents a general method for flyback converter transient performance analysis based on the time-stepping finite element analysis (FEA) of electromagnetic field considering magnetic hysteresis effects. The soft magnetic core hysteresis is modeled by an improved scalar Preisach model [1], and is integrated in the FEA model. A new coupling method based on the system state observer, which takes advantage of both the direct and indirect methods, is introduced. The system model is implemented in Matlab/Simulink. The developed model demonstrates a good example how the FEA can be conveniently coupled with electrical and electronic circuit analysis to provide high accuracy. As an example, an existing flyback dc/dc converter is simulated. The effects of magnetic hysteresis on the converter performance are clearly shown by the simulation results with and without incorporating the Preisach model of magnetic hysteresis.

2. Coupling of FEA with Hysteresis Model and Feeding Circuit

Fig.1 shows the flyback converter circuits corresponding to three different operational modes. The FEA region is marked by the dotted line, which couples the feeding and output circuits. In the improved Preisach model, the magnetization M corresponding to magnetic field strength H can be derived as in Fig.2. The most significant advantage of the improved model is that its implementation only needs the limiting B-H loop, which is usually available from manufacturer.

Solving the governing equation (Fig.3) with the relative permeability determined by the Preisach model and the applied current density steps in time, we can obtain the magnetic field distribution in the transformer in each time step. The differential inductance of the primary winding of the transformer can then be calculated, where k refers to the k -th time step.

Fig.4 gives the state-space variable equations of feeding circuit in different operational modes and uniform format. Description of the equations, as well as the coupling method based on system observer, will be detailed in the full paper.

3. Simulation

An existing flyback dc-dc converter is simulated. The specifications include: input voltage of 370 Vdc; output voltage/current of 5V/3.6A; 67 kHz; duty ratio of 0.33; winding turns of 96/8; TDK PC40-EE25 ferrite for transformer core [2].

The developed model is implemented in Simulink and comprehensive performances of the converter are simulated. As an example, Fig.5 shows the primary winding current, where the red (inner) line is obtained by including hysteresis and the blue (outer) line is obtained by considering the initial B-H curve only. The effect of magnetic hysteresis on the converter performance is clearly shown.

Complete simulation and experimental results will be presented in the final paper.

Chaoization of Permanent Magnet Synchronous Motors Using Stator Flux Regulation.

Z. Wang, K. Chau

Department of Electrical and Electronic Engineering, The University of Hong Kong, Hong Kong, China

I. INTRODUCTION

Because of the random-like but bounded nature, chaos has been positively utilized in many industrial applications [1]. Rather than using mechanical means to generate chaotic motion for some niche applications such as mixing and compaction, electrical chaoization of motors takes the definite advantages of lightweight and compact size. In [2], a design-oriented approach was developed to chaoize a doubly salient permanent magnet motor for soil compaction. Although it can spontaneously produce chaotic motion once power on, this design-oriented approach is inflexible since the motion boundary can not be tuned once the motor is designed. In [3], a time-delay feedback control approach was developed to chaoize a DC motor for liquid mixing. Although the motion boundary can be controlled by tuning the feedback control parameters, the corresponding torque response is sluggish. Also, the use of DC motors for industrial application is inefficient and needs regular maintenance.

The purpose of this paper is to propose and implement a new stator flux regulation based direct torque control approach to chaoize the permanent magnet synchronous motor (PMSM). Thus, it can produce electrically chaotic motion, while offering the advantages of controllable chaotic boundary, fast torque response, inherently high efficiency and maintenance-free operation.

II. CONTROL SCHEME

For a PMSM with no saliency, the electromagnetic torque T can be expressed as $(3/2)(n_p/L_s)|\psi_s||\psi_f|\sin\delta$ where n_p is the number of pole pairs, L_s is the stator inductance, ψ_s is the stator flux, ψ_f is the rotor flux, and δ is the angle between ψ_s and ψ_f . Consequently, T can be directly controlled by regulating the ψ_s . Fig. 1(a) shows this direct torque control block diagram. The reference torque T^* is generated by a sliding mode speed controller, which is robust to load changes and system disturbances. By defining the sliding surface S as $\omega - \omega^* + c(\omega - \omega^*)d\tau$, it can be derived that $T^* = -Jg\text{sgn}(S) + B\omega^*$ where J is the rotor inertia, B is the viscous damping, c is a positive control parameter, and g should be large enough to satisfy $g > |c(\omega - \omega^*)|$. Then, Fig. 1(b) shows the selection of switching status for stator flux regulation. It is determined by the section where ψ_s locates, and the outputs of two hysteresis loops for torque and flux. By properly choosing the control parameters for stator flux regulation such as the hysteretic limitation of flux $\Delta\psi$, the chaotic motion with controllable boundary can be realized.

III. SIMULATION AND EXPERIMENTAL RESULTS

The key motor parameters for the proposed chaoization are listed in Table 1. Firstly, by setting $\Delta\psi$ as 0Wb, the stator flux trajectory and rotor speed waveform are simulated as shown in Fig. 2. It illustrates that chaotic motion can be successfully generated, exhibiting random-like but bounded nature. Then, by changing $\Delta\psi$ to 0.01Wb, the corresponding simulated trajectory and waveform are shown in Fig. 3. It confirms that the boundary of chaotic motion can be successfully regulated, which is an important feature that cannot be achieved by design-oriented chaoization.

In order to verify the proposed chaoization, the whole system is prototyped. Figs. 4 and 5 show the measured stator flux trajectories and rotor speed waveforms when $\Delta\psi=0$ Wb and $\Delta\psi=0.01$ Wb, respectively. They well agree with the simulated trajectories and waveforms. It should be noted that the corresponding chaotic patterns do not match in general, which is actually the random-like nature of chaos. Nevertheless, the corresponding boundaries do closely match.

Fundamental Research about Parameter Design of Contactless Power Station for Moving Electric Loads.

N. Nakajima, Y. Kakubari, F. Sato, H. Matsuki
Tohoku University, Sendai, Japan

1. Background

Contactless Power Station (CLPS) is a power transmission device. When a moving electric load is supplied power, many problems will occur in the case that its terminal contacts like a pantograph of a train. For example, electrification, generation of dust by the wear of the terminal. To solve these problems, we think contactless power supply by electromagnetic induction is effective.

2. Principle

In this research, CLPS is a power transmission system using a transformer which is constructed by two flat coils facing to each other. Fig.1 is Equivalent circuit schematic of this transmission system. Now, we analyze appropriate parameter which stabilizes output voltage.

In Fig.1, the ratio of output voltage and input voltage are expressed like formula (1).

Formula (1) HERE

Output voltage depends on load resistance,

so output voltage decreases as load resistance decreases. Internal impedance and output open voltage of this equivalent circuit are expressed like formula (2) and formula (3).

Formula (2) HERE

Formula (3) HERE

Internal impedance causes output voltage fluctuation by load disturbance, so we needed to devise internal impedance minimization method to restrain output voltage fluctuation. From formula (2), the condition that internal impedance becomes zero is expressed like formula (4), and formula (5) expresses output voltage in this time.

Formula (4) HERE

Formula (5) HERE

Formula (5) indicates that output voltage is not depends on the load reactance. So we are able to avoid the effect of impedance which decreases voltage when we set the value of primary capacitor as it fills the formula (4).

Additionally, the capacitance of secondary capacitor is configured from the viewpoint that the transmission efficiency becomes maximum value. From the formula of the transmission efficiency of this system (Fig.1), the capacitance of secondary capacitor which makes transmission efficiency maximum is formula (6) (r_1 and r_2 is the resistance of the primary and secondary coil).

Formula (6) HERE

When we make coils, we often use strand wires in parallel to make a coil that has the inductance and the size we want. This time, difference of current is often generated by difference of inductance which is generated between each strand wire. As a method to control this difference of current, we can use the method that we divide the resonant capacitors into number of strand wires and connect the capacitors and the strand wires (Fig.2 and Fig3). Formula (7) is current ratio of two strand wires when a capacitor is divided. Formula (8) is the one when a capacitor is not divided.

Formula (7) HERE

Formula (8) HERE

Fig.4 is characteristic of current ratio vs. inductance ratio of each strand wire. According to Fig.4, the current ratio with non divided capacitor fluctuates widely. One the other hand, the current ratio with divided capacitors hardly fluctuates.

3. Consideration

We transmitted power with the scale model which we made experimentally on condition of output voltage stabilization. As a result, we succeeded in restraining voltage decrease in Fig.5. And Fig.6 shows load characteristic of efficiency. From the result, the precepts of stable contactless electricity supply for moving electric loads that have large fluctuation of load resistance are expected. In the future, we will put more proper setting for moving electric loads in perspective of coil geometry.

$$\frac{V_{out}}{V_{in}} = \frac{\omega^2 C_{1p} k \sqrt{L_1 L_2}}{AR + j\omega L_2 \{ \omega^2 C_{1p} L_1 (1-k^2) - 1 \}} \quad \dots(1)$$

$$A = -\omega^4 C_{1p} L_1 C_2 L_2 (1-k^2) + \omega^2 (C_{1p} L_1 + C_2 L_2) - 1$$

$$Z_0 = \frac{j\omega L_2 \{ 1 - \omega^2 L_1 C_{1p} (1-k^2) \}}{1 - \omega^2 (L_1 C_{1p} + L_2 C_2) + \omega^4 L_1 C_{1p} L_2 C_2 (1-k^2)} \quad \dots(2)$$

$$\frac{V_{out(open)}}{V_{in}} = \frac{\omega^2 k C_{1p} \sqrt{L_1 L_2}}{-\omega^4 C_{1p} L_1 C_2 L_2 (1-k^2) + \omega^2 (C_{1p} L_1 + C_2 L_2) - 1} \quad \dots(3)$$

$$C_{1p} = \frac{1}{\omega^2 L_1 (1-k^2)} \quad \dots(4)$$

$$\frac{V_{out}}{V_{in}} \bigg|_{Z_0=0} = \frac{1}{k} \sqrt{\frac{L_2}{L_1}} \quad \dots(5)$$

$$C_2 = \frac{(R+r_1)\sqrt{r_1}}{\omega^2 R \sqrt{L_2} (r_1 L_2 + k^2 r_2 L_1)} \quad \dots(6)$$

$$\frac{I_2}{I_1} = \frac{M-L_1}{M-L_2} \quad \dots(7)$$

$$\frac{I_2}{I_1} = \frac{2 + \omega^2 C_{1p} (M-L_1)}{2 + \omega^2 C_{1p} (M-L_2)} \quad \dots(8)$$

Experimental Verification and Performance Analysis of Permanent Magnet Wind Turbine Generators considering Magnetic Losses using D-Q Axis Model.

S. Jang¹, J. Choi¹, K. Ko¹, B. Kim²

1. Chungnam National University, Dae-jeon, South Korea; 2. Korea Electric Power Research Institute, Daejeon, South Korea

Introduction

Owing to concern over the environment, there is currently a significant amount of interest in renewable sources of electrical power generation of which one of the most promising is wind power [1]. Generators for this application are widely classified into two types: one is gearbox-coupled generator such as an induction generator (IG), the other is gearless direct-coupled generator such as a permanent magnet synchronous generator (PMSG). Compared with the IG, the direct-drive wind PMSG have many advantages, such as a much reduced size of the overall system, a rather low installation and maintenance cost, etc [2]. Therefore, particular attention has been paid to study on the direct-drive wind PMSG such as design and performance analysis.

In order to implement the performance analysis of the PMSG, a variety of techniques such as finite element (FE) method, equivalent circuit method (ECM), method using d-q axis model can be employed. In particular, d-q axis model not only provides rapid and quite accurate performance analysis of the PMSG in itself but also can be easily coupled with dynamic model of the wind turbine and power conversion devices for dynamic analysis of wind power systems.

Therefore, this paper deals with experimental verification and performance analysis of PM wind turbine generator considering losses using D-Q axis model. First, voltage and output equations of the PMSG are derived from D-Q axis model. And then, mathematical expressions for losses such as core and copper losses are also made. Using these equations and MATLAB/SIMULINK, a simulation block diagram shown in Fig. 1 is obtained. Finally, the performance of the PMSG such as output power, efficiency and losses under various speed and load conditions are predicted. In particular, measurements and FE results for its performance are given to confirm the analysis.

Results and Discussion

Figure 2(a) shows a rotor and a stator of the PM wind turbine generator used in performance analysis. As shown in Fig. 2 (b), since predicted results for core loss are shown in good agreement with data provided by manufacturer, it can be judged that the values for derived coefficients (k_h , k_e and k_a) in core loss equation of Fig. 2(b) are reasonable. The values and derivation procedures of coefficients will be given fully in final paper. Fig. 3 shows the performance analysis results of the PM wind turbine generator under various load and speed conditions. The results predicted by D-Q model are shown in good agreement with FE results and measurements. It can be seen that iron losses are not affected by the variation of the load, while they are varied by the rotational speed. It can also be seen that as the load and the rotational speed are increased, the output power decreases and increases, respectively. From the fact that the efficiency is much more affected by the variation of the load than speed, it can be predicted that the main loss of the PM wind turbine generator is the copper loss. Nevertheless, since the generator is a totally enclosed non-ventilated machine and is located on a tower out of doors in hot environments due to solar absorption, calculation of the iron loss has important meanings in terms of thermal sources. More detailed results, discussion and mathematical expressions will be given in final paper.

Design, Fabrication and Experimental Validation of a Miniaturized Generator with Planar Coils via Genetic Algorithm.

P. Chao¹, J. Shen², E. Chiu¹, J. Huang²

1. Electrical and Control Engineering, National Chiao Tung University, Hsinchu, Taiwan; 2.

Mechanical Engineering, Chung Yuan Christian Univ., Chung Li, Taiwan

This study presents an optimal design process of a miniaturized generator in size of 5x5x2mm³ using the method of Genetic Algorithm (GA) [1]. The associated experiments are also conducted to validate its performance. This generator is capable of serving as a transducer in a self-power system to scavenge energy from translational or rotational vibrations [2-10]. The obtained power could be applied to a rotor balancing ring [11], as schematically illustrated by Fig. 1, or to the pervasive networks of wireless sensor and communication nodes [12-13]. The designed generator (Fig. 2(a)) consists of patterned planar copper coils (Fig. 2(b)) and a multipolar hard magnet made of NdFeB (Fig. 2(c)), where the patterned coils are fabricated using the method of filament winding and the NdFeB magnet is magnetized to induce 1.1 Telsa around each pole. To perform modeling, a periodic magnetic model along the circumferential path of the magnet is first assumed with help from measured peak magnetic flux densities. This is followed by the application of Faraday's law, as illustrated by Fig. 3, to predict generated electromotive forces (emf's) in terms of the relative rotational speed between the magnet and coils. The predicted emfs are further validated by finite element analysis and experimental data, as shown in Fig. 4(a). It is also found that the generated current would be saturated to some limitation while the relative speed increased to a certain level, as shown in Fig. 4(b). Finally, the Genetic Algorithm is successfully applied to optimize the miniaturized generator, with varied geometric sizes, configuration and loop number of planar as design parameters.

Electromagnetic Analysis and Parameter Estimation of Permanent Magnet Wind Turbine Generators Considering Skew Effects.

S. Jang, J. Choi, K. Ko

Chungnam National University, Dae-jeon, South Korea

Introduction

Stimulated by the demand from the wind energy industry and with the advent of rare earth magnetic materials which combine high remanence and coercive force, particular attention has been paid to the development of various types of permanent magnet (PM) generators for low speed, direct-coupled wind turbine application [1]. Generally, since the wind power systems are very expensive and require high reliability, their performance must be verified by dynamic simulations performed under various conditions. In order to facilitate the accurate dynamic simulations of wind power systems, the parameter estimation of the machines is essential.

Therefore, this paper deals with electromagnetic analysis and parameter estimation of the PM wind turbine generators considering skew effects. First, this paper predicts the open-circuit and the armature reaction field distributions using analytical solutions derived in terms of the magnetic vector potential and a two dimensional (2-d) polar coordinate system. On the basis of the field solutions, parameters such as back-emf constant and inductance are estimated, and the influence of stator skew on the cogging torque and back-emf wave form is also investigated. The analytical results are validated extensively by non-linear finite element (FE) analyses. In particular, test results such as back-emf, inductance and cogging torque measurements are given to confirm the analyses. Finally, using estimated parameters and equivalent circuit method (ECM), the variation of generating characteristics such as output power, terminal voltage and load current according to load are investigated and validated by FE calculations and measurements.

Structures and Experimental Sets of PM generator

Figure 1 (a) shows the schematic and the picture of the actual manufactured PM generators, which consists of a 16-pole rotor with parallel magnetized NdFeB magnets and a slotted stator with 3-phase windings. Figure 1 (b) shows the testing apparatus for the measurement of generating characteristics. As shown in Fig. 1(b), the testing apparatus consists of the PM generator, an induction motor, V/F inverter for drive of the induction motor, a 3-phase resistance load and a power analyzer for the measurement of the generating characteristics.

Results and Discussion

Figure 2(a) shows the comparison of predictions with FE calculations for magnetic fields due to PMs and stator currents considering slotting effect. Figure 2(b) also shows the comparison of predictions with FE calculations and measurements for the cogging torque according to stator skew. The analytical results are shown in good agreement with FE results and measurements. It can also be seen that the cogging torque is dramatically reduced by stator skew. Figure 3 shows the predictions, FE calculations and measurements for the line-line back-emf according to stator skew. It can be observed that stator skew make the line-line back-emf have more sinusoidal waveform and smaller root mean square (RMS) value. As shown in Fig. 4, since the generating characteristics of the PM generator with skew predicted by the ECM are shown in good agreement with those obtained from non-linear FE calculation and experiment, it can be judged that the validation for the electromagnetic analysis and parameter estimation of the PM generator presented in this paper is confirmed. The more detailed results, discussion and mathematical expressions will be given in final full paper.

Introduction

A high power flywheel Energy Storage System (FESS) has focused largely on developing the distributed power source in summer or midnight and power utility load-leveling systems that are competitive with traditional electrochemical battery installations [1]. The flywheel rotor is rotated by an electric machine operated as a motor at ordinary times, whilst in case of a breakdown of electric current, that rotated by its inertia makes the electric machine operate as a generator. In general, since the faster rotational speed of the flywheel rotor in motoring mode is, the larger its motion energy due to inertia in generating mode is, high speed machines as motor-generator mounted on flywheel rotor are mainly used in the flywheel energy storage systems (FESS). Here, the important factor is to be continuously offering the electrical energy from mechanical rotation energy of flywheel rotor for a long time. Thus, high speed machine for the high power FESS must be designed considering high power requirement for rotating the large and heavy flywheel in high speed and rotational loss reduction for supplying the electric energy for hours. the rotational loss is defined as mechanical loss by mechanical friction including windage loss and iron loss by magnetic field parts including eddy current loss when flywheel is rotated. Therefore, the aim in our works is to offer operating time estimation in acceleration and deceleration mode of the high power FESS from calculation of required power and core loss using electromagnetic field analysis of the applied high speed machine.

In this paper, permanent magnet synchronous motor (PMSM) is designed by analytical method of electromagnetic field to satisfy the required power in motoring and generating mode. This design model consists of the surface-mounted PM rotor with diametrical magnetization and slotless iron-cored stator as shown in Fig. 1. And, its performance is evaluated in generating mode with various resistance load and idling mode without generating load considering the required electric power and core loss. In order to facilitate design, analysis and accurate dynamic range of high speed PM machines, a variety of techniques can be employed to predict the magnetic field distribution. Numerical techniques, such as finite element (FE) analysis, provide an accurate means of determining the field distribution, with due account of saturation etc., while they remain time-consuming and do not provide as much insight as analytical solutions into the influence of the design parameters on the machine behavior [2]. Therefore, this paper places the focus on characteristics for the generation of electricity of high speed machine and derives analytical solutions for open-circuit field, armature reaction field and back-emf in terms of magnetic vector potential and a two dimensional (2-D) polar coordinate system as shown in Fig. 2.

In verification for analysis and design, a 5kWh-class FESS with the whole flywheel rotor weights 215kg, the Active Magnetic Bearing (AMB) for elimination of mechanical friction and Floating Magnetic Bearing (FMB) for stable levitation of flywheel is manufactured as shown in Fig. 3(a). And, the designed 15kW-class PM Synchronous Motor/Generator (PMSM/G) is used for high power energy storage in dynamic range of flywheel speed 12000~18000rpm. These all parts are installed in vacuum chamber. As the experimental result for storage energy evaluation of the presented high power FESS, Fig. 3(b) shows the phase Back-emf of PMSM/G at a flywheel speed 3600rpm and Fig.3 (c) shows the flywheel speed for operating time determination according to

driving mode of the PMSM/G. The more detailed results and discussion will be given in final paper. The mathematical expressions related to analytical results will also be given fully in final paper.

Magnetic Switch Topologies.

W. Johnson

Electrical and Computer Engineering, University of Kentucky, Lexington, Ky, KY

Paper Overview:

After a brief history of control technology a discussion of several magnetic switching design styles is given. The magnetic switching styles are compared to solid-state switches using solid-state terminology and magnetic theory to detail the physical differences between the two.

Perspective:

Solid-state switches have vastly improved switching capabilities over magnetics switches but only within a limited range. Due to material advances saturation can be reached very quickly allowing for good state transitions. This is especially significant in high voltage and high current applications where the magnetic core allows for true decoupling of the source and control thus showing the magnetic technology's primary benefit of inherent isolation.

Topologies of Magnetic Switches:

As with solid-state devices, two fundamental types of magnetic switches can be created, normally-Off (inherently Off or n-type) and normally-On (inherently On or p-type). Both types of switches from a magnetic perspective are created using a core that can quickly reach magnetic saturation, equivalent to the solid-state ohmic region.

In Figure 1 an anhysteretic B-H curve, shows the areas of operation for amplification and switching of a magnetic device. Notice that the B-H curve saturates in two quadrants and thus has bi-directional capabilities, something that solid-state devices are unable to do. However, the magnetic device has difficulty when used in typical DC applications and is thus excluded from many applications. (Further discussion of the differences between the solid-state switching curves and the B-H switching curves will be presented.)

Inherently Off (n-Type) Magnetic Switch:

Most magnetic amplifiers and switches are designed using the n-type topology due to its inherent safety and similarity to the transformer. (Literature on the n-type topology is abundant and references will be given.) This magnetic switch style is generally designed using an area-product methodology, similar to transformer designs, as the magnetic core during turn-Off must quickly drop out of saturation while absorbing worst case field energy. The switching time to turn-Off (t_{Off}) is governed by the turns count and the core area (A_c) where a larger A_c reduces the turn-Off time as shown in Figure 2. (The area-product design method and equations of the n-type switch will be given. Emphasis will be placed to the physical interpretation of the method.)

Inherently On (p-Type) Magnetic Switch:

In contrast to the n-type switch, the p-type magnetic switch obtains better turn-On (t_{On}) switching performance with a smaller A_c . A control coil is regulated to insure that the magnetic field of the core is zero (or of opposite polarity to the primary coil) during an 'Off' sequence. This switch style is not governed by the traditional area-product method of design as a smaller A_c improves performance. This is because the core is no longer designed to absorb field energy thus the traditional area-product rule no longer applies. (Further physical interpretation for not using the traditional area-product design method will be given.)

The p-type magnetic switch must now be designed around 'switching' losses that are governed by its $B \cdot H$ product and not its $I \cdot V$ product as with traditional area-product designs. (A full p-type design discussion will be given in the paper.)

Switch Extremes:

Magnetic switch designs (n-type or p-type) vary due to their inherent (On or Off) state which occurs when control coil current is removed. Physically, the difference can be resolved to the relative size of A_c and the two methods of design, $B \cdot H$ vs $I \cdot V$.

While the control methods of the two switches are exactly opposite, as shown in Figure 3, and their design methods appear different, this paper will give a proof that the two switches and design types are in fact a single switch where A_c has been taken to an extreme. This paper will conclude with a simple design and experimental results for verification of the given design procedures.

Influence of Notch Shape and Size on Current-Driven Domain Wall Motions in a Magnetic Nanowire.

H. Murakami¹, T. Komine¹, T. Nagayama¹, R. Sugita¹, Y. Hasegawa²

1. Department of Media and Telecommunications Engineering, Ibaraki University, Hitachi, Japan; 2. Saitama University, Saitama, Japan

1. Introduction

Spin-current-induced domain wall motion in a nanowire has attracted much attention [1], and new memory and logic devices with current-induced wall motion are suggested by some authors [2]. In order to control domain wall motion in memory devices with large capacity, a magnetic wall pinning such as a notch is necessary [3]. However, influence of notch shape and size on wall pinning in current-induced wall motion has not been discussed yet. In this study, influence of notch shape and size on current-induced wall motion has been investigated in the micromagnetic framework.

2. Calculation model

Fig. 1 shows the calculation model of nanowire with a rectangle and a triangle notch. The nanowire length of 200 nm was assumed and the infinite boundary condition was imposed at the nanowire edges along the longitudinal direction. The magnetic nanowire has a saturation magnetization of 800 emu/cm³, exchange stiffness constant of 1.0×10^{-6} erg/cm, Gilbert damping constant of 0.02, and non-adiabatic damping constant of 0.02.

The notch shape was assumed to be rectangle or triangle. The dimensions of notches are shown in Table 1. In order to investigate the domain wall motion, the Landau-Lifshitz-Gilbert equation with spin torque terms was solved by simultaneously calculating current distribution in a nanowire. The critical current density and critical magnetic field were calculated by varying an induced current and an applied field. The influence of notch shape and size on domain wall motion was discussed.

3. Results and discussion

Fig. 2(a) shows the phase diagram in a current density and an applied field for domain wall motion in a nanowire with a rectangle notch. The current density is defined as a maximum current density around a notch. In Fig. 2, the critical current density monotonically decreases as the applied field increases. The effect of wall trap on domain wall motion increases as the notch size becomes larger. Fig. 2(b) also shows the phase diagram for triangle notch. In triangle #1, the phase diagram is similar to that in rectangle cases. On the other hand, in other triangle (#2-4) the critical current is almost constant up to a certain applied field. Thus, the triangle notch is more effective than rectangle notch for wall pinning. Fig. 4 shows the wall motion modes in triangle #4. There were four wall motion modes in this case: (i) the domain wall oscillates around the notch by maintaining transverse wall, and stops. (ii) the domain wall moves beyond the threshold of applied field by maintaining transverse wall. (iii) the domain wall moves and alternatively changes from transverse wall into anti-vortex wall. (iv) the domain wall breaks down into multi-domain.

4. Summary

In this study, influence of triangle and rectangle notches with various sizes on current-induced domain wall motion has been investigated by utilizing micromagnetic simulation. Each notch plays a role of wall trap, and the effect of wall trap increases as the notch size increases. The phase diagram in a critical current density and a critical field for notch shape is clarified. There are four modes in domain wall motion by various current densities and magnetic fields.

NHK Science & Technical Research Laboratories, Tokyo, Japan

Introduction

The spin transfer switching (STS) technique has progressed remarkably since its theoretical prediction.¹ Especially, it is expected to use STS for the writing process of high-density random access memory. We have proposed new magneto-optical spatial light modulator (MO-SLM) driven by STS for high resolution and high speed applications such as holographic memories and 3-D TV systems. MO-SLM is the known device that controls light modulation by optical polarization rotating with the magnetization direction of the pixels.² We have succeeded to observe the fundamental STS properties by magneto-optical Kerr effect using visible light.³ In order to achieve gradational light modulation, we have considered that division of a pixel to some small segments and control of multi-level magnetization states by STS. In this study, we fabricated two closely-arranged spin valve (SV) pillars sharing a pair of top and bottom copper electrodes and tried to control of multi-level transitions by STS.

Experimental method

Fig. 1 shows a schematic configuration of our fabricated device. The structure of paired SV pillars consists of Cu bottom electrode layer, synthetic pinned layer of [Ru(5)/Cu(20)/Ir₂₂Mn₇₈(10)/Co₇₅Fe₂₅(5)/Ru(0.75)/Co₇₅Fe₂₅(5.5)], Cu spacer of [Cu(6)], free layer with capping of [Co₄₀Fe₄₀B₂₀(3)/Cu(5)/Ru(5)], and Cu top electrode layer, where the numbers in parentheses are thicknesses in nanometers, deposited by ion beam sputtering. The bottom and top electrodes are shared by the paired pillars. The each size of pillars is set at 300 nm × 100 nm as shown in Fig. 1, using electron beam lithography and liftoff processes. The distance d between two pillars was varied up to 1 μm . In this study, the single pillar (Sample A), the closely arranged pillars with d of 1 μm (Sample B) and 300 nm (Sample C) are discussed in detail.

Results and discussion

The MR ratio of Sample A was about 0.7 % and the critical current density J_{c0} , calculated from the pulsed current in the range from 10 μs to 10 ms, was about $5 \times 10^7 \text{ A/cm}^2$. The MR loops of Samples A, B, and C showed same shape, however, the loops of B and C possessed slight steps at the half-maximum of MR ratios. The STS characteristics from anti-parallel (AP) state to parallel (P) state and histograms of J_c s were shown in Fig. 2, where the STS characteristics were measured by applying a pulsed current with the duration of 500 μs without magnetic field. Samples B and C showed two-step transitions at J_{c1} (the first step) and J_{c2} (the second step). In the case of sample B, since J_{c1} was approximately equal to J_{c2} , both J_{c1} and J_{c2} were handled as J_c . The average values of J_c for samples A and B were $-3.9 \times 10^7 \text{ A/cm}^2$ and $-3.7 \times 10^7 \text{ A/cm}^2$, and the variances σ^2 of J_c for samples A and B were estimated almost same values of $4.9 \times 10^5 \text{ A/cm}^2$ and $5.1 \times 10^5 \text{ A/cm}^2$, respectively. The sample with d of 1 μm did not affect on the STS characteristics. On the other hand, the average values of J_{c1} and J_{c2} for Sample C were $-3.6 \times 10^7 \text{ A/cm}^2$ and $-4.5 \times 10^7 \text{ A/cm}^2$, and the J_{c1} and J_{c2} are clearly distinguishable. We succeeded to control the multi-level transitions in spin transfer switching of pillars with d of 300 nm. At the intermediate step, the magnetization directions of each pillar were considered that one was P-state and the other was AP-state, because the dV/dI at this step was a half value of $\Delta dV/dI$. The origin of the steady intermediate state and the smaller J_{c1} seemed to be the magnetic interaction and the peculiar switching mode of STS because the plateau width of the STS characteristics in Samples B and C showed the correlation with d .⁴ The σ^2 of J_{c1} and J_{c2} for sample C were $3.9 \times 10^5 \text{ A/cm}^2$ and $1.1 \times 10^6 \text{ A/cm}^2$, respectively. The σ^2 of J_{c1}

was smaller than σ^2 of J_c and the σ^2 of J_{c2} was larger than σ^2 of J_c . This result supports those assumptions.

Conclusion

Two closely-arranged SV pillars were fabricated and the STS characteristics were investigated. We succeeded to control of multi-level transitions using STS by changing the distance d between SV pillars. The origin of the steady intermediate state seemed to be the static magnetic interaction and the peculiar switching mode of STS.

To compete as non-volatile memory, MRAM elements based on TMR barriers have to keep path with the scaling down nodes in the semi conductor industry. Classical elements using magnetic field induced switching are limited, mainly since the creation of the external field requires too much current. A new switching regime avoiding an external magnetic field by using the current driven through the tunnel element may be one promising path to overcome this constraints. The current density necessary to switch the element is there nearly independent from the size of the elements. Current densities in the range of $1 \times 10^6 \text{ A/cm}^2$ have been actually demonstrated. For competitive storage cells it needs to be reduced further by almost one order of magnitude.

The crucial point is the formation of the MgO tunnel barrier. It is shown, that a switching of the tunnel element can be realized utilizing different production methods for the MgO. Either a sputtering from an MgO-target or sputtering metallic Mg with a subsequent oxidation step can be applied. We will present a direct comparison of three methods: By using the Singulus TIMARIS platform we are able to deposit identical layer stacks for bottom and top electrode and either use a rf-process or metallic deposition with a subsequent oxidation step (natural or remote plasma with low energy ions). Beside the switching behaviour we will also discuss issues important for large scale deposition of the different process.

First results utilizing sputtering from metallic Mg showed, that the TMR- and RA-values are only weakly depending on the Mg thickness and on the oxidation conditions. Subsequently we can achieve an easily controllable RA and MR uniformity. In addition to the good uniformity control, the RA can be adjusted in the $10 \Omega \mu\text{m}^2$ range, which is important for current induced switching. The mechanism of different barrier formation compared to the rf-sputter process will be discussed.

Dynamics of current-induced magnetic switching of a single-molecule magnet.

M. Misiorny¹, J. Barnas^{1,2}

1. Department of Physics, Adam Mickiewicz University, Poznan, Poland; 2. Institute of Molecular Physics, Polish Academy of Science, Poznan, Poland

Single-molecule magnets (SMMs) draw attention as potential candidates for applications in spintronics devices and information storage technology. Consequently, the key question arises how to effectively manipulate the SMM to write a bit of information on it. It has been shown that the current-induced magnetic switching (CIMS) [1,2,3] is a good alternative to the application of an external magnetic field.

There are, however, several challenging aspects of the current-induced manipulation of SMM's spin. First, one can hardly control the relative orientation of the molecule's easy axis and leads' magnetizations [4,5]. Second, intrinsic spin-relaxation time of the molecule significantly influences the switching parameters. The main objective of the following work is an analysis of how such intrinsic spin-relaxation affects the dynamics of the SMM's spin reversal induced by spin-polarized current.

When the energy ε of the lowest unoccupied orbital (LUMO) level of the molecule is sufficiently low, electronic transport between the leads takes place owing to tunneling between the electrodes and the LUMO level. The CIMS can then occur when the LUMO level is exchange coupled to the SMM's spin. When the energy ε is large enough, electron tunneling to the molecule is energetically forbidden at bias voltages of interest. However, current still can flow due to higher order processes, e.g. cotunneling ones, and CIMS of the molecule's spin is still possible [1] when the electrons virtually entering the molecule couple to the molecule's spin via the exchange interaction.

Switching of the SMM's spin takes place consecutively via the magnetic states of the molecule. These states are described by the eigenvalue m of the z -component of the total spin. Two main sources of SMM's spin relaxation processes are the coupling of the molecule to the ferromagnetic leads [1,2,3] and intrinsic spin-relaxation due to interaction with the environment. The latter ones are included into considerations as the relaxation time τ_R in addition to the current-induced transitions between the molecular spin states. The probabilities of finding the molecule in all possible molecular spin states are then determined from the relevant master equations. The molecule is initially saturated in the state $m=-10$, and then a constant voltage is applied.

In Fig.1(a) we show evolution of the z -component of the molecule's spin in the case of parallel magnetic configuration and high LUMO level (current flows then due to higher order processes). The results clearly show that the molecule's spin becomes switched when the voltage exceeds some critical value, Fig.2. The current-induced spin-flip processes become activated when eV is of order of the anisotropy energy gap. The intrinsic spin-flip relaxation processes, however, tend to restore the initial state. Therefore, the lowest threshold voltage occurs in the absence of intrinsic spin relaxation. The switching takes also place in the presence of intrinsic spin relaxation processes, although the threshold voltage becomes slightly increased. Apart from this, the switching time also increases with increasing τ_R^{-1} , Fig.1(a). Similar behavior also occurs in the case when magnetic moments of the leads are antiparallel.

Assume that the positive bias corresponds to electrons flowing from left to right ($e>0$). Spin-up electrons leaving the left electrode, Fig.1(b), can change its spin orientation when interacting via exchange coupling with the molecule's spin, and this way can increase the spin number m of the molecule's spin. Intrinsic relaxation processes tend to restore the initial state. When the current exceeds some critical value, the competition between intrinsic spin relaxation (lowering the quan-

tum number m) and current-induced processes (increasing the number m) leads to spin reversal of the molecule. This takes place in both, parallel and antiparallel magnetic configurations. For reversed bias polarization only switching from the state $m=10$ to the state $m=-10$ is possible.

1. SMI, Data Storage Institute, Singapore, Singapore; 2. ISML, ECE, National University of Singapore, Singapore, Singapore

Recent studies have shown that spin-current can be generated via spin orbit interaction [1] as a result of nano-mechanical torsion in some material system. In this article we will focus on the inverse effect whereby the spin current passing through the material system causes mechanical motion on the nanometre scale [2]. We propose to utilize this effect to exert a spin-current-induced strain on the free layer of a magnetic tunnel junction such that its anisotropy constant reduces, thereby lowering the field or the spin current density required to switch the magnetization of the free layer [3]. As is well known, the grave challenge faced by spin current switching is the high critical current density. This problem can be solved by using free layer material of low anisotropy constant, but this causes magnetization stability problem and magnetic noise. Our device allows the anisotropy constant to be modified in a time-select manner, enabling low current switching to be achieved at no expense of device stability.

The schematic design of our device is shown in Fig 1. During the writing process, control spin current is injected upwards in the SC layer and this induces mechanical torque about the vertical axis (x). The SC rotates about x, with respect to the lead, forcing a insulating “flag” structure to displace along the z-axis, which thus causes strain onto the memory multilayer whose plane is placed perpendicular to z-axis. The strain in the multilayer alters the anisotropy constant [4], thus lowering the switching field of the multilayer.

The underlying theory of this entire spin mechatronic process is related to the spin orbit interaction Hamiltonian of the semiconductor [5]:

$$H_{SOI} = \alpha [\sigma_x (u_{zx} k_z - u_{xy} k_y) + \sigma_y (u_{xy} k_x - u_{yz} k_z) + \sigma_z (u_{yz} k_y - u_{zx} k_x)] + \beta [\sigma_x k_x (u_{yy} - u_{zz}) + \sigma_y k_y (u_{zz} - u_{xx}) + \sigma_z k_z (u_{xx} - u_{yy})]$$

where α and β are spin orbit constants, k 's denote electron orbit momentum, σ 's are the Pauli matrices and u 's are the strain parameters.

The physical displacement that causes strain is expressed as: $d = L\gamma PJA/4Ke$ where L , K , γ , $A=ab$ are device geometry dependent parameters, J refer to the current density. From the value of d , the additional strain induced in the free layer and thus the change in effective magnetic anisotropy, K_{eff} is computed.

Our results are displayed in Fig 2, which show a considerably large change of K_{eff} with the variation of the electron spin polarization. One of the important finding crucial for the working of this device is that as the spin polarization (P) of the current increases, K_{eff} may decrease or increase with increasing P depending on the region of spin polarization. At low P , K_{eff} actually declines to its minimum first with the increase of P , before increasing linearly at the higher P values. The P value where K_{eff} is minimum depends on the thickness of the free layer (t). For larger t , higher P would be needed to achieve the minimum K_{eff} . These results show that using spin polarization to modulate K_{eff} might be a practical approach in view of the high sensitivity of K_{eff} to the change of P . Furthermore, this method has advantage that the entire spin mechatronic process is carried out at fixed control current and voltage, which can be set to low values way below the switching current density. This suggest that even non-insulating flag structure could be used in this device and the control spin current plays the role of exerting strain through the flag as well as switching the magnetization.

In summary, we have designed a memory device that utilize the spin mechatronic process to lower the storage layer's anisotropy constant in a time-select manner, enabling spin transfer switching to be achieved at low current density.

Spin transfer in Co/Cu/Co nanocontacts.

M. N. Baibich, M. P. de Lucena, D. L. Baptista, R. B. da Silva, J. E. Schmidt, L. G. Pereira
Instituto de Física UFRGS, Porto Alegre, Brazil

We present preliminary results on spin transfer in arrays of nanocontacts built on Co/Cu/Co sandwiches. The nanocontacts were obtained by punching holes on a PMMA resin film with an AFM tip, forming 5x5 arrays. We have observed characteristic jumps of nearly 1%

The discovery that a spin-polarized current can exert torque on a ferromagnet through transfer of spin angular momentum offers a new method to manipulate a magnetization without applying any external magnetic field. The concept of magnetization reversal by spin transfer from a spin-polarized current was introduced by Slonczewsky [1] and Berger [2]. Later experiments on nanopillar-shaped spin-valve structures [3-6] nanowires [7] and nanocontacts [8] have confirmed this effect. The magnetization reversal by spin injection should be of great interest for application in non-volatile magnetic memories, programmable fast magnetic logic, and in high frequency devices for telecommunications. In this work we present a study of current-driven effects in nanocontact-shaped samples using their magnetoresistance properties.

In order to study the spin-transfer effect, we grew a Co/Cu/Co magnetic sandwich by sputtering, deposited on a silicon (1,1,1) substrate covered by 800 nm of copper, which serves as the bottom electrode. The structure of the film can be represented by Co(30nm)/Cu(8nm)/Co(3nm). After deposition the samples were covered by a thick layer of a solution of 2% PMMA (of 950k a.m.u.) in Anisole by spin coating at 4500 rpm for 45 seconds. The average thickness was estimated to be 50 nm. Right after this, the resin was patterned by lithography using the tip of an AFM system (figure 1), producing a 5x5 holes matrix with average spacing around 250 μm and opening about 40nm.

We deposited 50 nm of gold over this structure, forming the top electrode.

All measurements were made at room temperature with the current perpendicular to the plane and the magnetic field in the plane. We took as convention that negative current corresponds to electron flow from the thinner to the thicker ferromagnetic layer.

The resistance of the system was measured initially at 1200 Ω for currents in the 10 nA range, and no spin transfer was observed. By sweeping the current up to 100 μA , the resistance dropped significantly. Measuring once again in low currents we have observed the typical plots of figure 2, where the top panel corresponds to 25 Oe, and the bottom one to 45 Oe. We believe this drop in the overall resistance by going to high currents is related to the rearrangement of the current paths within the sample. Only a few of the 5x5 contacts is really connected to the Co/Cu/Co at first. After a few measurements, these are "burnt" and the resistance increases. When the current is swept to very high values, we break the insulator and establish new current paths (new nanocontacts).

As can be seen in figure 2, spin transfer is clear from the discrete jumps in resistance (about 1 %); changing the external field displaces the current needed to have moment switching.

In conclusion, we have prepared arrays of nanocontacts on Co/Cu/Co that present spin-induced moment switching with jumps in the resistance that can reach 1 %. The actual paths for conduction are not known, for the final result comes through breaking the insulating layer to establish conduction.

The spin torque effect, in which the spins of the electrons in an electric current exert a torque on the magnetization of a magnetic electrode, is an effect of high fundamental interest [1] and large potential in applications [2]. In the standard description of this effect in all metal junctions derived by Slonczewski, the torque is created by elastic electron scattering [1]. With the observation of the spin torque effect in magnetic tunnel junctions [3], the additional parameter of bias voltage across the junction was introduced and inelastic contributions of the spin torque effect are currently discussed.

These inelastic contributions to the torque might be of utmost importance in spin torque effect. In case a magnetic electrode is intended to be switched between different metastable magnetic states, an energetic barrier has to be overcome and energy has to be pumped into the magnetic electrode. The switching process itself has been found to be related to a precession of the magnetization [4], which is the lowest magnetic excitation of the electrode, the coherent rotation or the momentum $q=0$ magnon. While this low excitation mode does not involve an increase of exchange energy, it has a finite energy due to shape or magnetocrystalline anisotropy of the magnetic electrode. In case the bias of the junction is larger than this energy, even higher magnon modes with non uniform precession, i.e. magnons with $q>0$, may contribute to the spin torque effect. So far, these excitations have not been intensively studied experimentally and it is unclear, how much they contribute to the size of the spin torque effect. In this contribution, we present the magnon creation by inelastic scattering of electrons and holes, relate the inelastic scattering probability to the spin polarization of the tunneling current and discuss the importance of this inelastic mechanism for the spin torque effect.

Microscopic theory of spin transfer torque based on the spin spiral texture.

Y. Le Maho¹, F. Piechon²

1. Institut d'Electronique Fondamentale, CNRS / Univ. Paris Sud, Orsay, France; 2. Laboratoire de Physique des Solides, CNRS / Univ. Paris Sud, Orsay, France

As spin transfer torque looks very promising regarding the control of domain wall dynamics in nanoscale ferromagnets, the recent observation of current induced domain wall propagation has drawn much attention. The required critical current density for spin transfer torque to depin ferromagnetic domain walls $10^{11} [\text{A/m}^2]$ is still much too high regarding applications and better understanding of the mechanism is needed in order to reduce the critical current as much as possible. Two parameters u and β are commonly used to describe spin transfer torque [1]. Several authors have calculated u and β within the sd model ranging from quantum Kubo formalism [1] or Keldysh formalism [4] to classical Boltzmann theory [2] and even drift diffusion [3]. Most of these theories focused only on linear deviations around the uniform magnetization profile. They do not apply when domain wall width is of the same order of magnitude as the Larmor precession length λ_L , as it is the case for films with perpendicular magnetic anisotropy.

We extend the latter classical theory of spin transfer torque by looking at the quantum Boltzmann transport equations for the Wigner distribution function in the spin spiral magnetization texture $m(r) = \cos(x/\lambda) \mathbf{y} + \sin(x/\lambda) \mathbf{z}$, where λ is the spin spiral period. Within this theoretical approach a full derivation of collision integrals is given, which provides means to study the microscopic processes more carefully and to account for non trivial spin accumulation beyond the classical local limit in the diffusive regime.

Our approach may be converted within a gauge transformation into a problem where the exchange field seen by an electron crossing the spin spiral contains a uniform component, which depends on the local magnetization of the d electrons, and a velocity dependent magnetic field. The latter field is proportional to the ratio λ_L/λ between the Larmor precession length λ_L and the spin spiral period λ . The use of this local frame is very convenient for our purpose because the exchange field is then translationally invariant. If λ_L is of the order of magnitude of λ , the velocity dependent magnetic field becomes of the order of the constant field and so conduction electron spins are no longer roughly aligned with respect to the local magnetization of d electrons. As a consequence conduction electron spin density is non local and there is a non trivial spin accumulation. Because of this non local feature, a traveling electron will not only be sensitive to the first order spatial gradients of the magnetization $\partial_x m$ as in the classical limit, but also to the higher order ones $\partial_x^2 m, \partial_x^3 m, \dots$. However since the spiral higher order derivatives $\partial_x^p m$ readily rewrite in terms of the magnetization and its first order derivative, we are able to represent the non local conduction electron spin density in terms of solely $m(r)$, $\partial_x m(r)$ and $m \times \partial_x m(r)$ and consequently to introduce an effective u_{eff} and an effective β_{eff} which naturally extend the usual spin transfer torque parameters u and β .

The Wigner distribution function is first solved by considering 1) scattering by quenched disorder and 2) the first Born approximation for the collision integral in the local frame. Term u is seen to depend only on the diagonal components of the distribution function in the local frame, corresponding to spin \uparrow and spin \downarrow channels. In contrast, term β depends only on the off-diagonal component of the distribution function and vanishes in the absence of spin flip processes, in agreement with recent theoretical works. Without a spin relaxation process it is seen that each conduction electron carries a finite contribution to β , however summation over all the conduction electrons make β vanish [2]. We show that these features still hold for dynamic spin flip scattering due to spin waves, which is in fact much more important than scattering by spin disorder at room temperature.

We show that scattering rates as well as scattering in depend strongly on the ratio $\eta = \lambda_L/\lambda$. As a result u and β are much modified when η varies from zero (adiabatic limit) to some small finite integers.

Current-induced domain wall motion in permalloy nanowires.

W. Zhang¹, P. Wong¹, Y. Xu¹, X. Zou², J. Wu²

1. Spintronics and Nanodevice Laboratory, Department of Electronics, University of York, York, United Kingdom; 2. Department of Physics, University of York, York, United Kingdom

It has attracted great interest recently to use polarised current induced magnetic switching in future spintronic devices such as random access memory (MRAM) and magnetic logic gates. In one of our previous studies[1], we have observed directly the magneto-resistance of domain wall from I-V measurements at zero external magnetic fields using current induced unpinning of a domain wall. In this report, we have further carried out a detailed study of the magnetic reversal and transport in the nanowires and found two different spin configurations at the nanocontacts.

Single-shot focused MOKE measurements with the laser spot close to the nanocontacts have been carried out to study the magnetic reversal in a longitudinal configuration with the magnetic field applied along the wire. As shown in Figure 1 by the MOKE loops from a $\text{Ni}_{80}\text{Fe}_{20}$ wire with a narrow contact of 200 nm, there are two different coercivities, one is around 63 Oe (Fig.1a) and the other one around 30 Oe (Fig.1b). This indicates that at zero applied magnetic field after reversal from saturation, there are two kinds of magnetization states near the nanocontact, one is parallel without a domain wall (Fig.1a), and the other one is anti-parallel with a domain wall at the nanocontact (Fig.1b).

I-V measurement was performed at zero applied magnetic field after reversal from saturation. It is found, as shown in Fig.2a, that the dc current induces a drop of the resistance, similar to our previous results[1] and the extra electrical resistance has been proved to be caused by a domain wall scattering in nanowires [2]. The current density at the nanocontact, required to change the resistance is of the order 10^7 A/cm^2 for the wire. This is related to the antiparallel configuration with a domain wall at the nanocontact as shown in Fig.1b.

In contrast with that in Fig.2a, there is a sharp increase of the resistance with the increasing current as shown in Fig.2b. This case is related to the parallel configuration as shown in Fig.1a. This further confirms that there are two kinds of magnetization configurations at zero magnetic field after reversal from the saturation also suggested from the MOKE Figure 1; one is with a domain wall at the nanocontact and the other without domain wall. In anti-parallel configuration in Fig.2a, the spin polarised current reversed the spin near the nanocontact from the right to the left and then pushed the domain wall away from the contact leading to a resistance drop, and in parallel configuration in Fig.2b, the injection of a domain wall into the nanocontact leading to an increase of the resistance and the formation of a domain wall at the contact.

Spin transfer switching in magnetic tunnel junction using a composite free layer.

W. Chen, D. Wang, C. Yen, Y. Lee, S. Yang, C. Shen, C. Tsai, C. Hung, K. Shen, M. Kao
Electronics and Optoelectronics Research Lab. (EOL), Industrial Technology Research Institute (ITRI), Hsinchu, Taiwan

Spin-transfer-driven magnetization switching has drawn considerable attention to potential applications of high density magnetic random access memory (MRAM). Such attention is aroused due to its simplified design and less cross talk [1]. Spin-transfer switching is performed through s-d interaction by injecting spin-polarized currents into magnetic cells. One of the most challenging targets of the spin torque switching architecture is to reduce the critical current of magnetization reversal and meanwhile keep the thermal stability at a reasonable level. In general, the reduction of the critical current requires that the magnetization of the free layer is lowered and the damping constant of it is reduced. In this report, spin transfer switching in the magnetic tunnel junction (MTJ) using the CoFeB/insert/NiFe composite free layer (CFL) is demonstrated to show a relatively low switching current density.

Two sets of MTJ structures are deposited on thermally oxidized Si substrates at room temperature using magnetron sputtering system. The first set of has a MTJ with a single free layer: Ta/PtMn/SAF pinned/AlOx/CoFeB (2 nm)/Ta capping layer. The second set has a CFL structure: Ta/PtMn/SAF pinned/AlOx/CFL/Ta capping layer, where CFL is CoFeB (x nm)/insert spacer (y nm)/NiFe (z nm). The insert spacers used in CFL are Ru, Ta and Cu, and the thickness (y) varies from 0.3 nm to 2.2 nm. After the film deposition, the samples are vacuum-annealed ex-situ in a field of 1 Tesla along the direction of the deposition field. The MTJs were fabricated by the e-beam writer and the reactive ion etching system. The MTJs are ellipses with a short axis of 150 nm and a long axis of 300 nm, and the resistance-area product (RA) ranges from 20 to 30 $\text{ohm-}\mu\text{m}^2$.

For the comparison with the MTJ using a single free layer, the critical current density (J_c0) is significantly reduced in MTJ using a composite free layer. J_c0 for optimum CoFeB/Ru/NiFe CFL and CoFeB/Ta/NiFe CFL is determined by extrapolation to be 7 MA/cm^2 and 2 MA/cm^2 respectively, as shown in figure 1. Thus MTJ with optimum CFL has a much lower critical current density (J_c0) than that using a single free layer. These results suggest that the precession of magnetic moment in the NiFe of CFL may assist the precession of magnetic moment in the CoFeB of CFL and make CFL switchable at a much lower current density. In a word, this kind of free layer structure has the potential to make low switching current density and high thermal stability coexist.

In a magnetic nanowire, a single domain wall (DW) can be generated in the interface separating two magnetic domains whose magnetization directions are opposite. The DW can be moved by applying current as a result of spin-transfer-torque effect. The dynamics of DW motion in magnetic nanowire opened the door to new practical applications such as novel magnetic shift register memory [1] and logic devices [2]. Many kinds of experimental and theoretical studies on the current-driven DW motion have been reported so far [3-5]. However, the current-driven dynamics of DWs is not well understood. We investigated the current-driven DW motion for L- and C- shaped Permalloy nanowires by magnetic force microscopy (MFM).

We selected L- and C-shaped nanowires of Py ($\text{Ni}_{81}\text{Fe}_{19}$), because these shapes are easy to generate a DW at the wanted place with external magnetic field. Two Py nanowires with different shapes were fabricated on a SiO_2/Si substrate by means of magnetron sputtering. The nanowires were patterned with standard electron-beam lithography and lift-off method. The samples are the 600-nm wide L-shaped and the 300-nm wide C-shaped nanowires with the same thickness of 20-nm, respectively. The width was determined with a scanning electron microscope (SEM) and the thickness was determined with an atomic force microscope (AFM). To visualize the current-induced DW motion, the MFM (SPI4000/SPA-300HV, SII NanoTechnology) was used. In order to minimize the influence of the stray field from the magnetic probe on the DW, a low-moment probe (SI-MF40L) coated with CoCr was used for MFM images.

In order to generate a DW at specific place, we employed the L- and C-shaped nanowires. A saturation magnetic field (200 Oe) was applied to -y(+y) direction for L-shaped (C-shaped) nanowire. After the whole nanowire formed a single domain, the external magnetic was reduced to zero. Due to the shape anisotropies of L- and C-shaped of the nanowires, the head-to-head DW is generated at the bending corner. For the given wire geometry, vortex DW is more stable than the transverse Néel wall. The detail head-to-head vortex DW is imaged as a dark contrast in Fig. 1 (a). After 500-ns duration pulse was applied to the L-shaped nanowire, we took MFM images as shown in Fig. 1 (b). It is clearly shown that the DW moved 1.2- μm as a result of the pulse-current-induced DW motion. From these experiments we found the critical current density (J_c) of L-shaped nanowire is $5.0 \times 10^{11} \text{ A/m}^2$, and the DW velocity (v) in L-shaped nanowire is 2.4 m/s. For the C-shaped nanowire, we performed the similar experiments to the L-shaped case. Successive MFM images were taken after each 1- μs pulse (Fig. 2 a-c) and (Fig. 2 d-f) for each polarity of the current. We found $J_c = 5.4 \times 10^{11} \text{ A/m}^2$ and $v = 2.0 \text{ m/s}$ for the C-shaped nanowire. It should be also noted that the J_c and v values are in agreement with those reported [5]. The J_c and v values are similar for both nanowires, while their curvatures and widths are quite different. The curvatures of the L- and C-shaped nanowires are 1.5- μm and 8- μm , respectively. We can conjecture the pinning potential from the curved geometry is weaker than one of the nanowire imperfections.

In conclusion, we designed L- and C-shaped nanowires in order to confine a DW at specific place. A head-to-head vortex DWs were placed at the bending corner at both geometries. Successive current-driven DW motions were imaged by MFM. We found similar critical current densities and DW velocities for the L- and C-shaped Py nanowires in spite of their different curvatures and wire

widths. We conjectured that the pinning effect of the curvature is smaller than one of the imperfections of nanowire.

1. Introduction

Intensive theoretical and experimental studies for a spin-transfer torque (STT) have been recently conducted in view of its application as well as fundamental of physics. Recently it had also presented that the thermally activated magnetization reversal with a STT should introduce a new effective temperature or effective energy barrier.[1][2] In this work, we obtained the thermal effect of STT in a nanowire structure with perpendicular magnetic anisotropy (PMA).

2. Experiments

A 500 nm width nanowire pattern was prepared on a thermally oxidized Si-wafer by E-beam lithography. In the nanowire pattern magnetic film of Ta(1 nm)/Co-Re-Pt(8 nm)/Ta(0.5 nm) structure with PMA was deposited using a DC magnetron sputter system, followed by removal of ER through lift-off process. On the top of the nanowire we deposited Ta(5 nm)/Au(100 nm) as electrodes as shown in Fig1. The magnetic properties was measured using a VSM for unpatterned films and MOKE for patterned nanowires. The thermally activated magnetization reversal process was measured by a nanosecond magneto-optical magnetization microscopy (NS-MOMM) system. By the NS-MOMM system, first we made an reversed domain on the nanowire by thermal assisted field writing and selected a strongly pinned position using magnetic field. Then we measured the depinning time for the domain propagation with varied current density in the presence of magnetic field.

3. Results and discussion

Magnetic property of continuous film of substrate/Ta(1 nm)/Co-Re-Pt(8 nm) showed M_s of 450 emu/cm³ and perpendicular anisotropy of 2.2×10^6 erg/cm³. As shown in Fig2, magnetic properties of the continuous film and nanowire did not change much although there is some change in loop shape due to rough nanowire edge effect. By using the very thin seedlayer structure, we tried to minimize the shunt current and maximize the STT effect on the nanowire. Reversal behavior of the nanowire showed mixed mode of reverse domain nucleation and domain wall motion although wall motion was slightly dominant.

Below the magnetization reversal field (coercive field; 580 Oe [Fig2(b)]) of the nanowire, we injected the 5 μ s current pulse from 2.0×10^7 A/cm² to 3.5×10^7 A/cm² for the thermally activated magnetization reversal. As shown in Fig3, the depinning occurs faster with increasing the current density. In addition, the increase of applied field H leads to the reduction of the slope of critical current density for depinning vs. depinning time. This result indicates that the measured depinning time, τ have the exponentially linear relation with current density, J, which means it follows Arrhenius' law as shown below.

$$\tau = \tau_0 \exp(E_b(H, J)/k_B T)$$

where τ_0^{-1} is an attempt frequency, E_b is the energy barrier as a function of J and applied field H, k_B is the Boltzmann constant, and T is temperature. This experimental results are consistent with the numerical analysis (the generalized Néel-Brown formula) of Z. Li and S. Zhang, which describes the effect of the spin torque by the modification of the energy barrier.[1]

4. Summary

We made a nanowire adequate for measuring the STT effect by using just 1 nm seedlayer structure films with PMA. In this nanowire the thermally activated magnetization reversal was investigated by injecting current for the thermal effect of the STT. The exponentially linear relations between τ and current density at a constant applied field are obtained and this is in accordance with the generalized Néel-Brown formula.

In 1996, Slonczewski [1] and Berger predicted that the current flowing through magnetic multilayer could induce magnetization switching. Recently the spin-transfer torque effect has been considered the next generation technology of magnetic random access memory. However, the shape dependence of the magnetization dynamics has been rarely discussed precisely while operating the magnetic tunnel junction (MTJ) cells. To estimate the spin-transfer dynamics with shape dependence, the spin transfer torque term predicted by Slonczewski is introduced into the Landau-Lifshitz-Gilbert equation thus it can be written as shown in Eq.(1). We assume the unit vector \mathbf{m} and \mathbf{x} are denoted along the magnetic momentum of pinned layer and free layer respectively and the current flows perpendicularly to the plane of the MTJ cell. The effective anisotropy field \mathbf{H}_{ani} includes the intrinsic anisotropy field \mathbf{H}_{in} and shape anisotropy field \mathbf{H}_{d} . \mathbf{H}_{app} is the applied field, P is the spin polarization coefficient and J is the current density. In our case, the shape anisotropy field is fully introduced in the LLG equation to get the whole picture about the shape dependence of switching properties (Eq. (2)) Where N_x , N_y , and N_z are demagnetization factor along x , y , z directions and the easy axis of the MTJ cell is assumed in the x direction.

The analytical approach based on the equations similar to Eq.(1) has been already demonstrated by some studies. However, our presented calculation is more general and holds for different shapes of MTJ cells. The shape-dependent switching behaviors caused by instability condition of magnetic momentum leads to the critical current density as shown in Eq.(3). Moreover, it is important to be noted that the shape anisotropy term is accompanied with a correction factor $(1-3N_x)$ instead of the pure out-of-plane anisotropy $2\pi M_s$ along the z axis. Thus the shape dependence of the magnetization switching can be explicitly described by the correction term. Fig.1 shows the calculated results of the critical current density while increasing the aspect ratio of the MTJ cells.

Besides, the shape anisotropy makes a significant contribution to the energy barrier of the MTJ cells. Fig.2 shows the increment ratio compared with the critical current density and the energy barrier. When the aspect ratio is up to 2.0, it should be noted that the energy barrier is greatly enhanced up to 240% while the increment of critical current density is just 4%. Therefore, it implies us the higher aspect ratio MTJ cell provides higher thermal stability but nearly the same critical current density.

A series of samples by using identical MTJ structure but different aspect ratio (1.2, 1.8, 2.1 respectively) have been demonstrated in Fig.3. It shows the experimental results of the switching phase diagram with the critical current density operated at different pulse width. The inverse of the slope stands for the thermal stability of the MTJ cells. It can be observed that the MTJ cells with larger aspect ratio provides higher thermal stability but almost the same current density. Thus, the experimental results show the great consistency with theoretical prediction that a well-designed aspect ratio MTJ cell would provide high thermal stability and proper critical current density.

I. Introduction

The current-induced domain wall motion (CIDWM) has attracted a considerable interest because of its fundamental physics and potential application for new spintronic devices [1, 2]. The adiabatic and non-adiabatic spin torque terms have been proposed to describe CIDWM. Despite lots of studies, there is a controversy over the so-called β term measuring the relative magnitude of the non-adiabatic torque with respect to the adiabatic one [3]. From the viewpoint of application, equispaced mechanical notches can be used to control the position of DW in a nanostrip. Therefore, it is important to investigate the depinning current density (J_C) of DW from a notch. In this work, we investigate J_C and its dependence on β by means of micromagnetic modeling. Two kinds of J_C 's are studied. The *static* J_C ($=J_{St}$) is a threshold to depin a DW initially placed within a notch. The *dynamic* J_C ($=J_{Dy}$) corresponds to the case that a DW is initially placed outside a notch. The J_{Dy} is determined by how large current density can let the DW pass through the notch. Note that the velocity of DW (v_{DW}) reflects the momentum of DW and is closely related to the tilting angle of DW. In the *static* case, the initial v_{DW}^0 is determined by the adiabatic spin torque. In the *dynamics* case, however, the v_{DW} at the position of notch is smaller or larger than v_{DW}^0 depending on β since the tilting angle of DW is significantly affected by β . In this work, we show that by comparing the J_{St} and J_{Dy} , it is possible to get a clue for resolving the controversy over the β term.

II. Micromagnetic Simulation

We use the modified Landau-Lifshitz-Gilbert equation with including the spin torque terms;

$$\partial \mathbf{M} / \partial t = -\gamma (\mathbf{M} \times \mathbf{H}_{\text{eff}}) + \alpha / M_s (\mathbf{M} \times \partial \mathbf{M} / \partial t) - b_j / M_s^2 (\mathbf{M} \times (\mathbf{M} \times \nabla M)) - c_j / M_s (\mathbf{M} \times \nabla M)$$

where \mathbf{H}_{eff} is the effective field consisting of the anisotropy, exchange, magnetostatic, and current-induced Oersted fields. The model parameter is selected for the Permalloy. The b_j ($= P j_e \mu_B / e M_s$) and c_j ($= \beta b_j$) present the magnitude of the adiabatic and non-adiabatic spin torque, respectively. Inhomogeneous current distribution due to a notch is calculated by solving the Laplace's equation. The model system is shown in Fig. 1(a). The dimension of nanostrip is $1000 \times 75 \times 10$ (length (l) \times width (w) \times thickness (t)) nm^3 divided into $2.5 \times 2.5 \times 10$ nm^3 cells. The shape of a notch is a triangle. The width of nanostrip at the center of notch is 50 nm. In case of the J_{Dy} , the distance between initial DW position and notch is assumed as 250 nm. Two types of DWs, clockwise transverse wall (CW-TW) and anti-clockwise TW (ACW-TW) are considered.

III. Results and Discussions

Fig. 1. (b) and (c) show J_C as a function of the non-adiabatic contribution (β/α) for ACW-TW and CW-TW, respectively. In both types of DWs, J_C decreases with increasing β/α . When $\beta < \alpha$, J_{Dy} is slightly larger than J_{St} . In this case, v_{DW} is smaller than v_{DW}^0 because the tilting angle of DW measured from the nanostrip plane is negative. When $\beta = \alpha$, the J_{Dy} and J_{St} are identical since the tilting angle is zero. When $\beta > \alpha$, the DW gains an additional kinetic energy due to a positive tilting in the *dynamic* case and therefore the J_{Dy} is smaller than the J_{St} .

Reminding the present debate over the magnitude of β term, our result indicates that it is possible to determine the non-adiabatic contribution, at least if $\beta > \alpha$, $\beta = \alpha$ or $\beta < \alpha$, by comparing J_{Dy} and J_{St} . When $\beta > 2\alpha$ (4α), J_{St} of ACW-TW (CW-TW) is larger than J_{Dy} by factor of 1.5 (Inset of Fig. 1 (b) and (c)). In this range of β , thus, it is difficult to stop a DW at the next notch, which can be a seri-

ous problem for the application of CIDWM in the mass storage device. Moreover, J_{St} of ACW-TW are different for different sign of current. The $(+)$ J_{St} is larger (smaller) than the $(-)$ J_{St} with $\beta > \alpha$ ($\beta < \alpha$). This asymmetric behavior is caused by the different shape of potential well at the notch. As shown in Fig. 1(d), the CW-TW experiences a single energy minimum at the center of notch whereas the ACW-TW does double minima. In our system, when the sign of current is minus, the ACW-TW experiences the minor energy barrier located at the center of notch. Thus, *static* depinning process with $(-)$ J is similar to the *dynamic* one.

IV. Conclusion

The J_C depends on the chirality and the initial position of DW, i.e. *static* and *dynamic* depinning. By comparing J_{Dy} and J_{St} , it is possible to get a clue about the non-adiabatic contribution.

Current-assisted variation of magnetization reversal process in tri-layer-ring spin valve.

D. Chen¹, C. Yu², Y. Yao^{1,3}

1. Department of Material Science and Engineering, National Chiao Tung University, Hsinchu, Taiwan; 2. Institute of Physics, Academia Sinica, Taipei, Taiwan; 3. The Department of Materials Engineering, Tatung University, Taipei, Taiwan

A tri-layer spin valve in ring shape has been fabricated by e-beam lithography and lift-off technique. The structure is Py(20nm)/Cu(10nm)/Py(10nm) from bottom to up with 1.2 μm in outer diameter, and 0.4 μm in width. Copper electric contacts are used to connect the spin valve device and pad leads. Magnetoresistance (MR) curves were obtained by current-in-plan (CIP) and two-terminal measurements (Fig.1) at room temperature. Single layers of Py ring (20nm and 10nm in thickness) were also fabricated and measured to compare with the tri-layer structure. The result of OOMMF simulation for 10nm single layer of Py ring shows no vortex state in the magnetization reversal process, that is, only one-step switch (onion to reverse onion) exists in reversal process. For 20nm Py ring, however, two-step switch (onion-to-vortex and vortex-to-reverse-onion) was observed. The experimentally obtained MR curves (Fig.2 & 3) for both single Py ring layers confirm the same results with simulation. The MR signal of tri-layer spin valve for 10 μA current (Fig.4) shows an obvious spin valve signal combined with anisotropic magnetoresistance (AMR) effect. With field relaxed and increasing toward negative direction till around -45 Oe (configuration 1), the 10nm Py ring switches to reverse onion state, whereas the 20 nm one remain onion state. This causes MR at the highest state due to AMR effect and antiparallel configuration between the two Py ring layers. At configuration 2, the 20nm Py ring is in the vortex state with the 10nm one remaining at reverse onion state. Therefore, about half of the moments are in the parallel state, hence the MR is lower than that in configuration 1. After field exceed -185 Oe (configuration 3), both Py layers are in reverse onion state. The MR is in the lowest level not only due to the parallel configuration but also AMR effect. The current dependent MR behavior has been observed by increasing the measuring current to 1 mA. With current magnitude higher than 700 μA , the obvious change in MR curves was observed. Fig.5 shows MR curve at 1 mA. The main difference from that at 10 μA (Fig. 3) is in the configuration 2, that is roughly -45 ~ -70 Oe. In this region (for 1mA current), the MR abruptly decrease and increase back to the level in configuration 3. Joule heat generated by current could be more proper to account for this phenomenon. The current density estimated (about $3 \times 10^{-6} \text{ A/cm}^2$) here is far lower than the order of spin transfer torque (STT). Hence, for 20 nm Py ring layer, thermal activation induced by joule heating could cause multi-domain magnetization during the transition from onion state to vortex state. This causes most of moments not in well order arrangement, thus decrease the antiparallel effect between the two Py ring layers.

The recent developments in current induced magnetization switching in nanopillars structures have onset a renewal in the field of current induced domain wall motion. The first theoretical ideas on the mechanism of spin-transfer torque from the conduction electron to the inhomogeneous magnetization configuration of a domain wall date to L. Berger [1]. But it is only recently that the improvement of the fabrication techniques and specially the design of adequate pinning sites have permitted to make significant progress from the experimental point of view [2-5].

To detect electrically the motion of a domain wall there are basically two strategies. The first one is to rely on the anisotropic magnetoresistance (AMR). This is the main technique used when the nanowires are composed of a single ferromagnetic material (very often NiFe). The other possibility is to use the giant magnetoresistance effect (GMR). Here the nanostripe is a GMR stack with a pinned and a free layer. In this case, the measured resistance is proportional to the domain wall position. We have fabricated stripes with various geometries with Co/Cu/NiFe structure; the domain wall is nucleated in the NiFe layer.

In the present study, we have used two different geometries: regular wires and a more complex “diode” geometry (see Fig. 1). Magnetic force microscopy (MFM) imaging has been used to verify that the domain wall is indeed pinned in the trap as shown on Fig 1.

By setting the right experimental conditions (field and dc current), we have observed two level resistance fluctuations. The statistical analysis of the dwell times has allowed us to estimate the energy depth of the pinning trap. This energy is highly dependent on the position in the (field, current) parameter space. The fact that we observed the two level fluctuations means only that the dynamic of the domain wall fluctuation occurs in the right time window (10-4 Hz to 100 Hz) to allow use of DC measurements techniques. It is therefore probable that outside this window the fluctuation are still there. This conclusion is supported by the dV/dI measurements at few kHz [6]: peaks are observed on the current dependence of the differential resistance.

In nanopillar geometry, the discovery of universal resistance fluctuations has paved the way to the microwave coherent emission. Having this in mind we have studied the microwave frequency response of a domain wall. We chose to make measurements where we inject ac power into the sample and we detect the dc voltage, this is the so called “spin torque diode effect”[7]. We have successfully observed the rectification effect (Fig. 2), with characteristic frequencies lying from 1.5 to 3.5 GHz. Furthermore they are tunable with modification of the external applied magnetic field. Those experiments are a first step toward understanding the magnetic domain wall behaviour in the microwave frequency range.

Current induced domain wall motion with step structure.

Fujitsu Limited., Atsugi, 243-0197, Japan

1. Introduction

Since the current induced magnetic domain wall motion (CIDWM) was theoretically predicted,^[1-3] the spintronics devices using CIDWM have been extensively studied. Domain wall (DW)-based shift register memory proposed by Parkin^[4] is expected to be the high integration memory (>1Gbit), because the data of the numerous bits can be stored in a narrow wire. The basic CIDWM phenomena can occur in a submicron-size ferromagnetic wire, and DW motion has been confirmed with the current density of $10^{11} - 10^{12} \text{ A/m}^2$. On the other hand, the stable control of the DW motion is important for the memory application. DW pinning by two-dimensional shapes such as the neck, and the zigzag structures has been reported to trap the DW.^[5-8] In this paper, we report on the pinning effect in three-dimensional step structure in order to achieve DW displacement control.

2. Experiment

The sequence of fabrication is shown in Fig.1. The steps (depth: $D_s = 20 - 60 \text{ nm}$) were fabricated on a silicon substrate by RIE (Reactive Ion Etching). After NiFe (40 nm) deposition, the wire was patterned with the width of 400 – 500 nm using the conventional lithography and the ion milling. Finally, the electrode pads were made by the lift-off technique. Fig.3 shows an AFM image of the sample. We evaluated the depinning magnetic field (H_{dpin}). Further more, the critical current density (J_{th}) of CIDWM was investigated from the displacement of the DW measured using MFM without an external assist magnetic field.

3. Results and Discussion

The DW was introduced by the external magnetic field and was easily trapped at the step edge. The H_{dpin} as a function of D_s is shown in Fig.2. H_{dpin} increases with increasing D_s . Therefore, DW pinning is able to be controlled by D_s . Fig.4 shows a result of CIDWM phenomena. Fig.4(a) is the AFM image, and Fig.4(b) is the MFM image before applying current pulses. In Fig.4(c) - (e), the DW was moved and trapped by the step edges by applying the pulse of $|J_{\text{th}}| \approx 3.0 \times 10^{11} \text{ A/m}^2$ (Pulse = 0.5 μs). It is probably because that the pinning potential of the step edges is larger than that of the straight line part.

Togawa *et al.* suggested that the Joule heating assists the DW motion because the DW motion occurred when the wire resistance was increased to more than 1.5 times of the initial value.^[7] In our experiment, there was a similar resistance increase. Therefore, we consider that the DW displacement of this result was induced by the spin torque effect and the Joule heating assist. To conclude, we investigated the CIDWM in the step structure. It was found that the step edge can block the DW motion and trap the DW effectively. Our experiments demonstrate the feasibility of controllable displacement of the DW in a magnetic wire using the step structure.

Magnetocaloric Effect in Ni-Mn-Ga Alloys.

K. Mandal¹, D. Pal¹, O. Gutfleisch², J. Lyubina², N. Scheerbaum²

During last few years, magnetic refrigeration has attracted significant attention as it is found to be more energy efficient and environment friendly compared to the conventional gas refrigeration [1, 2]. Recently, large MCE in non-rare-earth based Ni-Mn-Ga Heusler alloys, well known for their magnetic shape-memory effect, has also been reported [3].

Both stoichiometric and off-stoichiometric compounds with composition close to Ni_2MnGa show a cubic L2_1 austenite phase at higher temperature. Upon cooling the alloy, it undergoes a martensitic transformation to martensite phase. On changing the temperature a first-order structural transition takes place between these two phases at martensitic transition temperature causing an abrupt change of magnetization. It was found that martensitic transformation and Curie temperature are strongly influenced by the alloy compositions and a large change in entropy and hence MCE was observed when the structural transition coincides with the magnetic transition at Curie temperature. In the present work, $\text{Ni}_{2+x}\text{Mn}_{1-x}\text{Ga}$ ($x=0.16, 0.18, 0.20, 0.22, 0.24, 0.26$) alloys were prepared and studied to understand the effect of substituting Mn with Ni on the structural and magnetic transition.

The thermal behaviour of six samples studied by DSC measurements has been plotted in Fig.1. Martensite-austenite transformation temperatures increase significantly when the nickel content is increased from $x=0.16$ to 0.26 . Figure 2 shows the XRD pattern at room temperature of (a) $\text{Ni}_{2.18}\text{Mn}_{0.82}\text{Ga}$ and (b) $\text{Ni}_{2.26}\text{Mn}_{0.74}\text{Ga}$ samples with martensitic transition temperatures respectively below and above room temperature. The first sample shows a cubic L2_1 structures at room temperature whereas the second one shows non-modulated (NM) martensite phase at room temperature.

Magnetic properties of the samples have been studied in details. MCE has been determined for all the samples around their T_c and T_m by calculating the change in magnetic entropy due to a magnetic field change of 0-5 T using the Maxwell's thermodynamic relations. Among the above samples, $\text{Ni}_{2.22}\text{Mn}_{0.78}\text{Ga}$ composition in which T_c and T_m are very close to each other shows maximum change in $|\Delta S|$. Large change in magnetization with temperature along with significant hysteresis effect is observed within 290 K and 292 K. To study this part more carefully, M vs H data were taken within 287 K and 292 K at 0.5 K intervals. Maximum values of $|\Delta S|$ are found to be 28 J/Kg.K at 289.5 K with $\Delta T=3$ K and 96 J/Kg.K at 290.75 K with $\Delta T=0.5$ K as shown in Fig.3. The effect of hydrostatic pressure on magnetic and MCE properties has also been studied. A pressure of 8 kbar shifts the martensitic transition temperatures as well as the T_c of the samples towards higher temperature. The $|\Delta S|$ in presence of 8 kbar pressure is approximately 28.5 J/Kg.K at 297.5 K with $\Delta T=3$ K and 86 J/Kg.K at 297.0 K with $\Delta T=0.5$ K as shown in Fig.3 also. The large magnetic hysteresis observed in the M vs H curves at ambient pressure almost vanishes due to the application of 8 kbar pressure.

Magnetic properties and magnetocaloric effect in $\text{Tb}_8\text{Co}_{16-x}\text{A}_x$ compounds where A=Al or Cu and $x \leq 4$.

R. Tetean, E. Burzo, I. G. Deac

Physics, Babes-Bolyai University, Cluj Napoca, Romania

Magnetic materials showing a large magnetocaloric effect (MCE) have attracted considerable attention for their potential application in magnetic refrigeration technology. The RCO_2 intermetallic compounds (R= rare earth metal) were intensively studied due to the metamagnetic transition of cobalt. When R is nonmagnetic there are necessary high fields (> 70 T in YCo_2) in order to induce magnetic moments on cobalt atoms. If R is magnetic, the internal field is high enough to polarize the cobalt sublattice. Due to the high value of the R magnetic moment large entropy changes at the transition temperature were reported [1,2].

The $\text{Tb}_8\text{Co}_{16-x}\text{A}_x$ where A=Al or Cu and $x \leq 4$ compounds were prepared by arc melting the constituent elements in a purified argon atmosphere. The samples were heat treated in vacuum, at 1000°C , for 5 days. The X-ray analysis shows the presence of one phase only, for $x \leq 4$, of C15 type.

The magnetic measurements were performed in the temperature range 4.2-900 K and external fields up to 9T. The entropy changes were determined from magnetization isotherms. The saturation magnetizations, at 4.2 K, increase as cobalt is replaced by Cu or Al. The above behavior is in agreement with the presence of a ferrimagnetic type ordering, the cobalt and terbium magnetic moments being antiparallelly oriented. The cobalt moments are little dependent on A content having values in the range $1.15 \mu_B/\text{atom}$. The above value is in agreement with that obtained from band structure calculations. As example in TbCo_2 a value of $M_{\text{Co}}=1.12 \mu_B$ was obtained. The exchange interactions between Tb and Co are of 4f-5d-3d type. The Tb 5d band polarizations are parallelly oriented to 4f moments and decrease starting from $0.47 \mu_B$ ($x=0$) when increasing the content of non-magnetic elements. The Curie temperatures increase slowly and then decrease when A content increase.

The temperature dependences of reciprocal susceptibilities follow a hyperbolic law of Néel- type, characteristic for ferrimagnetic ordering. According to addition law of susceptibilities and supposing that the Curie constant of terbium is the same as that of Tb^{3+} ion, we have determined the contributions of Co, to the Curie constants and the effective cobalt moments, $M_{\text{eff}}(\text{Co})$, respectively. The $M_{\text{eff}}(\text{Co})$ values are only slightly composition dependent being $2.81 \pm 0.09 \mu_B/\text{atom}$. The ratio $r=S_p/S_0$ between the number of spins obtained from effective iron moments, S_p , and saturation moments, S_0 , is quite constant having values around 1.73 for A=Al and 1.76 for A=Cu. In the local moment limit we have $r=1.0$. The r values suggest that cobalt have rather high degree of itinerancy.

The above behaviour can be analyzed in the spin fluctuation model. When the amplitude of local spin fluctuations (LSF) is large and fixed, there is a local moment limit, where only the transverse components of LSF are important. As the amplitude of LSF is small, there is the weakly ferromagnet limit, where the longitudinal components of LSF or temperature variation of amplitude of LSF play an important role. From the r values in $\text{Tb}_8\text{Co}_{16-x}\text{A}_x$ system we conclude that there are significant contributions from longitudinal components of LSF which increase when A content is greater, although the transverse components dominate.

The temperature dependence of magnetic entropy change in 7T and 9T external applied fields for the compounds with $x = 1, 2, 3$ and A=Al are plotted in Fig.1. The entropy change values show maxima around the Curie temperatures and are rather high for compounds showing a second order phase transition. As example in $\text{TbCo}_{13}\text{Cu}_3$ a value of 7.3 J/kgK was determined while in case of

$\text{TbCo}_{13}\text{Al}_3$ the value was 6.7 J/kgK . Around 63 % of the heat is absorbed in a temperature range $\pm 12 \text{ K}$, centered at the Curie point.

The origin of the large magnetic entropy change in these compounds could be attributed to the considerable variation of the magnetization near the transition temperature.

In the hydrogen society coming in near-future, it must be important to transport and storage hydrogen with the high energy density as possible. The highest hydrogen densities with respect both to mass and volume are given by the liquid hydrogen. To liquefy hydrogen, we have to cool it down to 20K. In general, the efficiency of the conventional cooling system working with a gaseous refrigerant decreases with temperature, so that much energy is required to liquefy hydrogen. On the other hand, the magnetic cooling method may provide a higher efficiency even at these low temperatures because it is based on the magnetocaloric effect which associates intrinsically small irreversibility. From a ferromagnet, a magnetic entropy change ΔS is extracted by swinging external applied field, and it is maximized in the vicinity of its Curie temperature. Thus obtained ΔS is converted directly into heat, $Q=T\Delta S$. Its application to the hydrogen liquefaction system was indeed proposed [1]. To realize the magnetic cooling and liquefaction of hydrogen, it is necessary to find the suitable magnetic refrigerant material. We have pointed out mononitrides of rare earth elements, Gd, Tb, Dy, Ho, Er, are promising candidate materials because of its remarkable characteristics; (1) their packing densities of rare earth atoms are significantly higher than those of metallic phases of the hcp structure, (2) they are ferromagnetism and their Curie's temperatures lie in a region, 6 to 70 K. In these nitrides, magnetic moments undergoing the ferro-paramagnetic transition at relevant temperatures are closed packed.

We synthesized binary rare earth nitrides ($\text{Gd}_{0.5}\text{Tb}_{0.5}\text{N}$, $\text{Tb}_{0.5}\text{Dy}_{0.5}\text{N}$ and $\text{Dy}_{0.5}\text{Ho}_{0.5}\text{N}$) by two methods, carbothermic reduction (CTR) and hot isostatic pressing (HIP). To examine the phase occurring in the product, their XRD patterns were measured. To evaluate the MCE i.e. ΔS , we took two routes; one is measurements of specific heats as functions of temperature, $T=3\text{--}80\text{ K}$, under magnetic field, $H=5\text{ T}$ or zero field, $C_H(T)$ and $C_0(T)$. The $\Delta S(T)$ induced by isothermal demagnetization from H to 0 is given by equations $\Delta S(T)=S_0(T)-S_H(T)=\int_0^T C_0(T)/TdT - \int_0^T C_H(T)/TdT$, where S_H and S_0 are absolute entropies under magnetic field H and zero field, respectively. In executing these integrals, the specific heat below 3 K was assumed to obey the Debye's theory, proportionating to T^3 . The samples obtained by the CTR were too brittle and porous to measure the specific heat. Another route is measurements of magnetization as function of temperature and applied field, $M(T, H)$, $T=3\text{--}100\text{ K}$, $H=0\text{--}5\text{ T}$. From the data sets, $\Delta S(T)=\int_H^0 (\partial M/\partial T)_H dH$. Note that the latter equation is driven by using the Maxwell's relation, $(\partial M/\partial T)_H=(\partial S/\partial H)_T$.

The lattice parameters determined by the XRD patterns of the samples prepared by the two methods are plotted in Fig. 1 against average radius of trivalent ions of the constituent elements together with previously reported data [2-4]. They fall onto a straight line, indicating that they belong to a class of material. Fig. 2 shows $S(T)$ curves calculated from $C_H(T)$ and $C_0(T)$ measured at 5T and 0T of $\text{Dy}_{0.5}\text{Ho}_{0.5}\text{N}$ synthesized by the HIP method, and ΔS and ΔT calculated from these curves, where ΔT is the adiabatic temperature change. The same data processing procedures were done for other samples synthesized by the HIP method. Their $S(T)$ curves have peaks at temperatures varying in a range of 6K-70K continuously depending on the constituent elements and the composition. The obtained $\Delta S(T)$ curves reasonably agreed with each other regardless of synthesis methods, HIP or CTR, and of evaluation method, magnetization or specific heat. Fig. 2 indicates that magnetic refrigerants of $\text{Dy}_{0.5}\text{Ho}_{0.5}\text{N}$ would adiabatically cool itself down by five degree at least from a tem-

perature in a region of 20-40 K. We are going to show results indicating that the rare earth nitrides are promising magnetic refrigerant materials for hydrogen liquefying system working below liquid nitrogen temperature.

The first studies of the magnetocaloric effect (MCE) anisotropy were carried out rather long ago [1]; however, until recently, they were quite scarce [2-3]. The MCE anisotropy can be measured directly as the adiabatic temperature change ΔT or indirectly from magnetization and heat capacity [4]. The majority of studies use indirect measurements to measure the MCE. Also, the studies in this field mostly use polycrystalline samples. The present study shows the advantages of direct measurements of the MCE anisotropy in R₂Fe₁₇ single crystals and discusses some problems arising when polycrystalline samples are used. This study shows that the direct measurement of $\Delta T(H)$ in single crystals along different crystallographic directions makes it possible to get accurate data on MCE anisotropy. These data are important for developing new types of magnetic refrigerators. Fig.1 shows the temperature dependencies of MCE in Y₂Fe₁₇ single crystals (Fig.1a), Dy₂Fe₁₇ single crystals (Fig.1b), Er₂Fe₁₇ single crystals (Fig.1c), and Ho₂Fe₁₇ single crystals (Fig.1d), measured along the c-axis (a hard magnetization direction (circle)) and the a-axis (an easy magnetization direction (triangle)) for this group of compounds.

As we can see from this figure, for the Y₂Fe₁₇ compound, the temperature dependencies of MCE measured along different crystallographic directions differ near Curie temperature by 10%. This is caused by the fact that magnetic anisotropy of the compound in the Curie temperature region has a nonzero value. Consequently, when the MCE is measured on polycrystalline samples, the ΔT value is lower due to the random grain orientation.

For the compounds with magnetic RE metals, such as Dy, Ho, or Er, the difference in MCE values observed during the magnetization of a magnetic material along different crystallographic axes can reach 40-50% (Fig.1b-1d), which is considerably lower than the experimentally measured ΔT values on polycrystalline samples. In addition, as Fig. 1c-1d shows, the MCE measured along different crystallographic directions in the Curie temperature region has a different sign, which makes it impossible to determine the accurate values of this effect in polycrystalline samples. It should be noted that the MCE values for the compounds with Dy, Ho, and Er are almost the same as the values for the compounds with nonmagnetic Y. This is explained by the fact that, for this group of compounds, the main contribution to the MCE is made by the Fe sublattice.

Fig.1. Temperature dependencies of MCE, measured along a- and c-axes in R₂Fe₁₇ single crystals.

Magnetocaloric effect in $\text{Gd}_4(\text{Bi}_x\text{Sb}_{1-x})_3$ alloys.

N. A. de Oliveira, M. B. Gomes

Instituto de Física, Universidade do Estado do Rio de Janeiro, Rio de Janeiro, Brazil

The magnetocaloric effect, which is basically the temperature change of a magnetic material upon magnetic field variation, was first discovered by Warburg[1] in the later years of the 19th century. The early application of this effect was made to reduce the temperature of magnetic salts to very low values[2]. However, the most important application of the magnetocaloric effect happened in 1976 when Brown[3] developed a prototype of a magnetic refrigerator using gadolinium as magnetic refrigerant. Since the Brown's work, many efforts have been done in order to bring magnetic refrigeration to our daily life. In 1997 Pecharsky and Gschneidner[4] reported on large values of the magnetocaloric potential ΔS in the compound $\text{Gd}_5\text{Si}_2\text{Ge}_2$. After this discovery, a great deal of experimental and theoretical works has been developed in order to find new magnetic materials suitable for application in magnetic refrigeration. In order to be used as magnetic refrigerant in magnetic refrigerators, the magnetic material should exhibit large values of the magnetocaloric potentials ΔS and ΔT_{ad} in the temperature range of the operation of the refrigerator. Applied pressure and doping with suitable impurities are important physical mechanisms to enhance the magnitude of the magnetocaloric potentials and trigger their position to desirable temperature range. For instance, it has been shown that the magnetocaloric potentials in the compound $\text{Gd}_5\text{Si}_2\text{Ge}_2$ extremely depends on the Ge concentration. Besides, it has also been shown that when transition elements such as Fe and Ni are introduced in the compound $\text{Gd}_5\text{Si}_2\text{Ge}_2$ the magnetic ordering temperature is shifted towards room temperature and the magnetocaloric potential ΔS is somewhat reduced. Despite of much experimental works in this line of research, there are only a few theoretical papers dealing with the effects of applied pressure and doping on the magnetocaloric properties of metallic compounds. A complete discussion about this subject is very important not only to understand the physical mechanisms behind the magnetocaloric effect but also to help in the search of new magnetic materials suitable for application in magnetic refrigeration.

In this work, we theoretically discuss the magnetocaloric effect in the doped compound $\text{Gd}_4(\text{Bi}_x\text{Sb}_{1-x})_3$. It should be noted that in this doped compound the impurities enters substitutionally in the sites occupied by non rare earth ions. Although Bi and Sb are non magnetic ions, they play an important role in the magnetic properties of the doped compound $\text{Gd}_4(\text{Bi}_x\text{Sb}_{1-x})_3$. That is because, the exchange interaction between Gd ions in this doped compound depends on the impurity concentration. In order to describe the magnetocaloric effect in this doped compound, we use a model Hamiltonian of interacting 4f-spins with an interaction with the applied magnetic field. Since there is no evidence of first order phase transition in this compound, the magnetoelastic interaction can be neglected. The crystalline electrical field is not important either, because Gd ions has no orbital angular momentum. The chemical disorder in the electron gas in the compound $\text{Gd}_4(\text{Bi}_x\text{Sb}_{1-x})_3$, which modifies the conduction electron energy band and consequently affect the indirect 4f-4f spin interaction, is treated in the non-diagonal Coherent Potential Approximation (CPA). The 4f-4f spin interaction is treated in the conventional mean field theory. The total entropy is considered as the sum of the contribution from the magnetic ions, the conduction electrons and the crystalline lattice. The magnetic part of the entropy is obtained after the self-consistently solution of the magnetic state equation. The crystalline lattice entropy is taken into account in the Debye approximation. The contribution from the conduction electrons to the total entropy is taken as γT where γ is the Sommerfeld coefficient.

For a fixed set of model parameters, we calculate the magnetic, the thermodynamic and the magnetocaloric properties in the doped compound $\text{Gd}_4(\text{Bi}_x\text{Sb}_{1-x})_3$ as a function of Bi concentration. Our theoretical calculations show that as the Bi concentration is increased, the conduction electron bandwidth and the exchange interaction parameter increase. As a result the Curie temperature in the doped compound $\text{Gd}_4(\text{Bi}_x\text{Sb}_{1-x})_3$ increases with increasing Bi concentration. As far as the magnetocaloric is concerned, our calculations show that the magnitude of the magnetocaloric potential ΔS smoothly decreases and the magnetocaloric potential ΔT_{ad} remain almost the same as the Bi concentration increases. These conclusions are in good agreement with the available experimental data[5]. We also calculate the effect an applied pressure on the magnetocaloric properties of this doped compound. In this case experimental data are necessary to compare with our theoretical calculations. The present model can be straightforwardly extended to systematically calculate the effect of applied pressures and impurities on the magnetocaloric properties of many rare earth based compounds.

Magnetocaloric effect in $\text{La}(\text{Fe}_x\text{Si}_{1-x})_{13}$ under applied pressure.

N. A. de Oliveira¹, L. G. de Medeiros Jr¹, A. Troper^{1,2}

1. Instituto de Física, Universidade do Estado do Rio de Janeiro, Rio de Janeiro, Brazil; 2. Centro Brasileiro de Pesquisas Físicas, Rio de Janeiro, Brazil

The magnetocaloric effect[1] has been intensively studied in the literature in the last years. Since the discovery of the giant magnetocaloric effect in $\text{Gd}_5\text{Si}_2\text{Ge}_2$ experimentalists and theoreticians have been searching for new magnetic materials with large values of the magnetocaloric potentials ΔS and ΔT_{ad} . Experimental data [2] show that the isothermal entropy changes ΔS in the compounds $\text{La}(\text{Fe}_x\text{Si}_{1-x})_{13}$ ($x=0.88, 0.89$ and 0.90) exhibit large values around the phase transition which is of first order. Moreover, experimental data [2] also show that the peaks of the isothermal entropy changes in this series of compounds doped with hydrogen are pushed towards higher temperatures. However, the magnitudes of the magnetocaloric potential ΔS are almost the same. On the other hand, it has been experimentally [3] shown that an applied pressure as large as 8 kbar changes significantly the magnetic ordering temperature in the doped compound $\text{La}(\text{Fe}_{0.89}\text{Si}_{0.11})_{13}$ and yields large values of the magnetocaloric potential ΔS . These experimental evidences indicate that the series of compounds $\text{La}(\text{Fe}_x\text{Si}_{1-x})_{13}$ has an enormous potential to be used as magnetic refrigerants in magnetic refrigerators in a wide range of temperatures. The theoretical description of the magnetocaloric effect in the compounds $\text{La}(\text{Fe}_x\text{Si}_{1-x})_{13}$ is very important not only to explain the available experimental data, but also to understand the underlying physics behind the magnetocaloric effect in these compounds.

In order to calculate the magnetocaloric effect in the compounds $\text{La}(\text{Fe}_x\text{Si}_{1-x})_{13}$, we use a microscopical model in the framework of the band theory of magnetism. We use a Hubbard like model Hamiltonian and treat the electron-electron interaction in the mean field approximation. The effect of an external pressure was taken into account through the renormalization of the electron dispersion relation. The magnetoelastic coupling interaction, which governs the nature of the phase transition, was also phenomenologically included in the model through the renormalization of the 3d-electron band width. The crystalline lattice entropy was considered in the Debye approximation. We apply the model to calculate the magnetocaloric effect in the doped compound $\text{La}(\text{Fe}_{0.89}\text{Si}_{0.11})_{13}$ at ambient pressure and under applied pressure. Our theoretical calculations show that the isothermal entropy change upon magnetic field variation from 0 to 5 T is in a very good agreement with the available experimental data at ambient pressure and low applied pressure[3] (see figure). We also calculate the magnetocaloric effect when both the magnetic field and pressure are changed. Our calculations predict that both the isothermal entropy change and the adiabatic temperature change upon magnetic field variation from 0 to 5 T and a linear pressure variation from 4.5 kbar to 0 reach large values in a wider range of temperatures. This kind of behavior of the magnetocaloric potentials are due to the competition between the magnetic field and pressure in the establishment of the magnetic order. This result points out that this procedure of changing both the magnetic field and pressure can be very useful to improve the performance of magnetic refrigerators working in Ericsson cycle. We also calculate the barocaloric effect in $\text{La}(\text{Fe}_{0.89}\text{Si}_{0.11})_{13}$ at constant magnetic field, i.e., the magnetic field is kept constant while the applied pressure is changed. Our theoretical calculations show that the barocaloric potentials $[\Delta S]_B$ and $[\Delta T_{\text{ad}}]_B$ upon pressure variation from 4.5 kbar to 0 reach sizeable values in a wider range of temperatures as compared with the magnetocaloric counterparts, calculated at fixed applied pressure of 4.5 kbar. These theoretical results, which need experimental data to be confirmed, show that the barocaloric effect and the magne-

tocaloric effect under variation of pressure and magnetic field can be an important tool to develop magnetic refrigerators.

Magnetocaloric Effect of the PrNi₅-xCox Hard Magnets.

Departamento de Física Gleb Wataguin, Universidade Estadual de Campinas – UNICAMP, Campinas, Brazil

The PrNi₅-xCox hard magnets compounds are derived from quite different materials (from the magnetic point of view): PrCo₅ e PrNi₅. While PrCo₅ shows a high ordering temperature (TC), higher than Nd-Fe-B magnets [1], PrNi₅ compound is paramagnetic due to the high crystal field [2]. However, the gradual substitution of Co by Ni leads to the competition between the magnetocrystalline anisotropy of both 4f (Pr) and 3d (Co) sublattices causing therefore a spin reorientation and decreasing of the magnetic ordering temperature. This feature is quite interesting due to the possibility to adjust the TC around room temperature, which allows these compounds to be used as refrigerant material in the magnetic refrigerator operating at room temperature. The magnetic refrigeration (MR) is a new technology and is considered as a promising alternative to replace the well-established compression-evaporation cycle [3]. The physical phenomenon associated to magnetic refrigeration is the magnetocaloric effect (MCE), which corresponds to the temperature increase of a magnetic material when there is an alignment of its magnetic moments with an external magnetic field, under adiabatic conditions [4].

In order to control the critical temperature around the room temperature and then analyze their potential for application on MR, we prepared a set of the samples of PrNi₅-xCox (x = 2.07, 2.15, 2.25 and 2.40) by arc melting. Ingots were melted and then annealed in an evacuated quartz tube at 1020 K for seven days. X-ray diffraction shows a hexagonal CaCu₅ (P6/mmm) type structure. EDS analyze shows that the annealed samples are single phase. We also performed magnetic characterization, and figure 1 shows the temperature dependence of magnetization for all studied compounds. We can note that those measurements have, at low temperatures, a peak at TSR ~ 143 K, which is associated to spin reorientation (SR) process [5,6]. In fact, the spin reorientation transition starts, increasing temperature, when the magnetic moment leaves the ab-plane at TSR1 and assumes a cone-type magnetic structure. Further increasing of the temperature, at the TSR2, leaves the magnetic moment from the previous position to then point along the c-axis [7]. We still can see in figure 1 at higher temperatures the magnetic transition from the paramagnetic disorder phase to the ferromagnetic order regime. It is important to emphasize that we found the critical temperature around room temperature for x~2.20. The inset of figure 1 shows the TC and SR transition as function of Co content x. In spite of the apparent linear behavior of Tc(x) –inset of figure 1-, we could show in [8] that the behavior is not linear, but there is a logarithmic dependence that is associated to a percolation process. However, the SR transition is constant as x.

From the M vs H curves near TC, and using the appropriate numerical approximation [9], it was possible to determine the magnetic entropy change (ΔS) or, equivalently, the MCE under an external applied field of 1 T. Figure 2 presents these results for the x= 2.07 and 2.40 compounds. Samples with lower values of Co content (x<2.15) presents an overlap of the ΔS curves associated to the SR and para-ferro transition; and therefore provides a quite large full width at half maximum ($\delta TFWHM$) of the ΔS . For instance, $\delta TFWHM=160$ K for x = 2.15, which corresponds to 8 times

higher than the value of the pure Gd. Thus, this series has an appreciable relative cooling power (RCP), which therefore is useful to be used in magnetic refrigerator operating in a large range of temperature, from room temperature down to 150 K.

Laser induced magnetisation switching in films with perpendicular anisotropy: a comparison between measurements and an LLB macro-spin model.

C. Bunce¹, J. Wu¹, G. Ju², B. Lu², D. Hinzke¹, N. Kazantseva¹, R. Chantrell¹, U. Nowak¹

1. Department of Physics, University of York, York, United Kingdom; 2. Seagate Research, 1251 Waterfront Place, Pittsburgh, PA

This paper presents time-domain measurements of the magnetisation reversal process induced by an ultra-fast laser pulse in a perpendicular anisotropy CoPt thin film experiencing a constant reversing field less than its coercivity. It also presents the comparison of the experimental data with that from micromagnetic simulations based on the Landau-Lifshitz-Bloch (LLB) [1,2,3] equation.

The sample presented here is a CoPt multilayer thin film sputtered on a 2 1/2 glass inch platter with perpendicular anisotropy. It had a square hysteresis loop (squareness = 1) with a coercivity (H_c) of 0.8 T and a magnetic moment M_s of 320 emu/cc at room temperature. The dynamic coercivity measurements allow the anisotropy and anisotropy constant and associated grain size to be estimated as 4×10^6 ergs/cc and 10 nm.

The all optical pump-probe stroboscopic time resolved MOKE experiment measures the evolution of the perpendicular component of magnetisation over 1 nsec after an intense 150 fs ‘pump’ laser pulse arrives at the sample causing transient heating. The experiment was arranged in a way such that the sample was initially saturated in one direction and then placed in a reversing field with a strength (0.52 T), much lower than its DC coercivity, whilst the measurement was conducted. It was observed that for pump pulses with a fluence higher than about 0.14 mJ/cm², ultrafast demagnetisation of the sample occurred within 500 fs followed by a partial recovery along the original magnetisation orientation in spite of the applied field direction during the first 50 ps. After this the magnetisation gradually started switching into the direction of the applied field. This final process is occurring at a similar rate to the temperature changes (ns). It is interesting to note a partial recovery along the original magnetisation orientation. We believe that this reflects the two different characteristic times for longitudinal relaxation and super-paramagnetic relaxation.

For comparison with the experimental data, we numerically solved the LLB equation [3] for a granular film with a weak exchange coupling between the grains using material parameters measured from our experiments as well as from atomistic calculations. The latter are the input parameters for the LLB equation such as the temperature dependent perpendicular and parallel susceptibility as well as the equilibrium magnetisation. The values for the exchange stiffness are gained from [4,5]. The temperature profile used is derived from fitting the two-temperature model to the experimental reflectivity data measured.

Figure 1 shows the experimental measurement and the calculated z-component of the magnetisation versus time, for two different laser powers – one high enough to cause reversal and one not. The key parameters used for the simulations were $M_s = 520$ emu/cc, a uni-axial anisotropy $K_u = 1 \times 10^6$ erg/cc, a cell size of 9.5 nm, no inter-grain exchange coupling, $\alpha_T = 0.133$. The peak electron temperatures used were 600K and 900K corresponding to the low and high pump-powers used in the experiment respectively. The laser pulse causes a rapid demagnetisation followed by a recovery with a characteristic time depending on the degree of demagnetisation [6]. The second important energy transfer process is from the conduction electrons to phonons which result in a heating of the lattice on a time-scale of 5 ps. Thereafter, in the experiments, we note a gradual reversal of the magnetisation over the nano-second timescale – for the higher power case. This behaviour is qualitatively reproduced by the LLB model calculations supporting our interpretation of the measure-

ments, namely that the reversal is a super-paramagnetic one, and suggesting LLB equation based models as a powerful approach to understand pulsed laser processes.

Spin dynamics in patterned nanoscale Fe dot arrays.

J. Wu¹, S. Lepadatu¹, C. Bunce¹, X. Zou¹, D. Niu², Y. B. Xu², R. Chantrell¹, G. P. Ju³

1. Physics, University of York, York, United Kingdom; 2. Electronics, University of York, York, United Kingdom; 3. Seagate Research, Pittsburgh, PA

The ultrafast spin dynamics in patterned magnetic structures is one of the most important issues for the applications including high density magnetic recording and spintronics. In this presentation, we report time-resolved MOKE measurements of single crystal Fe film patterned into dot arrays with feature sizes down to 50nm. The effect of the enhanced shape anisotropy and modified magnetocrystalline anisotropy on the magnetization recovery process has been observed following femtosecond optical excitation in these nanometer scale structures.

The samples were grown by molecular beam epitaxy, and then patterned with focused ion beam milling into square dot arrays with size varying from 500nm to 50nm. Spin dynamics responses of the Fe dot arrays have been measured with pump-probe technique using a femtosecond laser. The results from a 50 nm dot array with the magnetic field applied in the sample plane and along the easy magnetic axis of the Fe film are shown in figure 1. Here the pump fluence is kept fixed at 28mJ/cm² and the magnetic field strength is varied from 735Oe up to 1.84kOe for the different measurements. After femtosecond optical excitation an ultrafast demagnetization process is observed in the first 400fs. Following this, the magnetization begins to recover monotonically and after about 50ps a damped precessional response is observed before the magnetization fully recovers to the initial state. The frequency of the precession increases with the increase of bias field strength while the damping of the precession decreases with the increase of bias field strength. The measured frequency as a function of bias field has been fitted the Kittel formula $f = (\gamma/2\pi)[H(H + 4\pi M_{\text{eff}})]^{1/2}$, where $\gamma = 221000$ is the gyromagnetic constant, H is the applied bias field and M_{eff} is the effective magnetization [1]. Because of the reduced uniaxial anisotropy as indicated by the Focus MOKE results, its contribution to the precession frequency is neglected. The best fitting is obtained for a value of $M_{\text{eff}} = 800 \text{ emu/cm}^3$ which is smaller than the actual $M_s = 1700 \text{ emu/cm}^3$. It has been previously found by Xu et al [2] that there is a large interface induced perpendicular anisotropy $K = 10^7 \text{ emu/cm}^3$. Considering the influence of the interface perpendicular anisotropy, $M_{\text{eff}} = M_s - (K/2\pi M_s)$ is around 760 emu/cm^3 which is in good agreement with the reduced effective magnetization.

We have also measured the continuous Fe thin film without patterning and no precession process was observed. The results suggested that the magnetization recovery process in the patterned dot arrays is related to the modified magnetic anisotropies. We have further carried out MOKE measurements to determine anisotropies as shown in figure 2. The continuous Fe film shows a strong uniaxial anisotropy of around 1000Oe, but this uniaxial anisotropy has been greatly reduced in the patterned dot arrays. The modified magnetic anisotropy of the Fe dot array is expected to be a combination of shape anisotropy and possible change in intrinsic anisotropy due to the patterning.

In summary, we have demonstrated that the modified magnetic anisotropy of nanopatterned structures plays an important role in determining the magnetization relaxation dynamics following femtosecond optical excitation, which should be significant for understanding and controlling the fast switching in patterned magnetic recording media and spintronics devices.

In the recent years much attention has been given to the study magnetic properties of periodically patterned metallic magnetic films. This area is important since magnetic periodical structures can be used for magnetic memory [1], magnetic logic [2], and microwave signal processing [3] applications.

Structuring centimetre-sized areas of films into dots or rings with diameters 100-400 nanometres using traditional lithography tools requires high precision instruments and is very time consuming. However there is another way to achieve the same goal in a more cost-efficient way. This is using a “natural lithography” based on a self-organization of polystyrene nanospheres on a hydrophilic surface into a highly in-plane periodic monolayer array. Such a structure formed on a surface of a multilayer stack containing magnetic metallic layers may serve as a lithographic mask for fabrication of a periodic array of magnetic dots [4]. Fig. 1 shows an AFM image of an exemplary array of nanodiscs fabricated using this technology. Such a perfect periodicity is observed over an area more than 1 cm in diameter.

Dynamic collective behaviour of the self-organized arrays was characterized by conventional and coplanar-waveguide [5] ferromagnetic resonance (FMR). A sample with the dot thickness of 30 nm, the mean dot diameter of 300 nm and the mean dot separation of 300 nm was studied. Fig. 2 shows results of measurements of in-plane and out-of-plane conventional FMR spectra for the sample. The out-of-plane trace shows several peaks which may be attributed to different radial standing spin waves on the dots. The presence of several peaks shows that this fabrication technique is able to produce samples with small dispersion of geometrical and magnetic parameters. However the parameter dispersion is not entirely negligible, since one sees that the resonance line is about 10 times as large as expected for an unstructured Permalloy film. We explain this by a small difference in “magnetic” diameters and shapes of individual elements resulting in a small variation of resonance fields from dot to dot.

The frequency difference between the main in-plane and the main out-of-plane resonance is about 3.8 GHz. This value is much smaller than the usual one for unpatterned Permalloy films. This shows that the static internal magnetic field and the static magnetization in the dots are considerably inhomogeneous. Furthermore, considerable effective dipole pinning of dynamic magnetization at the edges of the dots is present [6]. The work is now underway to extract the mean “magnetic” diameter of dots from these measurements.

Fig. 3 shows the results of the measurements using the coplanar-waveguide FMR technique. The measurements were done in a range of frequencies and in-plane magnetic fields. Using this technique we were able to trace the ferromagnetic resonance response of the array in the range of frequencies 4-15 GHz. Note that this is not an easy task for this technique, since the amount of magnetic material contained in the sample is very small, and the measurements are done at the response levels close to the setup sensitivity threshold. The experimental point obtained by the conventional FMR technique is also shown in the figure. One sees a very good agreement of results of both measurements.

Recently dynamic properties of magnetic nanostructures such as thin films, multilayers and laterally patterned media attracted much attention both from fundamental and applications points of view. Spatial regularity of the arrays of magnetic dots as well as epitaxial growth of magnetic multilayers permits observation of well defined modes of collective excitations. For magnetic dots with sufficiently large diameters a vortex state is expected to give rise to variety of radial and azimuthal modes [1-3]. Magnetic field dependence of resonant frequencies of these modes remain poorly understood. As to the magnetic multilayers, the optic and acoustic modes excited in these magnetic nanostructures have been mainly investigated for fixed frequencies above 9.7GHz with samples inside RF cavities. Magnetic field dependence of the dynamic response in these nanostructures remains practically unexplored for the frequency range below 9 GHz.

Two-port vector network analyzer (VNA) technique up to 8.5 GHz in transmission mode was used to measure the complex dynamic response of the samples placed on the top of a coplanar wave guide (CPW). A microwave signal was supplied from the VNA port 1 and the transmitted signal crossing the CPW was detected by port 2. Magnetic susceptibility was evaluated by using information from scattering matrix parameters S21 and S11 [4]. This technique was applied to measure in-plane dynamic response in Fe/Cr multilayers and in the periodic arrays of FeNi circular magnetic dots.

For the arrays of FeNi dots with diameter of 1 μ m, aspect ratio L/R=0.1 and with centre to centre distance varying between 1.2 to 2.5 μ m both VSM and MOKE measurements show a typical magnetization curve for the vortex ground state with a nucleation field of \sim (200-300 Oe) and annihilation field of \sim (400-600 Oe). In the previous ferromagnetic resonance (FMR) studies the in-plane resonance peak has a resonance field H_r of 1100 Oe and resonance linewidth ΔH of 26 Oe [2]. In the present VNA study resonance peak occurs in the fields above 300 Oe, i.e. above nucleation field. The FMR peak in the whole frequency range (5–13 GHz) was perfectly described by Kittel formula that takes into account the demagnetizing factor of individual magnetic dot.

Room temperature FMR studies of the array of FeNi dots also found that the main FMR linewidth (close to vortex annihilation/creation region) may be dependent on the magnetic history and that FMR linewidth broadens close to the vortex nucleation field (Fig.1). For the magnetic fields below 300 Oe, where magnetic vortex state forms, we have observed the field dependence of the at least two different radial/azimuthal modes ($f > 6$ GHz) to show minima close to the zero magnetic field. Dynamic response in the antiferromagnetically coupled [Fe/Cr] n multilayers ($n=10,20,40$), which was investigated as a function of magnetic field (up to 60 kOe) and in a wide temperatures range (between 300K and 2K), mainly reveal acoustic resonances. Magnetic field dependences of this resonance for different orientations of magnetic field in respect to crystalline axes (easy vs. hard) allow to resolve field induced orientation transition below 400 Oe between these axes when magnetic field is directed along hard direction (Fig.2). The high field dynamic response reveals presence of multiple resonant modes at frequencies below GHz. These modes are visible only at low enough temperatures (below 100K) and at magnetic fields close to the saturation field (of about 10 kOe). We tentatively relate these features to merging of optic and acoustic modes predicted to exist

close to complete the alignment of initially antiparallel ferromagnetic layers in the Fe/Cr superlattice [5].

Linear and Nonlinear Dynamics of the Gyrotropic Motion of a Magnetic Vortex in Ferro-magnetic Nanodots.

K. Lee, S. Kim

Research Center for Spin Dynamics and Spin-Wave Devices & Nanospintronics Laboratory,
Seoul National University, Seoul, South Korea

A magnetic vortex (MV) in confined magnetic elements continues to grow in considerable interest in the research area of nanomagnetism and spin dynamics because of its peculiar static and dynamic properties [1-3], and practical application to information storage devices [4]. Recently, the non-trivial dynamic phenomena, including resonant excitations [1] and dynamic reversal of vortex core (VC) [2], driven by small amplitude oscillating magnetic fields or ac currents, have attracted much attentions because these properties are crucial to realize magnetic memory devices or resonators based on MVs. Quite interestingly, it was also found that the underlying physics of the VC reversal is related closely to the gyrotropic motion. It is thus essential to understand complex VC gyrotropic motions including initial transient motion and steady-state orbital motions driven by single harmonic oscillating magnetic fields or currents.

In the present work, we conducted micromagnetic numerical [4, 6] and analytical calculations [5] of MV motions under time-variable in-plane magnetic fields, $\mathbf{H}(t) = A \sin(2\pi\nu t)\mathbf{y}$ with different frequency ν and amplitude A for the model system of a Permalloy (Py) circular dot of $2R = 300$ nm diameter and $L = 10$ nm thickness. Figure 1 (a) shows the simulation results of initial transient and steady-state motions for the given ν and A values. From the frequency spectra of these motions [the third column in Fig. 1], it is found that there are clear two peaks: one is a sharp large peak at ν , and the other is a relatively wide small peak at the eigenfrequency, $\nu_0 = 330$ MHz, characterized by the given material and geometry parameters. The former and latter correspond to the stable and transient motions of the VC, respectively. The transient VC motion is not chaotic but is associated with the eigenmode of the gyrotropic motion in the given material and geometry.

In order to compare those simulation results with the analytical calculations based on Thiele's equation of motion with a "side-charge-free" model [3], the VC orbital trajectories and their frequency spectra are numerically calculated using Thiele's equation, as seen in Fig. 1(b), including the potential energy profile, $W(\mathbf{X}) = W(0) + \kappa\mathbf{X}^2/2$, where \mathbf{X} is the VC position, and κ is the stiffness coefficient (a function of R, L [3]). These comparisons (orbital trajectories and frequency spectra) show excellent agreements in not only the steady-state but initial transient motions between the micromagnetic simulations and the numerical solutions.

In the case of relatively large amplitude applying fields, nonlinear motions of the VC are dominating as seen by the frequency spectra in Fig. 1(c). The relatively broad peak corresponding to the initial transient motions is shifted far away from $\nu_0 = 330$ MHz (for the linear case) with increasing amplitude of the oscillating field. Such nonlinearity of large-amplitude VC gyrotropic motion can be verified by taking into account some higher-order terms in $W(\mathbf{X})$, which is demonstrated by the numerical calculations of Thiele's equation with a forth-order potential energy term ($\beta\mathbf{X}^4/4$) in $W(\mathbf{X})$. For a specific value of $\beta/\kappa = 4.5 \times 10^{13} \text{ m}^{-2}$, the orbital trajectories and the frequency spectra agree quite well with the simulation results [compare Figs. 1(d) and (e)].

This work not only offers a theoretical way to understand complex responses of the gryomotions of a VC to an external driving force in the linear and nonlinear regimes, but also opens up a new opportunity to explore the nonlinear regime of vortex dynamics with the help of the generalized Thiele's analytical equation of motion.

Nonlinear phenomena in magnetic nanoparticle systems at microwave frequencies.

M. Pardavi-Horvath¹, G. S. Makeeva², O. A. Golovanov³

1. SEAS, The George Washington University, Washington, DC; 2. Penza State University, Penza, Russian Federation; 3. Penza Military Institute of Artillery, Penza-5, Russian Federation

Magnetic nanocomposites of nanometer size magnetic particles embedded in a non-magnetic, insulating matrix provide a novel solution for low loss microwave materials up to mm wave frequencies. The electromagnetic properties of magnetic materials change drastically upon reducing the dimensions into the nano-range, including the early onset of nonlinear effects, important for high power applications and non-linear signal processing. To investigate this effect, the nonlinear interactions of electromagnetic waves (EMW) in magnetic nanoparticle materials at microwaves were numerically simulated using rigorous mathematical models to solve the 3D nonlinear diffraction boundary problem. The solution is based on the full Maxwell's equations with electrodynamic boundary conditions, complemented by the Landau-Lifshitz equation of motion of the magnetization vector, including the exchange term.

A monochromatic plane EMW (TEM mode, magnitude $C_{1(1)}^+(\omega)$, frequency ω) is incident on the input cross-section S1 of the array of ferrite spheres (Fig.1). A bias magnetic field H_0 is applied normal to the direction of the propagating plane EMW. The modulus of scattering parameters of the multimode, multi-channel S matrix was calculated by the numerical method of autonomous blocks with virtual Floquet channels. The results of computing of the transmission coefficients $|S_{12}|$ on an array of 250 nm spheres, depending on the normalized frequency ω/γ (γ gyromagnetic ratio), for various separation of the spheres are shown in Fig.2. The minima (1-3) in $|S_{12}|$ correspond to the eigenfrequencies ω_p of characteristic magnetostatic oscillations of the ferrite spheres. The central line is the homogeneous magnetization precession low-order mode, others are the inhomogeneous magnetization precession modes in ferrite spheres. The increase of the interaction effects upon decreasing separation is clearly visible.

The instability regions of parametric generation in the nonlinear ferrite sphere array, depending on the magnitude $C_{1(1)}^+(\omega_H)$ of the pumping wave ω_H , are simulated using our computational algorithm for the numerical analysis of the bifurcation points of the nonlinear Maxwell's operator. The threshold magnitudes of the pumping EMW, $C_{1(1)}^+(\omega_H)$ are determined by computing the bifurcation points. The curves shown in Fig.3. divide the instability regime for the parametric generation from the stable regime of regenerative parametric amplification at $f_0 = 9.330$ GHz for the three separations shown of Fig.2. With decreasing separation, i.e. increasing interaction between the spherical elements of the array, the instabilities occur at lower power, demonstrating the power sensitivity of small particle systems.

Using this approach it is possible to investigate the nonlinear effects (nonlinear diffraction, frequency multiplication, Suhl instabilities, self-excited oscillations, chaos, parametric amplification and parametric excitation of dipolar magnetostatic waves, dipole-exchange spin-waves) in three-dimensional systems of magnetic nanoelements microwave and magnetophotonic applications, sensor arrays, Tbyte information storage, taking into account the topology of nanoarrays and constrained geometries.

Geometry of the system

Diffraction of TEM- waves on a 250 nm radius ferrite nanosphere array for various separation h of spheres: 1 – $h=3000$ nm; 2 – 750 nm ; 3 – 600 nm. Bias field $H_0 = \omega/\gamma$, $M_0 = 0.026$ T; $|S_{12}|$ - modulus of transmission coefficient; γ - gyromagnetic ratio; $C_{1(1)}^+(\omega) = 0.01$ A/m - magnitude of the incident wave.

Threshold of parametric instability for various separation, h , of spheres, as in Fig.2.: 1 – $h=3000$ nm; 2 – 750 nm ; 3 – 600 nm; the frequency of the signal wave $f_0 = 9.330$ GHz; $\omega_0 = 2\pi f_0$, ω_H - frequency of the pumping wave; $C_{1(1)}^+(\omega)$ - magnitude of the incident pumping wave.

Parametric spin wave excitation and cascaded processes in thin films.

K. Livesey, M. Kostylev, R. Stamps

School of Physics, University of Western Australia, Crawley, WA, Australia

When there are weak nonlinearities in a system, parametric excitation can occur whereby energy is resonantly transferred from one excitation mode to another. An example of this is seen in magnetic systems where the uniform spin wave ($k=0$) decays into travelling spin waves above a critical amplitude or angle of precession.

This has long been known to occur in high power ferromagnetic resonance (FMR) experiments but recently there has been evidence of nonlinear processes occurring during large-angle magnetic switching of thin films [1]. These nonlinearities are therefore important in understanding the writing of magnetic information. However, the thresholds observed during switching are apparently much larger than those measured in FMR. The question then is: is parametric excitation really occurring during switching?

We use a classical perturbative approach [2] to write the magnetic Hamiltonian of a finite thickness film. We include contributions from exchange, uniaxial anisotropy, Zeeman and dipolar energies. The Hamiltonian goes through a succession of transformations (Holstein Primakoff, Bogolyubov and quasi-linear transformations) in order to be split into a linear part and a nonlinear part consisting of terms due to three-wave interactions, four-wave interactions, etc. We then solve Hamiltonian equations of motion to determine analytic thresholds when both three- and four-wave interactions are resonant during switching. These thresholds are given both in terms of precession amplitude and in terms of the average angle of precession [3].

We find that the threshold is the same as in FMR and is in fact exceeded during switching. However, as switching occurs on very short time-scales - on the order of a few nanoseconds - there may not be enough time to excite spin waves to an amplitude sufficient for detection in experiment. This is illustrated in Fig.1. The minimum precession angle required to excite a detectable number of waves in a given time (solid line) and the parametric threshold angle (dashed line) are plotted for a 10nm Permalloy film. These two curves converge as time goes towards infinity. The apparent experimental discrepancies between FMR and switching are thus due to the different time-scales of the experiments.

Lastly, we have examined the effect of finite thickness on the threshold using Permalloy material parameters. Even for nm-thick films, finite thickness effects are considerable and a 2D model is inappropriate. The comparison between our 3D model and the 2D model is given in Fig.2. The confined direction allows for so-called “cascaded” spin wave processes [2] to occur. These cascaded processes correspond to four-wave interactions consisting of two three-wave interactions (hence second order in perturbation theory) and two possibilities are illustrated in Fig.3. When the first exchange branch is exactly double the FMR frequency of the film, process (b) in Fig.3 is on resonance, which leads to a minimum in threshold. By varying the film thickness for a fixed field this can be made to occur, for example, with applied fields around 20 Oe the threshold is at a minimum for film thickness of 70nm (see Fig.2).

Support by the Hackett Student Fund (UWA), the Australian Research Council and Seagate is acknowledged.

Figure 1. The average angle of precession needed to measure the effect of parametrically excited waves (solid line) in a given duration of precession. As time goes towards infinity, this angle approaches the threshold angle which is given by the dashed line.

Figure 2. The threshold angle to measure parametric excitation as a function of film thickness. The solid line shows the result of our 3D model and the dashed line shows the result for a 2D model with no thickness variation allowed. Material parameters are those for a Py film with bias field 20 Oe and pulsed field 10 Oe, and the precession is taken to last for 2ns.

Figure 3. Two examples of cascaded processes.

Micromagnetic modeling of the magnetization dynamics in a circularly exchange biased tunnel junction.

O. G. Heinonen¹, D. K. Schreiber², A. K. Petford-Long³

1. Seagate Technology, Bloomington, MN; 2. Materials Science and Engineering, Northwestern University, Evanston, IL; 3. Materials Science Division, Argonne National Laboratory, Argonne, IL

The magnetic vortex structure is typically the stable magnetic configuration in micron-sized ferromagnetic (FM) Permalloy (Py) disks with a thickness of tens of nanometers. The vortex affects both the quasi-static and the dynamic response of the magnetization to a magnetic field pulse. Recently, the magnetization dynamics of both single-layer and exchange-biased bilayer vortex structures excited by a magnetic field pulse has been investigated experimentally and through simulation [1, 2], as has the quasi-static response of an FM/I/FM trilayer (I=spacer) [3]. However, for the trilayers there has been no discussion of the exchange and magnetostatic interactions between the two FM layers across the spacer, which should affect the magnetization dynamics of the system. Simulations of the dynamic response of a circular AF/FM/I/FM tunnel junction structure (AF=anti-ferromagnetic layer) have been carried out using the Landau-Lifshitz-Gilbert (LLG) equations of motion. The magnetization in the FM layers was set in a vortex configuration, and the simulation parameters were selected to simulate an IrMn AF layer and two Py FM layers, separated by a thin MgO layer of different thicknesses. The AF-exchange bias and the magnetization in the adjacent pinned FM layer have parallel chirality. The sign and strength of the interlayer exchange coupling between the pinned and free FM layers were varied and ground states with vortices in the FM layers that are either of the same or opposite chirality were chosen, resulting in four unique configurations (Figure 1).

A magnetic field pulse normal to the plane gave rise to strongly coupled circularly-symmetric eigenmodes with one radial node (the so-called (1,0) mode) in the pinned and free layers, for both positive and negative interlayer exchange coupling. A simple analytical model was used to further study these circularly symmetric eigenmodes. The radial part of the (1,0) mode was taken to be $J_1(k_R r)$, where $x = k_R R$ is the first zero of $J_1(x)$, and it was assumed that the out-of-plane component of the magnetostatic field, resulting from the magnetization dynamics in one layer, was zero in the other layer, while the in-plane magnetostatic field was the same in both layers. Coupling between the layers due to the out-of-plane magnetization at the vortex cores was ignored.

The resulting coupled modes had two branches, a center-of-mass (CM) mode (magnetization in the two layers moves in phase), and a difference (DM) mode (magnetization in the two layers moves out of phase). As the main restoring force is given by the magnetostatic field, the CM modes have higher frequencies than the DM modes.

The linearized equations of motion were solved for the four local equilibrium configurations, shown in Figure 1, and the results are plotted in Figure 2. The lower branch for AF interlayer exchange and opposite chirality vanished with vanishing exchange bias. However, the lower branch for same chirality and AF interlayer exchange softens with decreasing exchange bias and vanishes at finite exchange bias. This correspond to a static displacement of the vortex magnetization structures in the two layers, which, for low enough exchange bias, becomes a minimum energy-configuration as the reduction in interlayer exchange energy can balance the increase in magnetostatic energy as the vortices magnetizations are displaced.

This manuscript was created by UChicago Argonne, LLC, Operator of Argonne National Laboratory ("Argonne"). Argonne, a U.S. Department of Energy Office of Science Laboratory, is operated under Contract No. DE-AC02-06CH11357.

Figure 1: Schematics of the magnetization structure. The filled arrow indicates the chirality of the pinned layer and the empty arrow the chirality of the free layer. The exchange interaction between the layers is '+' for FM and '-' for AF exchange. In all cases the interlayer exchange coupling strength was 40 Oe.

Figure 2: Plot of the coupled (1,0) mode frequency versus AF exchange bias strength for the CM modes (upper branch) and DM modes (lower branch) for the magnetization structures shown in Figure 1. CM modes (a) and (b) are degenerate, as are DM modes (c) and (d).

Size dependence of the magnetic switching of Co-nanoislands studied by spin-polarized scanning tunneling spectroscopy.

D. Sander, S. Wedekind, G. Rodary, K. Jürgen
Max Planck Institute, Halle, Germany

The magnetic properties of nanometer size Co islands on Cu(111) are studied by spin-polarized scanning tunneling microscopy and spectroscopy (spin-STM, spin-STs). Co islands are prepared by deposition of sub-monolayer quantities of Co at 300 K onto a clean Cu(111) surface. STM reveals the growth of double-layer high Co islands, which exhibit often an equilateral triangular shape with base lengths between 3 nm and 45 nm. Spin-dependent STM measurements are performed with a Cr-covered W-tip, where 100 layers of Cr are deposited at room temperature onto a chemically etched and subsequently flashed (2100 C) W-tip. We obtain spectroscopic data of the differential conductance dI/dV , by applying a small AC modulation voltage (10 mV, 4 kHz) to the gap voltage V , and we monitor the resulting modulation of the tunnel current I by phase sensitive detection with a lock-in amplifier.

The spin-dependent measurements are performed at the center of the Co islands at 8 K and in a magnetic field of up to 6 T, which is oriented normal to the sample surface. It has been reported before that the magnetic field dependence of the differential conductance of the tunnel current measured on a Co island can be ascribed to a field-driven change of the Co magnetization direction along the sample normal, in response to the external field [1]. Thus, a switching of the magnetization direction of a Co island can be identified from a characteristic change of the differential conductance signal. In an extension of the previous study [1] we investigate here the size dependence of the magnetic switching of individual Co islands comprised of several hundred up to several thousands atoms.

Our measurements of the differential conductance during a magnetic field scan show a sharp drop of the differential conductance at field values which depend on the Co island size. We ascribe this drop to the magnetic switching of the Co islands, where we find switching fields between 0.6 T for islands containing 1300 atoms (base length 12 nm), and 2.2 T for larger islands with 8500 atoms (base length 31 nm). For even larger islands of 17000 atoms (base length 41 nm) a reduced switching field of 1.95 T is observed. For smaller islands with 1100 atoms or less, we find, starting from zero external field, a smooth drop of the differential conductance in proportion to the magnetic field, and no abrupt switching is observed. The drop of the differential conductance with respect to field saturates around 1.5 T for islands with 450 atoms (base length 7 nm). At this field the drop of the differential conductance equals within error margins of $\pm 10\%$ the drop of the differential conductance observed for the magnetic switching of larger islands.

Our results suggest that double-layer Co islands on Cu(111) exhibit a size-dependent transition from superparamagnetic to single-domain ferromagnetic behavior with increasing island size. We have not observed magnetic domains within the Co islands under investigation. Therefore we may tentatively analyze the maximum coercive field according to the Stoner-Wohlfarth model of magnetization reversal by coherent rotation [2]. This approach gives $K = 0.5 \text{ Ms Hc} = 1.6 \text{ MJ / m}^3$, with the switching field $Hc = 2.2 \text{ T}$ and the saturation magnetization of Co of $Ms = 1.447 \text{ MA / m}$. This value of $K = 1.6 \text{ MJ / m}^3$ is a factor of three larger than the value of bulk hcp-Co [3]. Such an increase of the magnetic anisotropy is often observed on the nanoscale, and it points towards potential contributions of strain, strain relaxation, and interfaces to the magnetic anisotropy [3]. The decrease of the switching field from 2.2 T (8500 atoms) to 1.95 T (17000 atoms) with increasing

island size is ascribed to a possible multi-domain and/or incoherent magnetization state, which is expected to induce a lower switching field [4].

Chemical order and size effects on the magnetic anisotropy of FePt and CoPt nanoparticles.

F. Tournus¹, S. Rohart^{1,2}, V. Dupuis¹

1. LPMCEN, Université de Lyon; Univ. Lyon 1; CNRS, Villeurbanne, France; 2. LPS, Université Paris Sud; CNRS, Orsay, France

The effect of the L10 ordering in FePt and CoPt on the magnetic anisotropy in bulk crystals or thin films has been widely studied on both experimental and theoretical points of view. In the case of nanostructures, although many experimental studies have been performed, the impact of the dimension reduction on the magnetic anisotropy energy (MAE) has not been clearly evidenced. As the surface modifies the local chemical environment, it can have a large impact on the MAE. As it will be shown in this paper, contrary to the results on pure Fe and Co clusters it induces a lowering of the MAE for L10 ordered clusters. In this paper, we extend the phenomenological anisotropy model of Néel to describe the effect of chemical ordering in FePt and CoPt clusters. Taking advantage of its simplicity, which allows us to perform an extensive study of FePt and CoPt clusters, we use this phenomenological model to investigate the MAE of clusters. Taking into account finite size effects by mean of a statistical analysis on a large number of nanostructures, we demonstrate the impact of L10 chemical ordering on the MAE and show how the surface and the finite size modify the results as compared to the bulk.

The magnetocrystalline anisotropy (MCA) is directly linked to the local environment around magnetic atoms. For a whole structure, it is the signature of the system symmetries. It can be described using a phenomenological pair model, first introduced by Louis Néel. In its original form, for a single element crystal, the MCA energy is written as a pair interaction over the first neighbors. Considering a given structure of volume V , the total MCA energy is evaluated by performing a sum over all the nearest neighbors pairs, assuming that the magnetization is homogeneous over the whole structure (macrospin approximation). This leads to a quadratic form, that can be diagonalized into an orthonormal

basis set (biaxial second order magnetic anisotropy), allowing us to determine the easy magnetization direction and the anisotropy constant K_1 corresponding to the magnetization switching from one minimum to the other one ($K_1 \cdot V$ is the energy barrier).

This crude model, which is suitable for systems where symmetry is locally broken (surfaces), can be extended to the case of an alloy, by introducing a different Néel anisotropy parameter for each type of neighbors pairs. Then, in the bulk case, using statistical considerations we can find an analytical expression of the MAE variation with the long-range order (LRO) parameter S corresponding to the L10 chemical order. The model appears to be in satisfactory agreement with experiments and with first-principle calculations.

In the case of a finite size system, we need to perform a statistical analysis to determine the relation between the LRO parameter S and the anisotropy constant K_1 . We have used this Néel anisotropy model to investigate the consequence of the size reduction in FePt and CoPt nanoparticles, with respect to their chemical order, focusing our study on nearly spherical clusters, with a perfect truncated octahedron shape. We have found a significant deviation from the bulk behavior (see Fig. 1). Moreover, our calculations have revealed that, while the anisotropy constant K_1 is enhanced in the case of small chemically disordered particles, it decreases in the case of perfectly L10 ordered particles when going to small sizes (see Fig. 2).

Fig. 1: Variation of the anisotropy constant K_1 versus $|S|$ for a 201 atoms FePt cluster. The color scale represents in the $(|S|, K_1)$ plane, the density of probability for a cluster with chemical LRO parameter $|S|$ to have a MCA K_1 (the corresponding color bar is shown in inset). The dashed line corresponds to the bulk behavior.

Fig. 2: Variation of the mean anisotropy constant K_1 versus the number of atoms in the cluster for FePt clusters of different $|S|$ parameters. The dots correspond to the calculated K_1 , the error bar representing the dispersion of the K_1 distributions. The lines are obtained by fitting the calculated values with a power law.

A study of the optimum dose of ferromagnetic nanoparticles suitable for cancer therapy using magnetic fluid hyperthermia.

M. Pavel^{1,2}, G. Gradinariu^{1,2}, A. Stancu¹

1. Department of Solid State and Theoretical Physics, "Alexandru Ioan Cuza" University, Faculty of Physics, Iasi, Romania; 2. Department of Oncology, University of Medicine and Pharmacy "Gr. T. Popa", Iasi, Romania

Magnetic fluid hyperthermia (MFH) is a modern topic of interdisciplinary research of applied physics (in particular magnetism) and biomedicine. Presently, a successful realization of this promising therapy is hampered by some unsolved problems. One of these problems is the choice of the correct particle concentration in order to achieve a defined temperature increase in the tumor tissue. A computer-based model was created using COMSOL:Multiphysics in order to simulate the heat dissipation within the tissue for typical configurations of the tumor position in relation to neighboring blood vessels as well as particle distribution within the tumor. The temperature achieved on the tumor border was investigated taking into account physiological parameters of different types of tissue. Using the correct nanoparticle dosage and considering their specific loss power, it is possible to estimate the efficiency of this therapeutic method. If the tumor shape and position are known by suitable medical imaging techniques (e.g. MRI, CT), simulations like this one could provide data in order to achieve the optimum dose and particle distribution in the tumor. Using biocompatible strengths and frequency values for the alternating magnetic field, we studied the reactions of different types of cancerous tissues when MFH therapy is used. We designed distinct simulations of a spherical tumor located in a cubical region of volume 1 cm³ from the tissue we intended to analyze.

A systematical variation of the parameters involved (e.g. tissue density, tumor/tissue perfusion rate, tumor diameter, particle concentration and physical properties, field amplitude and frequency) was performed in order to understand the effect of these parameters on the outcome of hyperthermia treatment. We focused on studying the variation of particle concentration in order to achieve an optimal therapeutically temperature at tumor border. Moreover we were interested in comparing the intra-tumoral temperature distribution for a single and respectively multiple point injection for several ferromagnetic materials. In all the simulations, we were interested in obtaining a temperature higher than 42.5°C, the minimum temperature that increases the susceptibility for apoptosis in cancerous cells. Further on some of the results from the simulations will be presented.

In the first simulation two small blood vessels are located at approximately 2.5mm and 4mm away from the tumor region. For different concentrations of ferromagnetic nanoparticles ranging between 6 and 10mg/cm³ homogeneously distributed in different cancerous tissues (brain, skin, liver, breast, rectum, lung), with a diameter of 2.7-3 mm, for a frequency of 260kHz and a field amplitude of 7kA/m ($LP=4.15 \cdot 10^9 \text{ W/m}^3$), a border temperature ranging between 44-46°C was obtained (Figure 1). Moreover, for larger tumors (diameter of 3.5-4mm), in the conditions of lower nanoparticle concentrations – 4-5mg/cm³ and using the same values for H, f and particle size, the temperature was 42.5-43.5°C at the border between tumor and healthy tissue.

Furthermore, we attempted to estimate a spatial temperature distribution in a liver tumor, using magnetite and maghemite nanoparticles comparatively. We opted for less homogeneity assuming that particles are injected in equal quantities in multiple regions (3-9) within the tumor. Although maghemite nanoparticles may be used at a lower concentration (3-4 mg/cm³) compared to magnetite, we observed that they tend to generate either too much or insufficient heat when we varied their radius within the limits of 21 and 23nm.

For the next simulations we assumed the presence of a single blood vessel with a diameter of 0.1 mm, positioned at 3.5-4 mm from the tumor. For liver tissue, we used constant field amplitude of 7.5kA/m, and we varied the frequency, the concentration of nanoparticles and their distribution. We then considered a tumor volume of 18mm³ (approx. 3mm*3mm*2mm), for a frequency of 250kHz and for concentrations ranging between 10mg/cm³ and 5mg/cm³ (the first being the upper biocompatible limit) the temperature around the tumor ranged from 46.19°C to 41.7°C thus providing us with a possible dose and type of particle distribution that could be used to treat small liver tumors.

In conclusion, our results show that, using these models, we can successfully estimate the impact of the particle dose on the efficiency of hyperthermia therapy taking also into account the local features (e.g. tumor density, type and perfusion rate) and external factors (e.g. field amplitude and frequency) involved. It could be thus a good method to evaluate the prospects of the therapy for a given patient who has a well described condition and also to establish an optimum starting dose for MFH therapy in such a case.

Spatial temperature distribution in a skin tumor tissue for $H=7\text{kA/m}$ and $f=260\text{kHz}$ and particle concentration of 10 mg/cm^3 (particle diameter = 18 nm), where T is the tumor border temperature.

Influence of dipole interaction and thermal effect on static magnetization process of magnetic nanoparticle assembly.

D. Hasegawa¹, T. Ogawa², M. Takahashi³

1. Electronic Engineering, Tohoku University, Sendai, Japan; 2. CRESS, Tohoku University, Sendai, Japan; 3. NICHe, Tohoku University, Sendai, Japan

Introduction

Many works on the synthesis and the magnetization process of magnetic nanoparticles have been investigated. In the case of the magnetic material with small magnetic anisotropy such as Iron, its nanoparticles which are magnetically isolated show superparamagnetic behavior, and their static magnetization process can be explained by the Langevin function. However, the magnetization process actually changes from simple superparamagnetic behavior with increasing volume fraction and decreasing temperature due to influence of the magnetic dipole interaction [1, 2]. Especially, the nanoparticles show super spin-glass behavior under the strong dipole interaction and/or low temperature [1, 2]. Therefore, in this study, we evaluated the influence of the dipole interaction and temperature effect on the static magnetization process quantitatively by the Monte Carlo simulation.

Model and parameter

Magnetic single domain nanoparticles that were arraying on the lattice points of $16 \times 16 \times 16$ unit cells of face center cubic structure were assumed as a geometric model. The directions of each magnetic moment were determined from thermal energy and total magnetic potential considering with the Zeeman energy and the dipole energy. Here, the dipole field was determined under the periodic boundary condition. Saturation magnetization (M_s) was assumed 1700 emu/cm^3 . Temperature (T), particle diameter (D_p), and volume fraction (v_f) were variable. The temperature dependence of M_s is not considered.

Result and discussion

Fig. 1 shows the temperature dependence of the static initial susceptibility (χ_{par}) for 3 and 9 nm nanoparticles with various volume fractions. Here, χ_{par} for none interaction case which is calculated from the Langevin function ($\chi_{\text{par}} = \chi_{\text{Langevin}} = VM_s^2 / 3k_B T$; V is the volume of a particle) is shown by a dotted line. For $D_p = 3 \text{ nm}$, χ_{par} with $v_f = 0.0001$ decreases monotonously with increasing T . This dependence coincides with that for none interaction case in the range from 10 to 900 K. For the nanoparticles with $v_f = 0.001$, χ_{par} also decreases monotonously with increasing T . However, χ_{par} is smaller compared with that for none interaction case at 10 K, and approaches χ_{Langevin} with increasing T , which results in agreement with χ_{Langevin} at about 50 K. Increasing v_f , χ_{par} at 10 K decreases, and the temperature to which χ_{par} and χ_{Langevin} are corresponding with each other increases. Moreover, χ_{par} with $v_f = 0.1$ and 0.5 shows independent behavior of T in the low temperature range. This indicates that nanoparticles cannot show magnetically isolated superparamagnetic behavior due to strong dipole interaction. In addition, for $D_p = 9 \text{ nm}$, χ_{par} with $v_f = 0.1$ and 0.5 also shows independent of T the range from 10 to 900 K.

Fig.2 shows the normalized susceptibility ($\chi_{\text{par}} / \chi_{\text{Langevin}}$) against the energy ratio of dipole interaction and thermal effect ($E_{\text{dipole}} / E_{\text{thermal}}$) for 3 and 9 nm with various v_f and T . Here, E_{dipole} and E_{thermal} were defined as follows,

$$E_{\text{dipole}} = 2\pi M_s^2 V v_p$$

$$E_{\text{thermal}} = k_B T \quad (k_B \text{ is the Boltzmann constant}).$$

The normalized susceptibility is uniquely scaled using the energy ratio though V , D_p , and T have changed. For $E_{\text{dipole}} / E_{\text{thermal}} < 0.01$, the normalized susceptibility is almost 1.0, suggesting that the influence of the dipole interaction can be negligibly small and nanoparticle assembly shows simple superparamagnetic behavior, which can be explained by the Langevin function. On the other hand, for $E_{\text{dipole}} / E_{\text{thermal}} > 5.0$, normalized susceptibility logarithmically decreases with -1.0 of slope. This indicates that χ_{par} is determined from only the volume fraction of nanoparticles as follow,

$$\chi_{\text{par}} = 1 / (6\pi v_p).$$

For $0.01 < E_{\text{dipole}} / E_{\text{thermal}} < 5.0$, nanoparticle assembly shows superparamagnetic behavior, however its static magnetization process can not be simply explained by the Langevin function due to the influence of the dipole interaction.

Fig. 2 Simulated susceptibility (χ_{par}) normalized by calculated susceptibility (χ_{Langevin}) from the Langevin function against the ratio between dipole and thermal energy ($E_{\text{dipole}} / E_{\text{thermal}}$) for 3 and 9 nm nanoparticles with various volume fractions (v_f).

Numerical Modeling and Characterization of Micromachined Flexible Magnetostrictive Thin Film Actuator.

H. Lee, C. Cho

Mechanical Engineering, Inha University, Incheon, South Korea

Many research groups had a great deal of interest in the theoretical and numerical design and fabrication of thin film structures using magnetic materials.¹⁻³ Most of the magnetostrictive thin film actuators are designed in the Si substrate for the use of the micromachining process.⁴⁻⁶ The development of micro-actuators based on magnetoelastic response requires high magnetostriction performance of the thin films with flexible substrates. Si substrate has highly brittle property, so it can not only be used in impact or bent environment but also high deflection. But flexible polyimide substrate can be an effective material for sensor and actuator applications in the harsher environment and higher magnetostriction with lower cost than Si substrate. For that reason, some researchers used the commercial polyimide film, but commercial polyimide film is not easy to get micromachining process for complex substrate shapes and various thicknesses. So, alternative flexible substrate should be adopted. And some studies show numerical models for magnetostriction, but there is limitations for large deformation as an actuator. So, in this study, a finite element model with in-plane and out-of-plane displacement for large deformation of the magnetostrictive thin film actuator is developed, and NiFe magnetostrictive thin film structures are designed with the micromachined flexible substrate using SU8-2025 and SU8-2075 (Shell Chemical Corp.). For the numerical analysis of large deformation of the magnetostrictive thin film structure, a plate element shown in Fig.1 is proposed. The element stiffness matrix and force matrix are calculated, and numerical analysis is performed from the plate model. A Magnetostrictive thin film actuator is also designed. Fig.2 shows schematic design and its principle of operation. It is fabricated from the first step of the micromachining of substrate with the suggested design using SU-8. After that, NiFe thin film is deposited using sputter and electroplating process, and thicknesses of deposited NiFe films are 2, 5 and 10 μm . The deposited film thicknesses are measured by X-ray diffraction (XRD). Fig.3 shows the fabricated actuator. After the fabrication, magnetic moment of the film is measured to characterize the magnetic properties of the NiFe film with the SU-8 substrate using VSM (Vibrating Sample Magnetometer) and deflections of the actuator under the external magnetic field due to the magnetostriction is measured using capacitance method to characterize the magnetomechanical characteristics. And also the numerical results of magnetostriction analysis from the developed finite element model are compared with experimental results in Fig.4. Maximum net deflection is about 147 μm under 0.5T for micro-device application.

Semi-analytical calculation of the armature reaction in a slotted tubular permanent magnet actuator with distributed windings.

B. Gysen, J. Paulides, E. Lomonova, A. Vandenput

Electrical Engineering, Eindhoven University of Technology, Eindhoven, Netherlands

Tubular actuators are increasingly employed in the industry due to their high force density, excellent servo characteristics, virtually zero attraction force and the absence of end windings. In order to obtain an optimal design subject to various specifications, accurate modeling of the behavior of the actuator is inevitable. Various techniques exist for modeling the magnetic behavior of the tubular actuator, including the magnetic equivalent circuit (MEC) [1], the Schwarz-Christoffel (SC) mapping technique [2], the finite element method (FEM) [3] and the semi-analytical approach [4]. The latter one is the most preferred for optimization, due to the high accuracy and fast computational time.

Extensive analysis of the magnetic field distribution in the air gap of a tubular permanent magnet actuator is found in the literature [4], however they all consider a slotless machine. This paper considers the field calculation due to the stator windings of a slotted tubular PM actuator. For simplicity, the end effects are excluded and an infinite length of stator and translator is considered. Since only the field due to the stator windings is considered, the magnets are regarded as an air region since their relative permeability is close to unity. The periodicity of the stator is used and therefore, the field solution can be written as a Fourier series with period $2\tau_{wp}$ with τ_{wp} the winding pitch. If a multi phase system is considered, superposition will be used in order to obtain the total field solution. A cross section of one period for a three phase system is given in Figure 1. During the calculation of the field solution of one phase, the influence of the slotting effect of the other phases is excluded, therefore the slot openings are considered as full iron as indicated in Figure 1. The iron is assumed infinitely permeable and since the magnets are considered as an air region, only two regions need to be distinguished, the air gap and the slot with current density, region I and II, respectively.

The current density of each phase can be described as a Fourier series with a fundamental period of $2\tau_{wp}$. The Maxwell equations can be described in terms of the magnetic vector potential, and therefore the field equations result in a Laplace equation for region I and a Poisson equation for region II. These equations are solved subject to the Dirichlet boundary conditions. In the final paper the extensive analysis will be given in terms of the geometric parameters and material properties. The solution is verified with a finite element calculation for linear iron where the current density in the coils is 5 A/mm^2 for the parameters given in Table 1.

The solution in Figure 2 is calculated at the center radius of region I. Excellent agreement with the FE solution within 2 % is obtained. In the final paper, figures of the total field solution due to all the phases will be given for both regions.

Sequential optimization method for the design of electromagnetic devices.

G. Lei¹, Y. Guo², J. Lavers³

1. College of Electrical and Electronic Engineering, Huazhong University of Science and Technology, Wuhan, China; 2. Faculty of Engineering, University of Technology, Sydney, NSW, Australia; 3. Department of Electrical and Computer Engineering, University of Toronto, Toronto, ON, Canada

Abstract—Sequential least square method and sequential linear Bayesian method are presented for the design of electromagnetic devices. In our implementation, optimization design is composed of coarse optimization process (COP) and fine optimization process (FOP). The main purpose of the former is to reduce the design space, while the latter is to update the optimal results. To illustrate the efficiency of the new methods, the TEAM Workshop problem 22 is investigated.

I. INTRODUCTION

Many electromagnetic optimization problems are solved by means of highly accurate models coupled with direct optimization algorithms, such as genetic algorithm, clonal selection algorithm and differential evolution algorithm (DEA) [1], [2]. However, these approaches are computationally expensive. As an alternative, many approximate models, such as response surface model, radial basis functions model and Kriging model are also widely used, which are proved fast, but not very accurate [3]. In traditional optimization methods, models and algorithms are almost discussed separately. But in deed, optimization is a simultaneous updating process about them. In this paper, we try to discuss both of them with sequential optimization method (SOM).

II. SOM

Given a set of n sample points $x[n]$ and responses $y[n]$, now, for an input x , the response value can be expressed as a realization of a low-order polynomial regression model and a random function. Quadratic polynomials are used in our implementation. Then we have a matrix notation of the approximate model as $y[n]=H\beta+w$, where β is a vector of regression parameters to be estimated, H is a known observation matrix of $x[n]$, and w is a noise vector with zero mean and covariance. Generally, β s are estimated by least square estimator (LSE) and linear Bayesian estimator (LBE). However, matrix inversions are required in LSM and LBE, and when the dimension of response vector is large or the step size is small, many difficult problems are what we must face. So we present two improved sequential estimation methods (SEM), which are termed sequential LSE (SLSE) and sequential LBE (SLBE) [4]. It is of great interest that, except for the initialization procedure, no matrix inversions are required in SEM. Fig.1 is the flowchart of SOM.

III. EXPERIMENTS AND RESULTS

The TEAM Workshop problem 22 (SMES) is a well known benchmark problem for optimization methods [1]. SMES is a superconducting magnetic energy storage device that consists of two solenoids. The dimensions of the inner solenoid stay fixed, while the dimensions of the outer solenoid ($R2, h2/2, d2$) should be optimized to reduce stray fields while keeping the stored energy close to 180 MJ. Table I shows the optimization results given by our proposed methods. Three main conclusions can be drawn from the Table. Here SLSM means LSE used in COP and SLSE used in FOP, and the similar meaning to SLBM.

1) For the direct optimization method, the optimal design parameters given by DEA are [3.11 0.302 0.301]. The mean stray field Bstray is 0.94 mT, energy E is 179.86 MJ, and 1910 finite element sample points (FESPs) are needed.

2) For the optimization with SLSM, 249 FESPs are needed to get the optimal results, which are [3.10 0.232 0.394]. Bstray is also 0.94 mT, E is 179.94MJ, and the error is 0.03%, which is smaller than that given by DEA.

3) For the optimization with SLBM, only 198 FESPs, about 1/10 that by DEA, are needed to get the optimal results. The optimal results are [3.08 0.260 0.364], E is 179.93MJ; the error is 0.04%. Bstray is 0.91 mT, which is better than that by DEA and by SLSM. Obviously, SLBM is the best one of the three methods.

IV. CONCLUSION

SOM presents a new way for the effective analysis procedure of electromagnetic optimization problems. Compared with the methods using direct optimization algorithms, SLSM and SLBE only need a small sample data, and the overall computational effort needed is much less than that by direct optimization method.

A new field-circuit coupled method for the computation of additional losses in transformer.

G. Jian¹, L. Heyun¹, H. Siulau²

1. School of Electrical Engineering, Southeast University, Nanjing, China; 2. Department of Electrical Engineering, Hong Kong Polytechnic University, Hong Kong, China

Apart from the standard copper and iron losses described in common textbooks, there are significant stray loss and winding eddy current loss in oil-type power transformers. The major challenge for modern transformer designers is to develop the necessary tools to precisely simulate the machine performance so as to realize optimum transformer performance at low cost in real practice [1]. Traditionally, finite element methods (FEM) are often used to calculate eddy current losses in transformers, in which the ampere-turns (ATs) in the primary and secondary windings are assumed to be equal. However, the primary windings ATs are balanced not only by those in the secondary windings, as the eddy current in the structure and the self-leakage magnetic field need to be balanced by the primary ATs as well.

A novel field-circuit coupled method for calculating the additional losses of transformer is presented to overcome the shortcoming of common FEM in this paper. For a three-dimensional eddy current field, the A - V - A formulations with the coulomb gauge can be derived whilst every phase winding is treated as an independent circuit [2]. By combining the A - V - A formulations and the winding circuit equations, a global system of equation for the field-circuit coupled solution can be obtained, in which the eddy current field and the circuit equations are solved simultaneously. Induced currents in the secondary windings and the additional losses of transformer are calculated.

To validate the proposed method, an 800kVA, 3-phase oil-type transformer is selected as the test sample and a quarter model of which is shown in Fig.1. The induced currents in the secondary windings are shown in Table I. It can be seen that the current ratio I_2/I_1 in all the three phases are smaller than N_1/N_2 . This means that the unbalance ATs between the primary and secondary windings are balanced by the sum of the eddy current in the structures and the self-leakage magnetic field of the primary windings.

Fig.2 shows the distributions of the structures losses. Table II gives the eddy current losses in the structures and the total copper losses. It can be seen that the calculated result of the field-circuit coupled method is in good agreement with the measured data. Compared with common FEM, the proposed method is more accurate in finding the additional losses of power transformers.

In summary, this paper presents a new field-circuit coupled calculation method for the computation of the additional losses in a transformer. As will be elaborated in the full paper, the computed results show that i) the current ratio $I_2/I_1 < N_1/N_2$ in all the three phases. This is because the unbalance ATs between the primary and secondary windings are balanced both by the eddy current in the structures and the self-leakage magnetic field of the primary windings; and ii) when compared with conventional FEM, the proposed field-circuit coupled method is more accurate for computing the additional losses in a oil-type power transformer.

Abstract:

The paper is based on an advanced time-domain modeling technique of eddy currents and their power losses in ferromagnetic cores for transformers, inductors and other electric machines, working in strongly distorted regimes, including switching regimes, as in power electronics.

The model takes its mathematical root from the Maxwell's theory, and does not deal with analytic approximation. The entry data are the first-magnetization curve given by the manufacturer data sheet, the specific power losses (given for a reference flux density and a reference frequency), as well as the geometric dimensions of each ferromagnetic piece. Any soft ferromagnetic materials, like ferrite, silicon steel sheet core or multilayered ferromagnetic amorphous alloy film can be modeled using this principle, according the given examples.

The model is suitable to be included in a time-domain circuit simulator, like SPICE, in order to simulate the whole circuit that includes the magnetic device (ferromagnetic core and their windings). The simulation results give us the time-domain flux distribution in the magnetic core, the eddy current losses on each piece, as well as any working parameter of the circuit which includes the magnetic device.

As a simple example, a common case of a single phase inductor is shown: experimental results are compared with the corresponding simulation, obtaining the expected similarity.

Totally feasible and linked to the practice of common modern applications, our method has the capability to become a valuable tool for applicative research and design activity.

Generalities:

Many actual industry applications are tightly linked to power converters, distinguished by strongly distorting working regimes. The presence of ferromagnetic cores makes the optimal design a very difficult task. The core may work on minor hysteresis loops, having or not a bias component that strongly modifies the dynamic permeability. In addition, the medium frequency magnetic field provokes important eddy currents which bring power losses and distort the B-H loop of the magnetic core. These losses are dominant in the core heating process.

Unfortunately, the designer has often the tendency to improve the magnetic core size in order to reduce the maximum flux density and consequently to keep the core losses on low values. Contrarily, a rigorous design requires a smallest weight and size, as guaranty of a lowest manufacturer price. One must find an optimal compromise between total losses and the device size: maximum power losses in a smallest size for a given insulation class and cooling conditions.

Our paper is focused on a totally feasible method for the time-domain modeling of soft ferromagnetic materials on behalf of the dominant effect of eddy currents. The model remains unchanged from low to medium frequencies, in the domain of Maxwell's theory restrictions. The model can be easily included in a time-domain circuit simulator, like SPICE, being suitable to simulate any device with ferromagnetic core, working in harmonic or distorting regime as in power electronics. The main principle is the well-known modeling of a magnetic circuit through an electric circuit, based on the formal similarity between the magnetic field and electric field laws.

The given magnetic circuit is treated as an assembly of many ferromagnetic pieces and air-gaps. Each ferromagnetic piece is chosen considering the simplifying assumption of a uniform magnetic flux density through its cross section.

In order to develop a useful implementation of the model, we performed a SPICE subcircuit which can be included in any time-domain circuit simulation (see the figure). The complete netlist of the subcircuit will be included in the full paper.

Conclusions:

Our method is remarkable through its degree of generality, simplicity and feasibility. It allows performing a high precision time-domain analysis of circuits with nonlinear magnetic devices. It is an excellent tool that helps to solve firmly the specific problems of magnetic devices through an efficient way, without groping and forced approximation. The method is explained by the Maxwell-Hertz theory.

Modeling of effect of plastic deformation on Barkhausen noise and magnetoacoustic emission in iron with 2% silicon.

M. J. Sablik¹, B. Augustyniak², F. J. Landgraf³

1. Mechanical and Materials Engineering Div., Bldg. 139., Southwest Res. Inst., San Antonio, TX; 2. Physics, Gdansk Institute of Technology, Gdansk, Poland; 3. Metallurgical Engineering, University of Sao Paulo, Sao Paulo, Brazil

Before one models the effect of plastic deformation on magnetoacoustic emission (MAE), one must first treat non-180 degree domain wall motion. In this paper, we take the ABBM model [1] and modify it to treat non-180 degree wall motion. We then insert a modified stress-dependent Jiles-Atherton model, which treats plastic deformation[2], into the modified ABBM model to treat the field and stress dependence of magnetic Barkhausen noise (HBN) and of MAE.

Sablik [3] derives the following expression for the Barkhausen noise power using ABBM [1] and a constant rate of field increase, h :

$$I_b = (A_c/A_g) S \{ M_c(H) / [S (M_c(H)/P_s) + \rho / (S)(G)(h)] \},$$

where $A_g = (G/\rho)^{**2}$ and $M_c(H) = (\mu_i/\mu_0)(\mu_i - \mu_0)$. S is the average surface area of a moving 180 degree wall, ρ is electrical resistivity, $G=0.1356$, μ_i represents the irreversible permeability as a function of field H , μ_0 is permeability of free space, P_s is the correlation length of coercive field correlations, and A_d is a parameter describing average spatial fluctuations of domain wall coercive field interactions. Here, $\mu_i = \mu_0 [1 + dM_i/dH]$, where M_i is the irreversible part of the magnetization, which is computed self-consistently [4] from an equation for dM_i/dH .

Under plastic deformation, the number of Barkhausen emission centers increases with increased dislocation density Z_d . We treat this change as proportional to the square root of the relative dislocation density increase, just as coercivity changes in the same way, so that:

$$A_d = A_{d0} (Z_d / Z_{d0})^{**1/2},$$

where the zero subscript refers to conditions prior to plastic deformation. In Fig. 1a, modeling results are compared with experimental data. The results are for the Barkhausen power integrated over all H in iron with 2%Si. Given the error bars (not shown) in the experimental data, the fit is reasonable.

MAE is due to motion of non-180 degree domain walls, whereas magnetic Barkhausen noise is due to motion of 180 degree walls. Extending the ABBM model to non-180 degree walls means one must now include a contribution given by

$$\begin{aligned} dM_e/dt &= \chi(H) [1.5 \sigma / \mu_0] [d2\lambda/dMdt] \} \\ &= \chi(H) [1.5 \sigma / \mu_0] [d2\lambda/dMdH] h, \end{aligned}$$

where σ is an average residual stress contributing to the effective field owing to the deformation, $\chi(H)$ is the susceptibility dM/dH , $M(H)$ is the total magnetization and λ is the magnetostriction. λ and χ are computed as in [4], but treating plastic deformation as in [2]. On using the ABBM formalism, one obtains:

$$I_m = [(A_c/A_g)/S_n] \{ M_c(H) F(M) / [(F(M) M_c(H)) S_n / P_s + \rho / (S_n G h)] \},$$

where $F(M) = (1.5 \sigma / \mu_0) (d2\lambda/dMdH)$. We use the total μ here instead of μ_i in the expression for $M_c(H)$ because MAE, involving elastic waves, is a more macroscopic phenomenon. The surface area S_n of the non-180 degree domain walls should be smaller than that of the 180 degree domain walls. We denote the MAE formalism up to now as Model 1. In this model, we use our previously stated result for A_d . However, Model 1 does not produce a good enough fit to the experimental data, as we shall see.

In Model 2, to get a better fit, we note that the number of 90 degree walls stops increasing once dislocation tangles set in. Correspondingly, we write:

$$A_d = A_{d0} (Z_d/Z_{d0})^{**1/2} \text{ if } e < e_c,$$

$$A_d = A_{d0} (Z_{dc}/Z_{d0})^{**1/2} \text{ if } e = e_c \text{ or } e > e_c,$$

where e_c is the deformation where dislocation tangles start and Z_{dc} is the corresponding dislocation density.

In Fig. 1b, modeling results for MAE are compared with experimental results. Results for both Model 1 and Model 2 are shown. Model 2 gives a much better fit.

We will present additional modeling, accounting for effects of changes in residual stress with increasing deformation. We expect to show that the decrease in the experimental MAE result beyond e_c is due to changes in the average residual stress as deformation e increases. This should be consistent with the result of Kleber [5], who shows in different materials an increase or decrease in MAE depending on whether the dominant effect is change in dislocation density or change in average residual stress.

Fluxmetric and Magnetometric Demagnetizing Factors in Cylindrical and Rectangular Geometries.

A. Vashghani Farahani, A. Konrad

Electrical and computer engineering, University of Toronto, Toronto, ON, Canada

Introduction and background

In magnetic measurements, instead of precise distributions of the internal magnetic field \mathbf{H}_i and the magnetization \mathbf{M} , one is interested in the average response of the magnetic material to the applied field \mathbf{H}_a . When \mathbf{H}_a is along one of the symmetry axes, the average demagnetizing field $\mathbf{H}_d^{\text{ave}}$ and the average magnetization \mathbf{M}^{ave} along that axis are related by the fluxmetric N_f and magnetometric N_m demagnetizing factors, $\mathbf{H}_d^{\text{ave}} = -N_{f,m} \mathbf{M}^{\text{ave}}$. To calculate N_f , the fields are averaged over the mid-plane cross section normal to \mathbf{H}_a , while to calculate N_m the fields are averaged over the whole volume of the magnetic body. The importance of rectangular and cylindrical geometries has motivated many researchers to work on accurate values of $N_{f,m}$ in these geometries. Analytic results have been found in a few special cases, but generally numerical methods are required. The most recent works on this subject appear in a series of papers [1-4] by Chen et al. These authors have developed results for the demagnetizing factors $N_{f,m}$ as a function of susceptibility χ and aspect ratio γ for both geometries, in tabular and graphical formats. Since they have assumed χ is constant and because the magnetic flux density \mathbf{B} is solenoidal, volume density of magnetic poles ρ_v is zero. Therefore the problem is reduced to finding the surface magnetic pole densities σ . The surface of the magnetic material is divided into elements and on each element σ is considered to be constant. Magnetostatic interactions of these elements leads to a set of algebraic equations that can be solved to obtain σ , which can be used to find $N_{f,m}$. Two different approaches to find N_f and N_m are used. In one of them \mathbf{M} and in the other one the demagnetizing field \mathbf{H}_d is averaged. Whenever the results are not the same, an interpolation/extrapolation technique is introduced to obtain the correct value for $N_{f,m}$. In rectangular geometries a limiting process is used to obtain $N_{f,m}$ as the number of elements N_p increases.

A different approach

This digest introduces a different approach to obtain $N_{f,m}$. The formalism considers $\chi = \chi(\mathbf{r})$ [5]. This is especially important for ferromagnetic materials where the relation between \mathbf{M} and \mathbf{H}_i is not linear. It is based on an iterative method that solves for the field distributions \mathbf{H}_i and \mathbf{M} in the magnetic material directly [6]. While in the approaches for the surface pole distribution the total number of elements is on the order of hundreds, in this approach it is on the order of 10000. Moreover, once the structure matrix (which summarizes the magnetostatic interactions between elements) for the geometry under consideration is calculated, the demagnetizing factors $N_{f,m}$ for different χ and \mathbf{H}_a can easily be obtained. Once the structure matrices for larger geometries are found, one can find the structure matrices for smaller inscribed geometries without further computation time. Another benefit of this approach is that the final results for \mathbf{H}_i and \mathbf{M} are supported by a uniqueness theorem [5]. Therefore it is possible to use the resulting $N_{f,m}$ with theoretical confidence.

Results

One can use the solutions \mathbf{M} , \mathbf{H}_d , and $\mathbf{H}_i = \mathbf{H}_a + \mathbf{H}_d$ to obtain necessary field averages on the whole magnetic body or over the mid-plane cross section. Two different equations are used to obtain $N_{f,m}$. These are the defining equation $\mathbf{H}_d^{\text{ave}} = -N_{f,m} \mathbf{M}^{\text{ave}}$ and $N_{f,m} = \mathbf{H}_a / \mathbf{M}^{\text{ave}} - 1/\chi$. To obtain this equation, $\mathbf{M} = \chi \mathbf{H}_i$ is used. In the following figures, subscripts 1 and 2 refer to these equations respectively. As the number of iterations n increases, the constitutive equation $\mathbf{M} = \chi \mathbf{H}_i$ is approached. Therefore the

solutions $N_{f,m,2}$ converge to $N_{f,m,1}$. Results for appropriate energy integral is calculated at the end of each iteration. This energy is minimized by the final unique distribution solution [5].

$\chi=0$ means a uniform \mathbf{M} . Therefore $N_{f,m,1}$ and $N_{f,m,2}$ converge very fast. Dimensions are $2a \times 2b \times 2c$. \mathbf{H}_a is along z .

Height of cylinder is L and its radius is a . \mathbf{H}_a is in axial direction. Convergence of $N_{f,m,1}$ and $N_{f,m,2}$ for $\chi=1$ is slower.

Transmutation of momentum into position in magnetic vortices.

S. Komineas¹, N. Papanicolaou²

1. Max-Planck Institute, Dresden, Germany; 2. Department of Physics, University of Crete, Heraklion, Greece

Introduction:

Magnetic vortices are magnetization configurations with a nontrivial topological structure and are thus characterized by a topological invariant. An antivortex is a configuration where the magnetization vector winds around the center in a sense opposite to that of a vortex and has been observed in a specially designed magnetic element. It is also possible to construct nontrivial magnetic configurations in the form of vortex-antivortex (VA) pairs. They play a central role in dynamical processes that lead to vortex polarity switching in ferromagnetic elements reported in recent experiments [1,2,3]. In the case of like vortex polarities, a VA pair undergoes Kelvin motion in a direction perpendicular to the line connecting the vortex and the antivortex [4], with velocity that is inversely proportional to the distance between the two vortex centers. In the case of opposite polarities, a VA pair undergoes rotational motion around a fixed guiding center [5]. As it turns out, the three-vortex process that leads to vortex-polarity switching involves both types of VA pairs and may be thought of as a composition of Kelvin and rotational motion. We will present a study for a three-vortex process in which a Kelvin pair collides against a single vortex initially at rest [6].

Vortex pair scattering:

We assume that a single vortex C is initially at rest at the origin. We further assume that a Kelvin pair consisting of a vortex (A) and an antivortex (B) is somehow created in the neighborhood of the original vortex. The AB pair will undergo Kelvin motion, we assume the case that this will be along the y axis, and eventually collide with the single vortex C. The process was simulated using the Landau-Lifshitz (LL) equation. During collision, antivortex B rotates around vortex C before rejoining its original partner A to form a new VA pair that scatters off at an angle in the third quadrant. The target vortex C is shifted to a new position in the fourth quadrant thanks to transmutation of VA pair momentum into vortex position. The scattering is slightly inelastic in the sense that the outgoing AB pair moves out with greater velocity ($v=0.15$).

The unexpected result in this numerical simulation is that the VA pair AB is scattered at an angle to the y axis which is the initial axis of propagation. In a naive approach to the problem one would think that the VA pair scattering and the corresponding change in its linear momentum does not seem to be accompanied by a corresponding change in momentum of any other object taking part in the process. This would appear to contradict the conservation of linear momentum in this conservative system.

Such a peculiar behavior can be explained (qualitatively and quantitatively) by the unusual nature of the linear momentum. The two components of linear momentum (impulse) P can be written as moments of the topological vorticity γ [7]. The latter is a key quantity which gives the skyrmion number N (multiplied by 4π) when integrated in space. It should be noted that P is actually a measure of position for an isolated vortex, it has really the meaning of linear momentum for a Kelvin VA pair. The numerical simulation of Fig. 1 shows that the linear momentum (impulse) of a VA pair is transferred to vortex impulse which is tantamount to a translation in the vortex position. A genuine transmutation of momentum into position takes place during the three-vortex collision. There-

fore, the definition of the impulse given is not only consistent with the symplectic structure of the Landau-Lifshitz equation [7] but it is indeed physically relevant.

Switching of vortex polarity:

The preceding numerical experiment was repeated for a Kelvin pair with relatively large velocity $v=0.5$. While the initial stages of the process are similar to those encountered in the case of slow Kelvin motion, as soon as antivortex B begins to rotate around the target vortex C they collide and undergo a spectacular annihilation leaving behind the vortex A which may be thought of as the target vortex C with polarity flipped (vortex core switching).

Reduction Design of Eddy Current Loss in Permanent Magnet.

J. Jung, S. Lee, J. Hong

Department of Mechanical Engineering, Hanyang University, Seoul, South Korea

1. Introduction

Interior permanent magnet synchronous motor (IPMSM) is used for traction motor and compressors because it can use both magnetic and reluctance torque and it is suitable for flux weakening control which realizes high power and wide speed range. In addition, by using the Nd-Fe-B permanent magnet (PM) in IPMSM, the maximization of the torque per unit rotor volume (TRV) and the minimization of the total size are possible.

The factors which affect the demagnetization in PM are divided into thermal, permeance coefficient and variation of external magneto motive force (MMF). Especially, demagnetization by the thermal effect is dominant because the rotor of traction motor is directly connected with the engine shaft. The eddy current loss in PM causes of the increase in temperature in PM and the high temperature decreases the performance of the PM [1]. Therefore, the eddy current loss in PM is important design factor in the design of IPMSM. In order to exactly calculate the eddy current loss in PM, transient analysis with 3-dimensional finite element method (3D FEM) is necessary. However, it requires huge computation time.

Since the flux variation usually affects the eddy current loss in PM [2], the flux variation should be minimized. Therefore, the variation of flux quantity per pole according to the change of the rotor position through 2D FEM is used and it is designated by the objective function in response surface methodology (RSM). In order to verify the validity of suggested method, optimized model is analyzed by transient analysis with 3D FEM.

2. Analysis model

The prototype is applied to the traction motor. The configuration of prototype is shown in Fig. 1. The PM of prototype is made of Nd-Fe-B magnet. Its nominal operating temperature is about 120 ~ 150deg.

3. Reduction method of eddy current loss in PM

Eddy current loss is proportional to the square of frequency and peak-peak quantity of flux variation [2]. The frequency of the flux variation per pole is determined by the combination of pole and slot number. However, peak-peak value of flux variation can be minimized by the change of geometry of the motor. Therefore, the peak-peak quantity of flux variation per pole is selected as the objective function in this paper. Fig. 2 shows comparison of the flux variation per pole in the flux weakening condition. The flux variation per pole is calculated by the difference between vector potential A_1 and A_2 as shown in Fig.1.

The value of the objective function is optimized by the magneto static analysis with 2D FEM. In the optimized model, the square of peak-peak quantity for the flux variation per pole is decreased about 40% compared with prototype as shown in Fig.2. Therefore it can be expected that eddy current loss of optimized model is decreased 40%.

4. Result and Discussion

In order to verify the suggested design method, transient analysis with 3D FEM is performed. Fig. 3 shows the configuration of the optimized model and the distribution of eddy current, respectively. The variation of eddy current loss in PM is expressed in Fig. 4. The reduction ratio of eddy current loss by 2D FEM and 3D FEM is about 40% and 50%, respectively. However, the tendency of the change of eddy current loss can be reasonably found using the suggested method in this paper.

Magnon thermalization and formation of coherent Bose-Einstein condensate.

S. O. Demokritov¹, V. E. Demidov¹, O. Dzyapko¹, G. A. Melkov², A. N. Slavin³

1. Institute for Applied Physics, University of Muenster, Muenster, Germany; 2. Department of Radiophysics, National Taras Shevchenko University of Kiev, Kiev, Ukraine; 3. Department of Physics, Oakland University, Rochester, MI

Bose-Einstein condensation (BEC) it is one of the few quantum phenomena that manifest themselves on the macroscopic scale. In particular, Bose-Einstein condensation in quasi-equilibrium ensembles of quasiparticles injected into solids using different types of pumping has recently attracted enormous attention (see, e.g., [1,2]). One of the main advantages of quasiparticles is their small mass and the possibility to pump a large number of quasiparticles, which both result in Bose-Einstein transition at relatively high temperatures. Recent observations have shown [3], that a magnon BEC can even be achieved at room temperature.

In this work we study in detail the processes in the magnon gas leading to the overpopulation of the lowest energy level of the system and prove the spontaneous coherency of the overpopulated state. The samples were cut from yttrium-iron garnet (YIG) film in the form of stripes with lateral dimensions of 1.5 mm by 30 mm. The stripes were placed into a uniform static magnetic field of $H=700-2000$ Oe. The injection of magnons was performed by means of parallel parametric pumping with a frequency of 8.1 GHz. Thus, primary magnons at a frequency $f_p=4.05$ GHz were created. The pumping field was created using a wire resonator with the diameter of 25 μm attached to the surface of the sample. The detection of magnons and their distribution over frequencies (energies) was performed by means of a time-resolved Brillouin light scattering technique [3].

For small powers below the threshold of formation of BEC, using continuous pumping we were able to study in detail the temporal characteristics of the process of redistribution of the primary magnons over the spectrum and determine the thermalization time as a function of the pumping power (see Fig. 1). We show that the redistribution of primary magnons occurs in a series of multiple scattering events [4]. The thermalization of the magnon gas to a quasi-equilibrium state is only possible for pumping powers above a certain value P_{th} . Above this threshold the thermalization time quickly decreases to 50 ns.

The spontaneous coherency of the created state has been studied using short-pulse magnon injection with the duration of 30 ns, which is smaller than the found thermalization time. The observed relaxation process is illustrated in Fig. 2, where the BLS intensity is shown as a function of the delay time with respect to the start of the pumping pulse and the magnon frequency. It is seen in the figure that, as in the case of continuous pumping, the short-pulse injection of magnons at a frequency f_p is followed by their accumulation at the frequency of the lowest magnon state f_{min} .

The studies of the decay rate for BLS intensity at f_{min} have revealed its dependence on the pumping power, showing a stepwise doubling of the decay with pumping power increasing from 2.5 to 4 W (see Fig. 3). This doubling was associated with different sensitivity of the BLS technique with respect to coherent and incoherent magnons. Since for incoherent magnons the BLS intensity is proportional to their number, and for coherent magnons it is proportional to this number squared, the doubling of the decay rate indicates an emergence of coherence in the magnon gas.

In this way our experimental data clearly show that the magnons accumulated at the lowest energy level are coherent at high enough pumping powers and this coherence emerges spontaneously if the density of magnons exceeds a certain critical value. This finding gives the direct experimental evidence of the BEC transition in a magnon gas at room temperature.

This work was supported in part by the Deutsche Forschungsgemeinschaft, US Army Research Office (MURI Grant No.W911NF-04-1-0247), and by the Science & Technology Center of Ukraine.

Critical Temperature for Thermal Runaway in a Magnetic Material.

F. Farahmand, F. P. Dawson, J. Lavers
ECE, The University of Toronto, Toronto, ON, Canada

Introduction

Magnetic devices are usually operated at elevated temperatures. However, the design must ensure that the core temperature does not exceed a critical value otherwise thermal runaway will occur. Thermal runaway implies that there is no steady-state balance between the generation of heat due to magnetic core losses and the removal of heat by radiation and convection. Estimates of the core temperature rise assuming a free convection environment and a core loss that is independent of temperature have been reported [1]. The core temperature rise that incorporates the core loss temperature dependence below the critical temperature has also been reported [2]. However, no attempt has yet been made in determining the critical temperature. This paper provides an analytical approach for calculating the critical core temperature. The core loss, as provided by manufacturers, is expressed as a quadratic function of temperature. The impact of the ambient temperature and winding losses on the critical core temperature is also included in the analysis.

Computing critical temperature

At the steady state temperature, losses generated in a magnetic component are balanced by heat which is dissipated from the component. The generation of loss can be defined as a function of temperature as follows:

$$Q_{gen} = Q_{cu} + Q_{core} = Q_{cu} + C_q \times (C_{t1} \times T_{core}^2 - C_{t1} \times T_{core} + C_{t0}) \quad (1)$$

Similarly, the dissipation of loss by convection is given by:

$$Q_{dis} = h \times A_{cnv} \times (T_s - T_{amb}) \quad (2)$$

In (1) and (2), Q_{gen} , Q_{dis} , Q_{cu} and Q_{core} are the generated loss, the dissipated loss, the winding loss and the core loss respectively; T_{core} is the mean temperature in the core; T_s is the mean temperature on the surface; T_{amb} is the ambient temperature; h is the effective convection coefficient; A_{cnv} is the convective area; C_q is a factor which depends on the frequency, flux density and the volume of the core and C_{t0} , C_{t1} and C_{t2} are constants for a given magnetic material.

The largest impact of the loss – temperature dependence in the core can be obtained assuming that $Q_{cu} = 0$ and $T_{core} = T_s$. Using these assumptions, Figure 1 shows the graphs of normalized Q_{gen} (blue line) and Q_{dis} . The following modes of operation are distinguished in Figure 1: (i) normal operation for which Q_{dis} intercepts Q_{gen} (green line); (ii) runaway for which Q_{dis} does not intersect Q_{gen} (cyan line) and (iii) the critical operation for which Q_{dis} is tangent to Q_{gen} (red line). The temperature obtained from the latter mode of operation is the critical temperature above which thermal runaway occurs.

These modes of operation are discussed in the full paper. The full paper also discusses the impact of the ambient temperature and winding losses on the critical temperature. A rise in the ambient temperature increases the critical temperature. However, the temperature rise of the core at the critical temperature is reduced. A winding loss of Q_{cu} displaces the loss – temperature curve to the right by a value equal to Q_{cu}/C_q . This results in an increase in the critical temperature.

Introduction

In continuous casting process of steel billet, in-Mold ElectroMagnetic Stirring (M-EMS) is often used for making high quality steel. M-EMS is effective to prevent entrapment of nonmetallic inclusions to solidified shell and to increase fine equiaxed structure. However deformation of free surface caused by M-EMS promotes engulfment of mold powder to the molten steel and gives bad effects to quality of steel. To resolve this issue, application of Double-Axis ElectroMagnetic Stirring (DAEMS) in continuous casting is investigated. DAEMS is composed of a rotational and a vertical EMS [1]. Vertical EMS suppresses the deformation of the free surface caused by rotational EMS and DAEMS can generate strong electromagnetic force without free surface deformation. Therefore intensity balance between rotational EMS and vertical EMS is important. In this study, basic characteristic of DAEMS is investigated with varying the vertical EMS force intensity and with keeping rotational EMS force constant by means of unsteady three-dimensional magnetohydrodynamic calculation [2] of continuous casting model using molten gallium.

Evaluation by means of numerical analysis

Continuous casting model of round steel billet using molten gallium is designed by using Re and Fr approximation. In this study, round shape model is transformed to square model (Fig. 1) with equivalent area in order to simplify the problem. To investigate the influence of vertical stirring intensity, the current applied to vertical EMS is varied from 0 to 4606 A^{rms}T with keeping rotational stirring constant.

In continuous casting process, the free surface stability is important to prevent the engulfment of mold powder to the molten steel. To evaluate the free surface stability, the averaged standard deviation of the free surface height σ is defined as equation (1). σ is considered to be an index of instability of free surface and large σ means that the free surface becomes instable.

$$\sigma = \Sigma (\sigma_i S_i / S) \quad (1)$$

Where, σ_i and S_i are the standard deviation of free surface height and cross sectional area of each cell respectively. S is cross sectional area of billet. From Fig.2, it is found that there is an optimum vertical stirring intensity from the view of meniscus stability. It is considered that there are three phenomena (Fig.3) depending on the vertical stirring intensity. Upward spiral flow caused by rotational-EMS generates instability of the free surface at A in Fig.2 [3]. Moderate vertical stirring force cancels this spiral flow and stabilizes the free surface at B in Fig.2. On the other hand, an excessive vertical stirring generates reversal flow under the free surface and causes instability of free surface at C in Fig.2.

Diamagnetic levitation of solids at micro scale.

C. Pigot, G. Poulin, R. Gilbert
Magnetic Microsystems, G2ELab, Grenoble, France

Friction is one of the major limitations of micro- and nano-systems. An original solution based on diamagnetic levitation is proposed. Diamagnetic media are repulsed by strong magnetic fields. Static levitation at microscale can be obtained at room temperature, with no supplied energy, no feedback loop nor superconductors. Successful levitation of bismuth, silicon and copper on integrated micro-magnets, was demonstrated both theoretically and experimentally.

As a simple solution is aimed, permanent magnets are used to achieve levitation. They provide everlasting permanent magnetic fields with no supply. Tough, diamagnetic forces are very weak. For instance, at millimetre scale, only a few grams of the best diamagnetic material can be made levitated and only with the strongest available magnets. Therefore this kind of levitation is seldom used. Diamagnetic volume forces are in proportion to the susceptibility of the materials, the magnetic field and its gradients. A way to increase these forces is to increase the gradients by reducing the size of the whole system, that is to say the size of the particle and the magnets. Effectively, as the size of a magnet is reduced, the field map is homothetically reduced. The value and the direction of the radiated field remain the same, but the gradient increase in proportion to the scale reduction. To sum up, the volume diamagnetic forces increase in proportion to the scale reduction. Since the density is constant at any scale, the diamagnetic forces are in the same order of magnitude than weight when the size of the system is some tens of micrometers.

First, the behaviour of a spherical particle of bismuth in air is considered. This particle has a diameter of $10\text{ }\mu\text{m}$ and a magnetic susceptibility of $160 \cdot 10^{-6}$. The magnets are infinitely long rails separated by a $45\text{ }\mu\text{m}$ gap. These NeFeB magnets are $50\text{ }\mu\text{m}$ large and $30\text{ }\mu\text{m}$ thick and present a measured remanence of 1.4 T . Fig 1 shows the total energy, sum of the gravitational and magnetic energies, in a plan perpendicular to the long dimension of the magnets. The total energy is minimum when the particle is some $10\text{ }\mu\text{m}$ above the surface of the magnets, in the middle of the gap, this position being a stable position.

The studied structure was then realised through adapted micro-system processes. A silicon wafer is etched with deep RIE. The magnetic layer is then high rate sputtered above the whole wafer and follows the pattern of the underlying wafer. Particles of bismuth are then spread over the magnetic arrays and observed with an optical microscope. Images such as Fig. 2 are obtained. All the bismuth particles are subject to the influence of the magnets. As shown Fig.1, the energy of the diamagnetic particles is maximum near the edges of the magnets and quickly decreases with the distance. The diamagnetic particles that are above the gap do levitate. Despite the use of non-spherical particles in real experiments, theory is fully validated. The levitating particles can also levitate on a long distance, up to 1 mm , in a direction parallel to the magnet, strongly guided by the rails. The particles that are above the magnets stick on the magnet, but are aligned along the medium axis of the rails. Further tests were performed with other materials such as silicon and copper. As their susceptibility is lower, they need either to be levitated in paramagnetic water or tested at smaller dimensions. In paramagnetic liquid, as tested, the particles are submitted to two added forces: the Archimede force and the magneto-archimede force. Archimede force results from the difference of density between the particles and the surrounding media. Magneto-Archimede force is due to their difference of susceptibility. The paramagnetic media is attracted by the magnets. It then applies a 'magnetic' Archimede force that repels the particle with lower susceptibility from the magnetic sources.

This allows the 'levitation' in liquid, that we may call 'confinement' of dense material (copper) or weak diamagnetic material (silicon), as shown Fig 3.

Diamagnetic levitation of solid is actually demonstrated at micrometric scale with thick integrated magnets. Scale reduction laws allow the levitation of material in air. Material with low susceptibility (silicon) and high density (copper) can be confined in paramagnetic milieu. This opens a wide range of applications in sensors, actuators or material micro-handling.

Construction of Quasi-Cyclic LDPC Codes and the Performance over Magnetic Recording Channels.

X. Liu¹, H. Cheng¹, Z. Wang²

Abstract: A novel algorithm for constructing Quasi-Cyclic low density parity check (QC-LDPC) codes is proposed. The experiment results show that the proposed QC-LDPC codes are superior in error-correction performance to other codes applied to the AWGN and magnetic recording channels.

1 Introduction

Low-density parity check (LDPC) codes, originally proposed by Gallager in 1962, were rediscovered by Mackay and Neal in 1996. Similar to Turbo codes, LDPC codes are also a class of Shannon limit approaching codes when decoding with the soft-decision belief propagation algorithms such as sum-product algorithm. The Quasi-Cyclic LDPC code is a class of code which can reduce the complexity of encoding and decoding, and lower the requirements of memory. These codes can be encoded with simple shift registers and decoded in parallel. At present, most QC LDPC codes are constructed based on geometry and algebra theories. However, the codeword length and code rate defined by the parity-check matrices constructed with these theories and the corresponding design rules are restricted by the parity-check matrix, can not be pre-defined and chosen. So the code parameters can not be chosen flexibly. Considering such factors as the error-correction performance, complexity of encoding and decoding, implementation with hardware and parameters choice, a novel algorithm for constructing QC-LDPC codes of flexible code length and code rate is proposed.

2 Construction of QC-LDPC Codes

Parity-check matrix of QC-LDPC codes can be constructed as follows. Firstly, two matrices are set as follows:

where, . If a parity-check matrix of dimension is required constructing with the circulant sub-matrices of dimension, the parameters c and t can be computed according to the expressions $c = m/L$ and $t = n/L$. Then, the mother matrix of dimension can be put in shape based on the PEG algorithm. The matrix (and the parity-check matrix H) that is constructed in this way has a large girth.

As for the shift-times matrix P , it can be expressed by

where, a_{ij} is known and defined in matrix, p_{ij} is the element defined in matrix, i is the row index in the matrix M , and z is defined as the sequence number, beginning with 0, of occurrences of the element '1' at each row of matrix where $a_{ij} = 1$. For example, z is equal to 0 at the first occurrence of '1' at each row, to 1 at the second occurrence of '1' at each row, and so on. So, z is equal to $k-1$ if the element '1' occurs at the k -th occurrence at each row.

Assume that a parity-check matrix is to be constructed on condition of the codeword length $n=48$, parity-check bits length $m=32$ and sub-matrix dimension $L=8$. With the above parameters, the matrix can be constructed with dimension computed as and $t=n/L=6$.

After the matrices are obtained, the parity-check matrix can be constructed through replacing each element '0' in matrix with a full-zero matrix of dimension $L \times L = 8 \times 8$ and each element '1' in matrix with a circulant permutation matrix of dimension $L \times L = 8 \times 8$ according to the rules predefined. The so constructed parity-check matrix, H , has the property of 'Quasi-Cyclic' and flexible

matrix-parameters because different QC parity-check matrices can be constructed by modifying the codeword length n , the parity-check bits length m and the sub-matrix dimension .

3 Simulation Results

In our simulation, three groups of codes with different codeword lengths are constructed, the parameters (n, m) of which are $(1008, 504)$, $(504, 252)$, and $(256, 128)$, respectively. Simulations are carried out with the BPSK modulation over the Gaussian noise AWGN channels and the magnetic recording channels. The comparison of the BER/FER performance between the QC-LDPC codes based on the proposed algorithm and the random LDPC codes generated by the original PEG algorithm is shown in Figs. 1-4, where different code word parameters are employed and the AWGN channels are employed (the results over the magnetic channels are ignored due to the limited 2 pages).

Fig. 1 BER/FER performance of code Fig. 2 BER/FER performance of code

Fig. 3 Performance of (1008, 504) code Fig. 4 Performance of (1008, 504) code at different iterations

4 Conclusion

This paper proposes a novel construction method of QC-LDPC codes based on the PEG algorithm. Simulation shows that the proposed codes have almost the same performance as the codes constructed with the random PEG algorithm. The proposed codes are easy to be implemented with hardware because of the quasi-cyclic structure of the codes. In addition, the parameters of the codes are flexible to be adjusted and the codes are applicable to applications compared to the codes generated by other methods of geometry and algebra.

A Novel Electromagnetic Device for Latching Valve in Automotive Engine.

J. Kim¹, J. Chang²

1. Mechanical Engineering, Yeungnam University, Gyeongsan, South Korea; 2. Transverse Flux Machines Research Group, Korea Electrotechnology Research Institute, Changwon, South Korea

One of the most promising way to improve fuel economy, reduce CO₂ emissions and increase torque output in internal combustion engine is to achieve variable valve timing (VVT)[1][2]. Here, we propose a novel electromagnetic valve drive system to achieve VVT, and discuss the design, finite element analysis and construction of the experimental apparatus. New engine valve system is composed of cam, springs (cam spring, disable spring and valve spring), spring latches, ring holders for springs, and engine valve. Fig. 1 shows the schematic diagram of actuator. The engine valve is operated by the rotation of cam, spring force and timed control of latches. First, the cam lobe compresses the cam spring. The cam spring stretches the disable spring and the disable spring compresses the valve spring and opens the valve. Timed release of ring controls energy delivered to the latch of valve spring and partially compresses the cam spring but, it does not has force to lock the disable latch. The valve spring opens and stretches the disable spring which then compresses the cam spring and latches the disable spring. The other lobe decelerates the cam spring and returns energy to camshaft. Variable valve timing can be accomplished by timed control of electromagnetic latches. Fig. 2 shows the schematic diagram of electromagnetic latch system. It consists of steel-made arms, compression spring, pivot and solenoid which is composed of coil and steel-made core. If coil is not energized, the disk on the valve stem can move up and down because the latch of arm is opened by spring force. If the current is applied to coil, the solenoid attracts the arm and the arm latches the disk. To prove the concept of the proposed electromagnetic engine valve system, an experimental apparatus was designed and constructed which are shown in Fig. 3 and the characteristics are measured. In addition, 2-D symmetric static finite element analysis (FEA) are performed. One of result of experiments and FEA, the attractive latching force is shown in fig. 4.

Air gap's influence on the performance of the transformer of an electromagnetic pump.

D. Morinigo^{2,1}, M. A. Rodríguez^{1,2}, A. Rivas¹, J. Martín¹

1. Light Alloys, CIDAUT Foundation, Valladolid, Spain; 2. Electrical Engineering, University of Valladolid, Valladolid, Spain

INTRODUCTION: An electromagnetic pump (EP) is a MHD device to drive molten metals by means of electromagnetic fields and without mechanical parts in contact with them [1]. The studied EP (Fig1) is made up of two elements series-connected: a transformer and a C-shaped electromagnet. The secondary of the transformer is a channel, containing a molten metal encased in electrically nonconducting ceramic walls (not shown in Fig1). When the primary coil is fed with a 1-phase AC voltage, an electric current density J is induced in the molten metal (Fig1b). The electromagnet produces a B field in a specific section of the channel (slot) and perpendicular to the induced J (Fig1c). The cross product of the J and B fields in the molten metal produces a 3D field of electromagnetic volumetric forces, distributed along the channel, which provides the pumping action on the molten metal. The total pressure developed by the EP is assumed to be proportional to the electrical current consumed by the EP to the second power. The control system that runs this EP was designed considering this relationship. This pump is used in a metallurgical process to produce automotive aluminium components [2]. Due to the difficulty in the assembly of the EP, the core of the transformer is divided into two parts, between which an airgap exists (Figure 2). The top U-shaped part rests on the bottom I-shaped part. The vibrational magnetic force that appears between this two sections when the primary coil is fed with an AC voltage is the cause of variations in the gap's length. The aim of this paper is to show the results of an experimental work carried out to demonstrate and study the influence of the length of the gap on the performance of the EP, which had been previously observed in real conditions in a foundry plant. As the airgap length increases, the magnetizing current also increases, and the pumping effect no longer is proportional to the consumed current to the second power, besides other negative effects.

EXPERIMENTAL TESTS AND RESULTS: To evaluate the effect of the gap's length, a number of traditional transformer no-load tests were performed at different lengths of the gap: Regular gap (RG), RG+0.2mm, RG+0.4mm, RG+0.6mm. By RG means the gap that exists when the top U-part rests on the bottom I-part. In all experimental tests, the electrical current and the voltage were registered using a PC-based DAQ. These two sets of data allowed us to calculate the parameters of the electric equivalent circuit of the transformer: Magnetizing reactance (X_μ) and Resistance equivalent to iron losses. Results are shown in Fig3. In Fig3a, the supply voltage of the no-load test is represented vs the consumed current for different lengths of the non-electromagnetic gap. This curve resembles a saturation curve because supply voltage is proportional to magnetic flux and current is proportional to magnetic field intensity. It is easy to conclude that, in order to keep the magnetic flux level in the core, a higher current is needed as gap length increases. The higher the gap is, the higher the current consumed by the transformer is. Saturation of the core is reached sooner for smaller lengths of the gap. When the gap is high, its magnetic reluctance is bigger than core's reluctance. This causes the saturation curve to lean to the right. In Fig3b it is represented the calculated X_μ vs supply voltage for different gap lengths. From Fig3 it can be observed that X_μ depends heavily on the gap length for low voltages and is bigger also for low voltages, and the value of X_μ drops dramatically as supply voltage increases, or a saturation level is reached. Fig3 shows the great influence of the gap on the performance of the transformer of the pump. All observed effects on the operation of the pump, by lab experimentation and real operation in a foundry plant, are negative. The gap means, above all, higher magnetizing current to keep the necessary magnet-

ic flux level in the transformer core. This high magnetizing current does not contribute to the creation of the output pressure on the molten metal and helps to saturate the core. Another side effect is the increment of the consumed power to produce the same output pressure and flow rate and therefore reducing the efficiency of the pump.

A New Calibration Procedure for Magnetic Tracking Systems.

A. Plotkin¹, V. Kucher¹, Y. Horen², E. Paperno¹

1. *Electrical and Computer Engineering, Ben-Gurion University of the Negev, Beer-Sheva, Israel;* 2. *Electrical and Electronic Engineering, Shamoon College of Engineering, Beer-Sheva, Israel*

The maximum possible accuracy of a magnetic tracking system (see Fig. 1) cannot be achieved without an efficient calibration procedure. However, it is a nontrivial task due to a large number of system parameters that has to be calibrated. These parameters include the magnetic positions of the transmitting coils, their magnetic moments, the magnetic position of the sensor, its sensitivity, and the gain of the sensor output amplifier.

According to the conventional approach [1], all the above parameters are calibrated individually [1]. This is not efficient because a large number of individual calibrations require many calibration setups. Individual independent calibrations also cause the accumulation of errors. Another principal disadvantage of the conventional approach is in its inapplicability to the assembled system. Thus, it does not consider the assembling tolerances.

In this work, we suggest a new approach that allows us to calibrate the entire system in a single setting. We calibrate all the parameters simultaneously by solving a system of equations. The constants in these equations are the parameters that define the origin, orientation, and scale of the reference coordinate frame and the sensor output acquired at different sensor positions. The unknowns are all the other systems parameters.

To define the origin and orientation of the reference frame (see Fig. 1), we first relate it to a mechanical object, for example to the housing of the transmitting array. We then use special mechanical supports to align the sensor with the edges of the transmitter housing.

To define the scale of the coordinate frame, we measure the distance between two arbitrary sensor locations with a precise tool (a caliper). This is the only external measuring tool that is involved in the entire calibration procedure.

To complete the calibration procedure, we place the sensor in a number of arbitrary positions to provide the uniqueness of the solution of the above system of equations.

To illustrate the efficiency of the suggested approach, we applied the calibration procedure to a magnetic tracking system employing 64 transmitting coils [2]. We first accurately defined a linear sensor trajectory (see the dashed line in Fig. 2) by moving it with the help of a specially designed mechanical slider. We then compared the sensor trajectories measured by the tracking system before (the grey circles in Fig. 2) and after applying the calibration (the black circles in Fig. 2).

We relate the large tracking errors in the first case to the difference between the magnetic and geometric positions of the transmitting coils (see Fig. 1) and the difference between the theoretical and true magnetic moments. These differences are caused by the non-ideality of the transmitting coils winding.

The suggested approach is generic and can be applied to many different types of tracking systems. It minimizes the number of calibration setups, simplifies the calibration procedure, and increases its accuracy. It is applied to the assembled system and does consider the assembling tolerances. All the system parameters can be calibrated not only by the system manufactures but also by the users.

Microstructural changes in Fe-doped $\text{Gd}_5\text{Si}_2\text{Ge}_2$

B. Podmiljsak¹, I. Skulj², B. Markoli³, P. McGuinness¹, S. Kobe¹

1. Jozef Stefan Institute, Ljubljana, Slovenia; 2. Institute of Metals and Technology, Ljubljana, Slovenia; 3. University of Ljubljana, Ljubljana, Slovenia

$\text{Gd}_5\text{Si}_2\text{Ge}_2$ -based alloys can exhibit a giant magnetocaloric effect (MCE); this gives them the potential for use in cooling and refrigeration technologies. The temperature at which the magnetocaloric effect is observed can be easily adjusted between ~190 and 300 K by varying the chemical composition [1].

It is generally accepted that the giant magnetocaloric effect in $\text{Gd}_5\text{Si}_2\text{Ge}_2$ -type alloys involves a magnetic-field-induced crystallographic structural change from the high-temperature monoclinic paramagnetic phase to the low-temperature orthorhombic ferromagnetic phase [2]. The problem here is the large hysteretic losses that occur in the same temperature range as the GMCE [3]. Provenzano et al [4] reported that a small amount of iron (substituting for 5 per cent of the germanium) reduced the hysteretic losses by more than 90 per cent. It also shifted the magnetic entropy peak from 275 K to 305 K and broadened its width.

In this investigation we have looked at the effect on the microstructure of $\text{Gd}_5\text{Si}_2\text{Ge}_2$ resulting from a substitution of Si by Fe, according to the formula $\text{Gd}_5\text{Si}_{(2-x)}\text{Fe}_x\text{Ge}_2$, with $x = 0, 0.125, 0.25, 0.5, 0.75$ and 1.

The electron microscopy secondary-electron images (Figure 1) show that the surface changed from one exhibiting regular pentagons and hexagons, reminiscent of a buckyball ($x = 0$), to a surface with a sinew effect, rather like columnar grains running at angles to each other ($x = 0.5$), to a smooth upper surface, much more characteristic of an intermetallic arc-melted button ($x = 1$). The formations – the buckyballs and the sinews – are clearly related to the cooling rate, which is very fast in such a system, but the very small amounts of iron are clearly the decisive factor.

Optical micrographs show that all the samples are composed of multi-phase structures. The composition with no iron consists of the $\text{Gd}_5(\text{Si,Ge})_4$ matrix phase and a grain-boundary phase. A new matrix phase appears with the addition of iron. The composition of this new matrix phase suggests that it is a $\text{Gd}_5(\text{Si,Ge})_3$ -type phase. With increasing amounts of added iron the amount of original matrix phase is seen to decrease until it disappears completely in the sample with $x = 1$, the point where half of the silicon is replaced by iron. Three different grain-boundary phases were identified. The grain-boundary phase found in sample $x = 0$ is not significantly different from that of the matrix phase, and this phase is only present in this sample. With the addition of iron a second grain-boundary phase appears. The composition of this phase does not vary with increasing amounts of added Fe, and the ratio for Gd:Si:Fe is approximately 1:1:1. A third grain-boundary phase starts forming in the structure of the samples when x becomes larger than 0.5.

The magnetic measurements (Figure 2) show that with the increasing amount of iron we have a continuous decrease of the magnetic transition temperature, with the T_c falling from 300 K for $x = 0$ to below 100 K for the $x = 1$ sample. The maximum values of ΔS follow the Curie temperatures and tend to decrease in line with the amount of iron. Sample $x = 0.125$ has the maximum ΔS value, equal to almost 10 J/kgK for a field change of 1.5 Tesla.

From our results we are able to conclude that $\text{Gd}_5\text{Si}_{(2-x)}\text{Fe}_x\text{Ge}_2$ alloys where x varies between 0 and 1 show very significant differences in terms of both their macrostructures and microstructures. The original matrix phase with the $\text{Gd}_5(\text{Si,Ge})_4$ composition when $x = 0$ becomes a new matrix phase with the $\text{Gd}_5(\text{Si,Ge})_3$ composition when $x = 1$. However, the iron contributes mainly to the grain-boundary phases that are formed.

Stress-strain relationship of magnetorheological fluids under tension mode.

S. A. Mazlan, N. B. Ekreem, A. G. Olabi

School of Mechanical and Manufacturing Engineering, Dublin City University, Dublin, Ireland

A magnetorheological (MR) fluid comprising micron-sized particles and a carrier liquid which has a unique ability to transform from liquid to solid, reversible and controllable, as a function of magnetic field strength. Tension in a squeeze mode is as an operational mode where two flat parallel surfaces, stand opposite each other, are pulled against each other by an external force, acting at the path of the magnetic flux lines. In the absence of the magnetic field, the particles initially in the space between two walls are unrestrained to move and are dispersed throughout the carrier medium. In the presence of the magnetic field, the particles are organized along the direction of the applied magnetic field; constructed into a uniform polarity and connected to the walls [1].

A tension apparatus was based on the same basic concept to that used for investigating MR fluid under compression mode done by us in the previous study [2]. The tension experiments were performed to determine the stress-strain curve behaviour of MR fluids under different initial gap sizes and tensile speeds. MRF-241ES (water-based MR fluid) and MRF-122-2ED (hydrocarbon-based MR fluid) were used in this investigation, supplied by Lord Corporation. The gap size was set initially to 1.0 mm, and 1.6 Amps of applied current value was maintained throughout the experiment. This was followed by pulling up the upper cylinder at various constant speeds of 0.5, 1.0, 1.5 and 2.0 mm/min, and simultaneously the load and displacement were recorded. The same sequence of the procedure was carried out in the second and third experiments, except that the initial gap size was set to 2.0 mm.

Stress-strain relationship of MR fluids under different initial gap sizes is depicted in Fig. 1. As can be seen, at 2.0 mm of the initial gap size, the values of the tensile stress are constantly smaller the values of tensile stress at 1.0 mm of initial gap size. Furthermore, MRF-241ES has showed a higher tensile stress as compared to MRF-122-2ED at the same initial gap size.

In another observation, the values of the tensile stress almost the same at different tensile speeds at constant applied current (1.6 mm/min) and initial gap sizes (1.0 and 2.0 mm). The stress-strain curves were observed to be well overlapped on each other as shown in Fig. 2.

The tension process of MR fluids showed similar trends notwithstanding that the initial gap size was varied from 1.0 to 2.0 mm and the tensile speeds ranged between 0.5 to 2.0 mm/min, depending on the type of carrier fluid. The stress-strain relationship during tension process can be divided into type 1 and 2. At a constant current, tensile behaviour of MRF-241ES showed different trends with the tensile behaviour of MRF-122-2ED for both initial gap sizes. Tian et al. found that the tensile behaviour of Electrorheological (ER) fluid depends on the strength of the external field [3]. The same tensile behaviour of MRF-241ES (type 1) and MRF-122-2ED (type 2) have been observed with the tensile behaviour of ER fluid at 0.6 kV and 0.4 kV of electric field, respectively. However, the values of tensile stress of MR fluids are higher than the tensile stress obtained in ER fluid.

This study showed that tensile behaviour is greatly affected by the type of carrier fluid which is highly dependent on its magnetic properties. Similar trends have been observed at different initial gap sizes. Higher values of tensile stress of MR fluid can be obtained at a lower initial gap size. Experimental results also revealed that the behaviour of MR fluids is not influenced by tensile speed.

Novel magnetic composite particles of carbonyl iron embedded in polystyrene and their magnetorheological characteristics.

F. Fang, H. Choi

Department of Polymer Science and Engineering, Inha University, Incheon, South Korea

Introduction

Magnetorheological (MR) fluids, named as fantastic and intelligent fluids, are capable of being solidified with an aid of an external magnetic field and re-liquefied by removing the magnetic field. This abrupt state-changing process which causes distinctive rheological properties has great potential in designing diverse high performance engineering products including active damper, torque transducer and MR polishing equipment [1-2]. Generally, high yield stress and low apparent viscosity without magnetic field as well as good stability and durability have become very crucial factors for the MR fluid application. Among various magnetic materials (magnetite, maghemite, carbonyl iron etc), carbonyl iron (CI) particles have been adopted as a superior candidate for MR fluids due to their high saturation magnetization as well as appropriate particle size [3-4]. However, the large density mismatch between CI particles and medium oil leads to serious sedimentation drawback. Therefore, many strategies have been explored to solve this problem [5-7]. In this study, we fabricated novel magnetic CI/polystyrene (CI/PS) composite via facile solvent casting method. The CI particles were found to be embedded within PS matrix, by which way prevent them contacting each other directly, consequently improving stability of the CI suspension.

Experimental

A facile solvent casting method was employed to prepare the CI/PS composite particles with spherical shape. Commercially purchased PS was dissolved in chloroform by sonication for about 3h at first. CI particles (particle size of 4.5~5.2 micron in diameter and 7.86 g/cm³ of density) were transferred into the above-prepared PS/chloroform solution and then quickly added into a water phase containing poly(vinyl alcohol) (PVA) and sodium dodecylsulphate (SDS) as a stabilizer and an emulsifier, respectively. The whole dispersion was energetically stirred at 500rpm for 12h. The obtained composite particles were washed with deionized water, dried at 60 degree C for 24h and finally dispersed in lubricant oil (Yubase 8 oil, SK Corp., Korea) to prepare MR fluid.

Information on morphology, density, composition and magnetic property was investigated via SEM, pycnometer, TGA and VSM, respectively. MR characterizations were performed at 20°C via a rotational rheometer (Physica MCR 300, Stuttgart, Germany) equipped with a MR device (MRD 180).

Results and Discussion

Figure 1 shows characteristic morphologies of the fabricated CI/PS composite particles. It is apparent that many CI particles are separately embedded in spherical PS matrix. Besides this, we can also assume that there must be several CI particles within the inner of PS spheres. Average size of the CI/PS composite particles was about 50µm which is much larger than individual CI particles.

MR characteristics of the CI/PS based suspension were examined via rotational and oscillation test modes. Figure 2 describes shear stress curves as a function of shear rate with and without a magnetic field. Dynamic yield stress was found to be enhanced by increasing magnetic field strength. Although the CI/PS particle based MR fluid exhibited relative lower stress value than that of pure CI suspension due to the introduction of non-magnetic PS matrix, it still represents an ordinary plateau region for the whole range of applied shear rate when the magnetic field was applied [6-7]. Without magnetic field, the MR fluid showed a Newtonian fluid behavior. In addition, the oscilla-

tion test was made to investigate the viscoelastic performances of the CI/PS suspension under a small deformation.

Finally dispersion stability of the MR fluid was found to be sustained, which may be attributed to the little difference in density between the continuous phase (density: 0.96 g/cm³) and the CI/PS particles (density: 2.5 g/cm³) detected by a pycnometer.

Barkhausen noise statistical properties in ferromagnetic thin films: dimensionality and range of the relevant interactions.

F. Bohn¹, M. A. Corrêa^{2,1}, A. Viegas³, L. F. Schelp¹, R. L. Sommer⁴

Barkhausen noise (BN) corresponds to the voltage pulses induced in a sensing coil wound around a ferromagnetic material when it is submitted to a variable magnetic field. BN is a measure of the complex microscopic magnetization process and, for this reason, it is used to characterize soft magnetic materials. Most of the studies were aimed to explain the statistical properties of BN such as the power law distributions of Barkhausen jump sizes and durations which present exponents, τ and α , respectively. These power laws are understood as the fingerprint of a critical behavior of the magnetization process. Statistical properties suggest a behavior independent of microscopic and macroscopic details, where just few general properties as the system as the dimensionality and range of the relevant interactions are needed to define the dynamical behavior of these systems. For bulk materials, Durin et. al.¹ suggested that the jump sizes distributions exponents can be grouped in two universality classes: $\tau=1.50\pm0.05$ and $\tau=1.27\pm0.03$. The first class includes the polycrystalline and partially crystallized amorphous alloys and it is associated to a dynamics governed by long-range interactions. The second one includes the amorphous alloys under stress and it is related to short-range interactions. The exponents for the jump durations distributions are $\alpha=2.0\pm0.2$ and $\alpha=1.5\pm0.1$, respectively, a behavior owed to the same short-long range character for the interactions governing domain walls (DWs) dynamics. For two-dimensional systems, $d=2$, the results are less clear due to experimental and theoretical difficulties. Theoretical models and simulations indicate that two and three-dimensional systems present distinctive exponents. Vásquez et. al.² approached the long-range interaction problem and predicted $\tau=1.33$ and $\alpha=1.5$, $d=2$, and $\tau=1.5$ and $\alpha=2$, $d=3$. Moreover, Queiroz³ studied the short-range single-interface model, neglecting long-range dipolar interaction, and predicted $\tau=1.06$, $d=2$, and $\tau=1.275$, $d=3$. On the experimental side, in the case of thin films, the study of the BN statistical properties is rather complicated because of the typical low signal levels. Although the exponents obtained for films are smaller than that obtained for bulk samples, even considering the thinner films reported to date, a true dimensional transition has not been observed.

In this work, we investigate the BN statistical properties in amorphous and polycrystalline ferromagnetic thin films, thickness range 10-1000 nm, in order to understand the effects of the interplay between the system dimensionality and the range of the relevant interactions governing the DWs and magnetization dynamics. The exponents obtained from the experimental distributions of jump sizes and durations, are compared with the ones predicted by the two and three-dimensional theoretical models. Selected results are shown in the figures below that display the general behavior of the experimental τ and α exponents as a function of thickness for amorphous $\text{Co}_{77}\text{Fe}_{23}$ and polycrystalline $\text{Ni}_{81}\text{Fe}_{19}$ films. The dashed lines indicate τ and α , related to the two universality classes¹ and the solid ones are the limits of the error bars. The key to understand the noise statistical properties in ferromagnetic thin films resides basically in the combination of the effects of system dimensionality and range of relevant interactions. For films thicker 50 nm, the exponents are very similar to the values observed for several bulk soft magnetic (split in two universality classes mentioned above). Irrespective to the thickness and intense modifications of the magnetic behavior,

observed in magnetization curves, for amorphous $\tau\sim 1.3$ and $\alpha\sim 1.5$, while for polycrystalline thin films $\tau\sim 1.48$ and $\alpha\sim 2$, which are in accordance with the predictions of ref.1, a clear indication that the films in this range of thickness present a typical three-dimensional magnetic behavior. The most striking feature is observed for films thinner than 50 nm, where the exponents decrease to $\tau\sim 1.07$ and $\alpha\sim 1.05$, for amorphous, and $\tau\sim 1.35$ and $\alpha\sim 1.5$ for polycrystalline films, values in a very good agreement with theoretical predictions for systems with two-dimensional magnetic behavior. We interpret the crossover of the experimental exponents as a clear indication of a dimensional transition of the magnetic behavior from a three to a two-dimensional magnetic character. We believe that this dimensional transition, around 50 nm, is mainly associated with the transformation of DWs from Bloch to Néel structures as the thickness is reduced. Thus, our results provide experimental evidences for the validity of the cited proposed models and indicate that the DWs dynamics and noise statistical properties are strongly affected by the system dimensionality and range of the relevant interactions.

Coloring media by using nanopipette to store more data.

M. Rashidi, F. Wang

Centre for Grid Computing, Cambridge-Cranfield HPCF, Cranfield, United Kingdom

1. Principle

Storage capacity can be increased greatly if one stored data is stored in 3D, i.e. by using the color of the media to store more information. As shown in Fig.1, eight colors are recognizable by overlapping dots to additively form a color from the three primary colors as well as the black color. For any specific color recognized by the “scanner”, the presence/absence of each primary color can be uniquely determined.

If every pixel represents a 3-bit color then each “super bit” could represent $2^3 = 8$ values. In the simplest scenario, a dot equaling 3 bits provides tripled capacity, compared with the 2D base case. This way of encoding information could be used to store much more information on CD-Audio, CD-ROM, DVD-Video and DVD-ROM media, which are volume produced through the injection molding process and may become fashionable again in the future, using nano-scale technology. The world’s smallest pipette is capable of dispensing droplets with a volume of a billionth of a trillionth of a litre [1]. This pipette and its related devices can be used to inject “ink” to color the media. The controlled delivery and manipulation of well-defined fluid volumes would be the key process in the above colorful storage system. Magnetic color particles $\alpha\gamma\text{-Fe}_2\text{O}_3$, whose diameter is about 20 nm [2], have been chosen as the coloring agent since they are stable against heat and light and do not fade or discolor for a long period of time. Because of the fineness of the magnetic particles, their transparency is good and the color emitted is clear and easily identifiable.

A focused laser beam is used in either writing or reading. To reliably and accurately scan one of multiple colors, one would need the “writer” and the “reader” set to use exactly the same color wavelength ranges. The bits are read by illuminating the disk with an optical stylus. Colors are identified by variations in the reflected light.

2. Experimental Demonstration

A prototype is being constructed at our lab (Fig.2). The binary digits are encoded to colors, with a minimum pixel size of $5.3\ \mu\text{m}$ (accordingly a 512×512 pixel array and a die size of $2.7 \times 2.7\ \text{mm}^2$) [3]. Such a pixel size is desirable to ensure sufficient dynamic range and signal-to-noise ratio taking into account the imaging optics parameters, the processor parameters and the sensor die size, etc.

The scanned image is of 256 color BMP format (Fig.3), where each pixel is represented by eight bits. This format can be stored uncompressed with 54 byte header followed by a 1024 byte palette table, in which 4 bytes define each color, one for red, one for green, one for blue and one reserved. The actual image pixel information starts after this from lower left hand corner. The header and palette are used to breakdown the image file and the image is then analyzed to decode the original information by a reverse mapping mechanism [3].

AFM friction investigation with temperature.

D. Kim

Samsung Information Systems America, Inc, San Jose, CA

ABSTRACT The adhesion/friction properties of magnetic media play a critical role in HDI dynamics in the pursuit of recording density of 1TB and beyond. In this study, AFM friction was investigated on different media lubricant system and found strong correlation both to strain gauge signal in component level and media surface energy which resulted in modification to classical friction theory suggested by Colomb.

EXPERIMENTAL The commercially available DI 3100 AFM instrument equipped with in-house Peltier plate was employed for measurement of friction force at the tip surface in various temperature. In the “friction” mode, the sample is scanned back and forth in a direction orthogonal to the long axis of the cantilever beam and the laser beam is reflected out of the plane by the degree of twisting which is related to the magnitude of friction force. Subsequently, total surface energy was analyzed by the contact angle method. Finally, VENA CSS system was used to explore the correlation between friction signal by AFM and strain gauge output by Vena System.

RESULTS AND DISCUSSIONS Different types of magnetic media were investigated to study the frictional behavior at various environmental condition and correlation was found with strain gauge signal during CSS take-off/touch-down cycles. Figure 1 illustrates typical example of friction signal at amb/high temperatures. As shown in Fig 1, pronounced shift in friction was observed with respect to temperature and hysteresis seems to be negligible after switching back to ambient condition. The transition in friction is attributed to lube mobility and surface energy with temperature as reported in various technical papers [1-5]. One intriguing feature of commercially available AFM tip is physical limitation of thermal conductivity even with the help of conductive metal coating. As an alternative solution, helium gas was supplied inside the enclosure of the AFM apparatus to minimize the effect on fluctuation of the resonant peak from thermal AFM tip which is manifested in Figure 2. Several high friction media was built into drive. The modulation at suspension sway mode due to excess friction and oscillation in fly height was discovered resulting in weak writes. In some extreme case, modulation at ABS frequency occurred. All these phenomena result in increased slider instability /head degradation/scratch attributed from lube bridge/excessive lubricant thickness. Finally, the empirical relationship between friction force at zero external load and surface energy was modeled as, where L is the applied load, u is the friction coefficient and A is the effective area with the help of experimental results in Fig 3. As a first order, the adhesive and ratchet mechanism accounts for friction force in the presence of asperities. Nevertheless, all the media used for this study had a similar roughness and thus microscopic adhesive force should be a vital factor accounting for transitions in friction force in different environmental condition.

CONCLUSIONS:

The nanoscale AFM friction study enables us to characterize tribological properties of various hard disk lubricant system in a more efficient manner without having to conduct time-consuming component level CSS as was done conventionally. Friction force was found to be linearly related to the surface energy and friction force went to zero when the surface energy approached finite bulk film energy and these results suggested modification to the classical adhesion theory is necessary for molecularly-thin boundary lubricants.

Arsenic Removal from Water by Magnetic Separation: A Review and a Case Study Using Magnetic Aggregates and Magnetic Stabilized Bed.

A. M. Estevez¹, P. A. Augusto^{2,1}, J. M. Rodriguez¹, A. Alvaro¹

1. Department of Chemical Engineering, University of Salamanca, Salamanca, Spain; 2. DEQ, Faculdade de Engenharia da Universidade do Porto, Porto, Portugal

Abstract

In this paper we present a short overview of the attempts performed so far to apply magnetic separation in order to achieve the removal or reduction of arsenic content in water; we also compare them with traditional methods.

We present the magnetic separation process we are using in order to remove arsenic. Finally we present some of the preliminary adsorption results.

Arsenic Toxicity

Water, when containing arsenic in amounts above the limits defined by law (10 µg/l) [1], represents an hazard for public health, specially if in taken continuously [2,3].

Arsenic is found commonly in water under an inorganic form, mainly as arseniate (As V) in superficial waters and as arsenite (As III) in underground waters. As(III), for ordinary biological systems, is more toxic than As (V) [4,5].

Arsenic Removal: Traditional Processes

Several processes to achieve the elimination of arsenic from water, were developed and applied, being the main ones based on precipitation-coagulation techniques, separation by membranes, ion-exchange processes, and adsorption [1,2]. They are usually expensive, not adequate to be applied in small water facilities, an require a previous oxidation of As(III) to As(V) in order to be more efficient, or they are sensitive to the presence of other substances in water.

Arsenic Removal: Magnetic Separation

The idea to use ferromagnetic iron oxides as adsorbent media for arsenic removal has been suggested. However, its application faces some difficult practical challenges. [6, 7, 8]. The only attempts to use the magnetic properties of this type of adsorbent media are: the removal of arsenic from geothermal water by HGMS [9], and a low-field magnetic separation of monodisperse Fe₃O₄ nanocrystals [10]. The first case, constitutes an expensive method, requires some pre-treatment stages, and the final removal efficiencies are between 40-80 %. The second case reduces the mass of waste associated with arsenic removal from water; however it is a laboratorial-scale device and constitutes a not very-well developed technique.

Case Study: Magnetic Stabilized Bed

Bearing in mind high adsorption capacity of the hydrated iron oxide FeOOH, we are performing, in the present study, the conjugation of the magnetic stabilized bed technique [11,12,13,14] with adsorption of arsenic by ferromagnetic iron oxides, by applying some magnetic aggregate structures [15,16].

We are using the Magnetic Stabilized Bed (MSB) system depicted in Figure 1.

Its working principles will be detailed in the conference and in the subsequent paper.

Preliminary experiments

Preliminary experiments were performed regarding arsenic elimination by promoting in a first stage its adsorption in the previously prepared adsorbents: hydrated iron oxide, magnetite and magnetic aggregates of iron and silicon with different ratios Fe/Si. Arsenic content determination, before and after the adsorption stage was performed by the semi-quantitative Quantofix® test.

Experimental results and discussion

Arsenic adsorption results are presented in Figures 2, where a high adsorption, very close to 100%, is observed. In general terms, we may conclude that iron is the main responsible for adsorption, while Si is the main responsible for mechanical consistence of the aggregate.

In Figure 3 is depicted the adsorption kinetics of arsenic. We may conclude from the figure that adsorption of As by our magnetic adsorbents is a fast process.

Investigation of Nanoparticle Clusterization in Magnetic Fluids Driven by Surface-Coating Desorption.

F. M. Oliveira, P. C. Morais, K. S. Neto, A. P. Canizares, L. C. Figueiredo
Instituto de Física, Universidade de Brasília, Brasília, Brazil

A key aspect related to magnetic fluid (MF) samples with important consequences to most of the applications is the clusterization process which tight single nanoparticle units together in a more complex agglomerate (Klokkenburg et al.). Clusterization in MF samples can be induced for instance by application of an external magnetic field, by either changing the sample's temperature or nanoparticle's concentration or by changing the characteristics of the molecular surface layer that ultimately helps stabilizing the magnetic colloid. Static magnetic birefringence (SMB) measurements provide important, though indirect, information regarding the clusterization process in MFs, such as average size and size dispersion of the built-in cluster (Skeff Neto et al.). Therefore, SMB measurements provide an indirect way to track the aging of MF samples by looking at the field dependence of the sample's SMB signal (Skeff Neto et al.). In the present study we report on the investigation of the aging of biocompatible MF samples consisting of maghemite nanoparticle, surface-coated with dimercaptosuccinic acid (DMSA), suspended in physiological solution. Magnetic fluids containing different nanoparticle sizes and different surface grafting were used as the stock samples. Samples were labeled DMSA1 and DMSA2, with average core-diameters of 7.9 nm and 7.2 nm, respectively. The sample DMSA1 presents lower surface grafting coefficient in comparison to sample DMSA2. Stock samples were diluted in pure water while the SMB data were collected at day zero, day two, and day five after dilution.

Figure 1 shows the SMB data obtained from sample DMSA1 after dilution, at day-0. Open symbols in Fig. 1 represent the normalized SMB data of sample DMSA1 at 1:2 dilution (circles) and at 1:6 dilution (squares). Figures 2 and 3 represent, respectively, the time evolution (day-0 and day-5) of the SMB data obtained from samples DMSA1 and DMSA2 after 1:4 dilution. The solid lines in Figs. 1-3 represent the best curve fitting of the experimental data (symbols) according to the model discussed by Skeff Neto et al.. Symbols in the inserts of Figs. 1-3 result from the curve fitting of the SMB signal.

The analysis of the SMB data shown in Fig. 1 indicates reduction on the average chain-length and chain-length dispersion as the stock sample is diluted down to 1:2 and further reduction for the 1:6 dilution. Nevertheless, the analyses of the SMB data shown in Figs. 2 and 3 indicate little changes on both the average chain-length and chain-length dispersion as the diluted samples are left to aging from day-0 towards day-5. These findings lead us to conclude that changes on the average chain-length and chain-length dispersion after dilution are more likely-driven by the onset osmotic gradient between the nanoparticle surface and the bulk solution. Further, changes on the average chain-length and chain-length dispersion are dominated by a fast process, more likely-related to desorption of molecular species from the nanoparticle surface (Oliveira et al.).

Detection of Low-Concentration Magnetic Fluid inside Body by Needle-Type GMR Sensor.

S. Yamada, C. P. Gooneratne, M. Iwahara, M. Kakikawa

Institute of Nature and Environmental Technology, Faculty of Engineering, Kanazawa University, Kanazawa, Japan

Introduction

Magnetic nanoparticles are injected inside the body to deliver medicines or to act as self heating agents to kill cancerous tumors. Recent cancer treatment research has focused on the effectiveness of killing localized or deeply seated cancer tumors. However, effective and minimally low-invasive detection of magnetic fluid inside the body is necessary to confirm the presence and location as well as for possible estimation of content density.

Detection Theory and Proposed GMR Sensor

The theoretical aspect of detection inside the body is based on the difference between magnetic flux densities (B_i and B_o) inside and outside a cavity with permeability greater than 1, under uniform magnetic fields as shown in Fig. 1. A uniquely designed, minimally invasive giant magnetoresistance (GMR) needle sensor is fabricated as shown in Fig. 2, for inserting into the body for detecting low concentration magnetic fluid (weight density, D_w of less than 1 %). A sensing area of $75 \mu\text{m} \times 40 \mu\text{m}$ is present at the tip of the needle. The bridge structure of the GMR sensor is able to detect a magnetic fluid filled area in the body (B_i) as opposed to an area without (B_o) simultaneously. When the ratio of the height to diameter, m , and the corresponding demagnetizing factor, N , of a given cavity remains constant, the relationship between the change in magnetic flux density inside and outside a cavity and the weight density of the magnetic fluid, D_w is given as [1],

$$(B_i - B_o)/B_o = 4(1-N)D_w/h_s\gamma_f \rightarrow (1)$$

where h_s and γ_f are the space factor (0.523) of spherical magnetite and the specific gravity (4.58).

It is also worth to note that physical dimensions of cancerous tumors are difficult to predict and more so the fluid spreads inside the tissue and decreases the density, so it is of interest to investigate the possibility of detection of low concentration magnetic fluid inside cavities with various shapes and sizes.

Experimental Method and Analysis

Initial experiments were done by measuring the applied flux density ($B_o = 100 \mu\text{T}$) and magnetic flux density inside magnetic fluid filled embedded cylindrical cavities of $m = 0.625$, and magnetic fluid weight density was estimated as shown in Fig. 3. Next, experiments to detect magnetic fluid inside a body were performed by injecting magnetic fluid of varying density into cylindrical pieces of agar ($m = 1$) and placing them in a potato starch medium. The needle-type GMR sensor was inserted at 10 mm intervals and hence, to the middle of agar pieces and the results are shown in Fig. 4 for a weight density percentage of 0.574 %. The change in signal corresponds to the difference between the signal obtained inside the magnetic fluid and in potato starch (reference medium). It can be seen from the results that the GMR needle sensor can detect the magnetic fluid inside cylindrical agar pieces with diameters ranging from 7 to 19 mm. Since m and hence N is the same, the signal do not vary so much between the samples.

Conclusion

Most applications such as hyperthermia therapy in cancer treatment can be performed with minimal error if detection and estimation of weight density of magnetic fluid inside the body are possible. The experiments performed in this paper shows that the fabricated novel needle-type probe has a good potential to be used for such purposes.

Suppression of electromyogram of hand muscle elicited by transcranial magnetic stimulation over the primary motor cortex.

M. Odagaki, S. Ohishi, H. Fukuda, O. Hiwaki

Graduate School of Information Sciences, Hiroshima City University, Hiroshima, Japan

1. Introduction

Transcranial magnetic stimulation (TMS) is a non-invasive technique for exploring all aspects of brain function in clinical use. Cortical motor neuronal activation by TMS produces efferent signals that pass through the cortico-spinal tracts. As a result, motor evoked potentials (MEPs) are observed at muscles innervated over the motor neurons.

Voluntary finger movements are performed by cooperative interaction of several muscle groups. TMS can evoke the excitation of particular peripheral muscles, and muscle contraction is observed. A large difference in behavior between voluntary movement and involuntary movement produced by TMS is likely to be observed.

In the present digest, both electromyograms (EMGs) and tracks of finger movement were measured during a finger tapping task, and the effect of TMS over the primary motor cortex on voluntary finger movements was examined.

2. Method

The experimental system consists of a magnetic stimulator, an EMG measurement device, and a three-dimensional tracking system. In order to observe the muscle contraction, measurement electrodes for EMGs were placed on the abductor pollicis brevis (APB) and first dorsal interosseous (FDI) muscles of the right hand. When the subject raises his/her thumb, this movement is detected by an LED sensor. The measurement of EMGs and the tracking system are then started simultaneously upon being triggered with by the LED sensor output signal.

A diagram of the time series of this experiment is shown in Figure 1. The subject performed a single thumb-tap synchronized to the sound of a metronome with an interval of 4.8 s. A magnetic coil for TMS is located over the left motor cortex, and stimulations were carried out at stimulation timings of 0, 10, 100, and 350 ms for each task. The stimulation timing was obtained from the time at which the thumb is raised. The number of stimulations was ten for each task. A TMS pulse with an intensity of 70% was applied over the left M1 area by changing the stimulation timing.

3. Results and discussion

Figure 2 shows the measurement result of the relationship between the finger tapping time and the TMS timing. As shown in the figure, the tapping time was significantly increased at stimulation timings of 0 and 10 ms. The measurement results of EMGs obtained from APB at the stimulation timing of 10 ms are shown in Figure 3. As shown in this figure, MEPs were evoked at a latency of 20 ms, and suppression of the voluntary EMGs was observed approximately 100 ms after MEPs disappeared.

The overlapped displacement waveforms with no-TMS and TMS with a delay of 10 ms are shown in Figure 4. Decreasing displacement indicates that the finger is moving upward. A loss of strength appears to have occurred during finger tapping. Furthermore there is a significant difference in positive slope between both displacement waveforms. These evidences indicates that both brain cells and muscles exceeded their respective thresholds at different times. It is thought that voluntary EMGs were inhibited for 100 ms while both tissues went into a refractory period.

4. Conclusion

The suppression of voluntary EMG was confirmed when TMS was applied at timings of 0 and 10 ms, indicating that tissue excitation elicited by TMS causes a loss of control of the peripheral muscle during voluntary movement.

Formation of beta-Sheet Rich Fibrils in Cortex Cells from Mice Fetuses Cultured with Ferritin and Exposed to Radio Frequency Magnetic Fields.

O. Cespedes, O. Inomoto, S. Kai, S. Ueno

Applied Quantum Physics Department, Kyushu University, Fukuoka, Japan

Summary:

In our work we have studied the effects of radio-frequency (RF) magnetic fields in brain cells cultured with iron-saturated cage proteins (ferritins). We have observed that the cultures show signs of protein aggregation, with microscopic fibrils rich in β -sheet structure visible under optical microscope. This may have dire consequences for neurodegenerative disorders and their relation with RF magnetic fields exposure.

Introduction:

Many forms of dementia, including Alzheimer's and Parkinson's, are related to the aggregation of misfolded proteins into insoluble fibrils with a β -sheet rich secondary structure where the free radicals play an important role acting as catalyst in the process. Iron is involved in the formation of oxygen-free radicals, and iron accumulation has been found within brain regions displaying vulnerability to neurodegeneration [1].

Between 15-25 % of the iron in the body is stored inside ferritins [2], an iron cage protein that has been associated to neurodegenerative diseases with evidence of having been produced locally by the glial cells. These proteins are composed of a peptidic cage of 12 nm in diameter and 440 kDa inside which there are stored up to 4500 iron ions in the form of a ferrihydrate nanoparticle.

Results and Discussion:

We observe a reduction in the optical absorbance of solutions of ferritins exposed to RF fields. The maximum change occurs at energies corresponding to half the ferrihydrate energy gap, indicating changes in the nanoparticle's surface structure, i.e. a possible decrease of the number of iron ions (Figure 1). The mechanism for this interaction would be in the changes in the internal energy of the nanoparticle when exposed to alternating magnetic fields.

We studied then the consequences of this effect in brain cell cultures extracted from the cortex of mice fetus (DDY strain) kept at standard conditions of 10 % serum in DMEM medium at a temperature of 37 C and 5 % CO₂. We divided the samples in four groups:

- 1.- Samples cultured with 1 microM of iron saturated ferritin and exposed to magnetic fields of 1 MHz and 25 microT for 1 hour a day during 4 days. The cells were kept at 37 C with no gas exchange (5% CO₂).
- 2.- Samples cultured with 1 microM of iron saturated ferritin and undergoing the same conditions for one hour a day but not exposed to magnetic fields.
- 3.- Samples cultured with ferritin and exposed to magnetic fields for only 15 minutes a day (with the remaining 45 minutes at the same conditions of the sham and 1-hour exposed samples).
- 4.- Samples exposed to magnetic fields of 1 MHz and 25 microT for 1 hour a day but with no added ferritins.

The first group showed the formation of β -sheet rich fibrils about 10 microm in length and < 1 microm in width accompanied of a swelling of the microglial cells. The cells from this group died after the fourth day of exposure to the magnetic field, whereas the other samples remained alive for 6 (# 2 and 3) and 10 days (# 4), with no fibril formation (figure 2).

We can therefore conclude that radio frequency magnetic fields in the 10 microT and 1 MHz range may have the potential to significantly alter the concentration of Fe²⁺ ions in areas with high con-

centration of iron rich ferritins, which might have dire consequences for oxidative stress and protein aggregation.

Effects of Radio Frequency Magnetic Fields on the Iron Release from Cage Proteins via 6-Hydroxydopamine.

O. Cespedes, S. Ueno

Applied Quantum Physics Department, Kyushu University, Fukuoka, Japan

Introduction:

In this study we show how radio frequency magnetic fields of 200 kHz to 3 MHz and amplitudes from 10 to 100 microT alter the 6-hydroxydopamine entry time and reduction rates of iron ions from iron cage proteins (ferritins). We propose a mechanism for this effect based on changes in the internal energy of the inner ferrihydrite nanoparticle, which is verified by iron-release spectroscopy experiments.

Materials and Proposed Mechanism:

Ferritin [1] is a ubiquitous protein which role is to capture and store the harmful Fe^{2+} ions in the body. It is formed by a roughly spherical peptidic cage of 440 kDa in mass and 12 nm in diameter (apoferritin) and an inner ferrihydrite nanoparticle containing the stored iron. To be released, the iron has first to be reduced from Fe^{3+} to Fe^{2+} . One of the molecules with this role is 6-hydroxydopamine, which goes into the ferritin cage and produces deprotonated quinone, H_2O molecules and Fe^{2+} ions. This reaction is related to Parkinson's disease via the catalyst role played by the Fe^{2+} ions in the oxidative stress. Iron release from the ferritin can be monitored by the addition of ferrozine, an iron chelator that acts as colorimetric probe.

We propose a mechanism for the interaction with RF magnetic fields as follows: when an alternating magnetic field of high enough frequency is applied, the magnetization of the nanoparticle (magnetic moment of about 0.1 Bohr magneton per iron atom) will lag the applied field, resulting in an increase of its internal energy. The nanoparticle may relax via either Néel or Brownian processes. The former will result in the irradiation of phonons from the nanoparticle (the magnetization rotates within the crystal). In a Brownian process, the nanoparticle will try to mechanically rotate and align itself with the magnetic field, colliding with the surrounding water molecules and the proteic cage that encloses it.

Results and Discussion:

In our experiments we have worked with iron-saturated ferritins with nanoparticle diameters of 8 nm (about 4500 Fe ions). We observe that proteins exposed to the RF magnetic fields have a higher rate of iron release during the first 1-3 hours at neutral pH with differences of almost 50 % at long exposure times (Figure 1a). However, as the molecule reaches its release saturation level or as the pH is lowered, the iron released from proteins exposed to magnetic fields is drastically decreased in comparison to control samples. At a constant frequency-magnetic field ($f \times B$) product, the biggest effect is obtained at frequencies of 1 MHz, suggesting a relaxation time of order 1 microsecond (Figure 1b).

The flow of iron ions released from control ferritin samples at low pHs is enough to block the hydrophilic terminals, and the molecules coagulate and precipitate. In contrast, in the case of ferritin molecules exposed to magnetic fields for several hours, the iron released by the 6-hydroxydopamine is almost quenched and the precipitation occurs more slowly or not at all (Figure 2).

Our study has given evidence that RF magnetic fields have the possibility to alter the iron release dynamics from iron cage proteins, with important changes in protein functioning and solubility. The good functioning of these proteins is essential to avoid oxidative stress and therefore this effect could have important physiological consequences.

Acknowledgments: This study is supported in part by the grants (S)17100006 and 19.07371 from the Japan Society for the Promotion of Science (JSPS).

[1] Pauline M. Harrison and Paolo Aorisio, *Biochim. Biophys. Acta* 1275, 161 (1996).

Figure 1: a) Normalized iron release from a solution of 1 microM ferritin in function of the exposure time to a magnetic field of 20 microT and 1 MHz after 1 hour of adding 200 microM of 6-Hydroxydopamine and 100 microM of ferrozine. b) Saturation level of iron release in function of the frequency of the applied magnetic field and total solution pH.

Figure 2: Precipitation of ferritins. After adding a low pH buffer to a solution of 200 microM 6-Hydroxydopamine, 100 microM ferrozine and 1 microM ferritin, the rapid iron release in control samples blocks of the ferritin hydrophilic terminals, leading to coagulation and precipitation. Samples exposed to RF magnetic fields have a much smaller and slower iron release, keeping free the hydrophilic terminals and avoiding aggregation.

Short and long duration of rTMS effects on perceptual reversals.

S. Ge¹, T. Hayami², A. Hyodo³, S. Ueno⁴, K. Iramina^{1,3}

In this study, we focused on the effect of repetitive transcranial magnetic stimulation (rTMS) on neuronal excitability. The rTMS is a non-invasive and painless method of modifying the excitability of the cerebral cortex, which allows repetitive pulses of electricity passed through a coil placed on the scalp. A magnetic field is generated around the coil. This field penetrates the skull and depolarizes underlying neuronal tissues. This causes the activation or inhibition of neuronal tissues to be changed.

Ambiguous figures are visual stimuli which are interpreted in multiple ways by the human visual system. For a given ambiguous figure, the perception will switch spontaneously between several possible interpretations even while the figure stays unchanged. This process is called perceptual reversals. Some studies about perceptual reversals of ambiguous figures indicated that the parietal area in the brain, especially, the superior parietal lobule (SPL) is involved in perceptual reversals [1] [2]. However, whether the activation in the superior parietal lobule inevitably causes the perceptual reversals or how it effects the perceptual reversals is unclear by using fMRI, EEG, MEG et al. In the present study, we explored the rTMS effect over the right SPL in the perceptual reversals of ambiguous figures.

The spinning wheel illusion was used as the ambiguous figure's stimulation in this study. The perception of a spinning wheel is moving in either clockwise or counterclockwise, with switches between these two percepts occurring spontaneously. Subjects were required to respond as quickly and accurately as possible by clicking a mouse button to indicate the perceptual reversals in the direction of rotation. The time interval between two successive perceptual reversals was recorded as the inter-reversal time (IRT) after rTMS. A figure-of-eight 70 mm coil was used as the TMS. Stimulus strength was set at 90% of the subjects' individual resting motor threshold. In this study, rTMS trains were applied over the right SPL or the right posterior temporal lobe (PTL). As a control stimulation, no rTMS trains were applied over the subject's skull. Furthermore, in order to investigate the rTMS effect with different stimulus duration, two kinds of experiments, i.e., short-duration experiment and long-duration experiment were performed. In the short-duration experiment, a 60-pulse train of 1Hz rTMS was applied. While in the long-duration experiment, a 240-pulse train of 1Hz rTMS was applied.

In a dynamic aspect of perceptual rivalry, a well-known empirical proposition, which called Levelt's proposition [3], says that the intervals of perceptual alternation follow a gamma distribution in both binocular rivalry and ambiguous figure perception. Hence, we considered that the IRT were followed a gamma distribution in the present study. For each subject, the frequency distribution of IRT was calculated. We then used the gamma distribution to fit the IRT data and calculated the parameter α, β and of gamma distribution. After that, the average of frequency distribution of IRT can be calculated ($\text{average} = \alpha * \beta$, hereinafter abbreviated as AIRT). The AIRT of each subject were calculated.

Based on the short-duration experimental results, it was found that compared to the PTL stimulation and no-TMS, rTMS applied over the right SPL leads to a significant facilitatory effect on perceptual reversals. On the other hand, there was no significant difference between the PTL stimula-

tion and no-TMS. In contrast, in the long-duration experiment, it was found that compared to the PTL stimulation and no-TMS, rTMS applied over the right SPL leads to a significant suppression effect on perceptual reversals. On the other hand, there was no significant difference between the PTL stimulation and no-TMS. Therefore, we considered that the difference of rTMS-evoked cortical activation should be the main reason to cause difference in IRT. Thus we concluded that the right SPL maybe plays a critical role in perceptual reversals of ambiguous figures. Under the circumstance of the present study, a 1 Hz 60-pulse rTMS probably causes facilitatory effect on perceptual reversals, while a 1 Hz 240-pulse probably causes suppression effect on perceptual reversals.

Prospects for Spin Memory Devices and Their Element Technologies in the Next 10 Years.

S. Nakamura

Corporate R&D Center, Toshiba Corporation, Kawasaki, Japan

The discovery of GMR in magnetic multilayers by Fert and Grünberg [1] led to the appearance of TMR, the ratio of which is currently about 500 % at room temperature. These MRs are due to the spin-dependent transport of two spin currents of up and down. In such systems, when the current crosses a magnetic layer, the layer receives angular momentum from the spin current. The spin-transfer torque, predicted by Slonczewski and Berger [2], has attracted much attention, since it generates a variety of magnetic dynamics including spin wave excitation, switching, and precessional motion.

The first spintronic device that has been realized is the GMR head, the commercialization of which started in 1998. With a view to achieving the next big market, the development of MRAMs that utilize the TMR and memory function of the magnet has been advancing rapidly. The MRAM using magnetic field for writing was commercialized two years ago. And currently, the competitive developments for practical use are shifting to those employing spin-transfer torques for writing. The latter MRAM will be put practical use within several years [3].

In this talk, at first, we will focus on the spin-memory devices that are expected to be available 10 years from now. The advantages and disadvantages of the spin-memory devices, among the competitive memories and emerging non-volatile memories, indicate the likely direction of development of the devices. Then, we will discuss element technologies needed for the evolution. One of the technologies is the spin-current modeling technique. It is already possible to calculate the spin-transfer torque in non-collinear multilayers with complex structures including Syn. AF, the results of which agree with the experiments [4]. Such spin current simulations would not only facilitate understanding of the underlying physics, but also help memory designers unfamiliar with spin-electronics to design devices with new functions.

Microelectronics Research Centre, University of Cambridge, Cambridge, United Kingdom; 4. School of Physics and Astronomy, University of Nottingham, Nottingham, United Kingdom

The history of spintronic devices, used already in hard drive read heads or magnetic random access memories, is reminiscent of that of the conventional microelectronics. It started about 15 years ago with a simple “spintronic wire” – an Anisotropic Magnetoresistance (AMR) sensor, followed by more elaborate diode-like spin-valve elements based on the Giant magnetoresistance (GMR) [1] or the Tunneling magnetoresistance (TMR) effects [2,3].

GMR and TMR also opened new paths to design magnetic random access memories (MRAM), where information is stored as the orientation of the magnetization of a small patterned structure, and read by a resistance measurement.

The transport characteristics of conventional GMR or TMR devices are controlled by external magnetic fields to fix the orientation of the magnetization. However, magnetic field control is not an efficient and scalable writing technique.

Building further on the analogy with conventional electronics, and with the field effect transistors in particular, adding a control by external electric fields [4] appears as a natural route to a new generation of nano-scaled spintronic elements.

In this talk we discuss two novel spintronics effects, the Tunneling anisotropic magnetoresistance (TAMR) [5] and the Coulomb blockade anisotropic magnetoresistance (CBAMR) [6]. The CBAMR effect reflects the magnetization orientation dependence of single-electron transport in a ferromagnetic SET. CBAMR devices are hybrid single-electron/spintronic elements delivering tuneable high magneto-sensitivity combined with non-volatile memory effect. This combined transistor and non-volatile memory functionality is inherent to the CBAMR effect and new logic-functionalities in CBAMR based devices may be envisaged.

The TAMR results from the magnetization orientation dependent density of states (DOS) at the tunneling barrier. After its discovery in diluted magnetic semiconductors, subsequent theoretical work predicted [7] that the TAMR is generic in ferromagnets with SO-coupling, including the high Curie temperature transition metal systems. Experimental demonstration of the TAMR in tunnel junctions with ferromagnetic metal electrodes has recently been reported in an epitaxial Fe/GaAs/Au [8] stack and in high magnetic field saturated conventional TMR devices with CoFe ferromagnetic electrodes [9]. The observed TAMR in these structures was relatively small, < 0.5%, consistent with the weak SO-coupling in the ferromagnetic electrodes.

We present a study of vertical tunnel devices in which the ferromagnetic electrode comprises alternating Co and Pt films [10]. Large and tuneable magnetic anisotropies are generated at the interfaces by combined effects of induced moments and strong SO-coupling in such ferromagnetic/heavy element transition metal multilayers. We show that placing these interfaces adjacent to the tunnel barrier opens a viable route to highly sensitive metal TAMR structures. In stacks with the ferromagnetic electrode terminated by a Co film the TAMR magnitude saturates at 0.15% beyond which it shows only weak dependence on the magnetic field strength, bias voltage, and temperature. For ferromagnetic electrodes terminated by two monolayers of Pt we observe

order(s) of magnitude enhancement of the TAMR and a strong dependence on field, temperature and bias.

A discussion of the usability of TAMR and CBAMR for magnetic field sensors in ultra-high density hard disk drive will finalize the talk.

Engineering magnetic nanostructures into complex devices for spin electronics.

C. Chappert

1. IEF, CNRS - UMR 8622, Orsay, France; 2. IEF, Université Paris Sud, Orsay, France

Since the first spin valve read head (IBM, 1997), the applications of spin electronics have undergone an outstanding acceleration towards nano-integration of magnetic devices into solid state electronics. Among best examples are the Spin-RAM demos recently proposed by Sony [1] or Hitachi [2], providing dense magnetic non volatile memories using spin angular momentum transfer switching. This move was made possible by a chain of scientific breakthroughs that illustrate how Nanosciences can impact electronics. For instance, giant magnetoresistance of multilayers arising when individual film thickness is of order of the mean-free path, the magnetic tunnel junction (MTJ) where the barrier thickness is below decay length of tunnelling wave functions, the perpendicular magnetic anisotropy in multilayers originating from interface effects, on more recently the spin angular momentum transfer torque, a quantum effect due to exchange interaction of electron spin with magnetization. One parameter should be important for future development: the fact that the intrinsic speed of magnetization dynamics lies in the GHz range and above, i.e. the range of CPU speed in CMOS electronics, and that of wireless communications. So intense research effort is currently devoted to improve the performance of today's devices, and fully understand and control the effect they use, for instance through new materials such as oxides or diluted magnetic semiconductors.

But today's spin electronics devices, although already quite efficient, retain at minimal functional complexity: basically, they are just variable resistances indexed on a magnetization direction, and their use is so far limited to sensor or memory use. Even though materials already exist with high enough magnetic anisotropy to fabricate thermally stable magnetic particles of size down to a few nm [3], the solid state implementation of such magnetoresistive "switches" will find scalability limits together with those currently predicted for CMOS.

So research should also start to focus on the challenges beyond the magnetic switch model. I can see several steps, which are summarized in Figure 1:

1- move beyond the sole memory application, by moving to magnetic logic devices.

In a first step, this will introduce MTJs inside CMOS, and this is already in progress [4]. A different approach tries to couple "analog logic" using interaction between magnetic nano-objects (particles, domain walls, vortices...) to "digital logic" (either purely CMOS or mixing also magnetic elements), in order to improve energy cost, speed, wafer area, etc... [5, 6].

On the longer term, going "Beyond CMOS" requires a more drastic integration of elaborate logic functions inside every single device. This requires development of multi-terminal spin electronics devices (by contrast to MTJ which is a 2-terminal device), where the magnetic function could also be used to operate re-programming of the logic function with voltage based logic inputs. This may require introduction of molecules, bottom up approaches, etc...

2- move towards a "carriers free" spin electronics

The move towards very complex "Beyond CMOS" spin electronics devices will also require new ways of controlling the magnetization. The trend should be to assist or replace today's action through electric currents (used to create magnetic fields or spin transfer torque) by electric field control, which is expected to dissipate less energy, and also may allow more local and individual control of separate magnetic parts in a multiterminal logic component. First reports of electric field control use direct influence on band structure [7, 8] or coupling of piezoelectric and magnetoelastic materials [9], the latter being actually be intrinsic into multiferroic materials [10].

The "holy grail" of spin electronics however remains a spin logic of spin current with zero charge current. Some preliminary results or propositions are already coming out with evidence of spin current induced switching of nanoparticles [11].

Manipulating single spins and coherence for semiconductor spintronics.

D. D. Awschalom

Center for Spintronics and Quantum Computation, University of California, Santa Barbara, CA

Potential applications of solid state spintronics and quantum information processing may require coherently controlling and reading single electron spins at gigahertz frequencies, as well as enabling engineering pathways for integrated communication [1]. Here we present recent developments within two experimental efforts aimed at manipulating individual spin coherence in semiconductors. The non-destructive detection of a single electron spin in a quantum dot (QD) is demonstrated using a time-averaged magneto-optical Kerr rotation (KR) measurement [2]. This technique provides a means to directly probe the spin off-resonance, thus minimally disturbing the system. The ability to sequentially initialize, manipulate, and read out the state of a qubit, such as an electron spin in a quantum dot, is necessary for future quantum information processing. To this end, we have extended the single dot KR technique into the time domain with pulsed pump and probe lasers, allowing for observation of the coherent evolution of an electron spin state [3]. The dot is embedded in a diode structure to allow controllable gating/charging and optical readout of the state. Measurements of single spin precession in an applied magnetic field allow a direct determination of the electron g-factor and transverse spin lifetime. These observations reveal information about the relevant spin decoherence mechanisms, while also providing a sensitive probe of the local nuclear spin environment. Recently, we have developed a scheme for high speed all-optical manipulation of the spin state that enables multiple operations within the coherence time [4]. The results represent progress toward the control and coupling of single spins and photons for quantum information processing [5] as well as quantum non-demolition measurements of a single spin.

Diamond is a material of extremes: it is the hardest naturally occurring material, it is the best thermal conductor on the planet, it has a very high semiconductor bandgap, and it is transparent over a wide range of optical frequencies. Furthermore, diamond-based materials have recently emerged as a unique electronics platform for quantum science and engineering [6]. The Nitrogen-Vacancy (N-V) color center in diamond is well suited for studying electronic and nuclear spin phenomena, since its spin state can be both initialized and read out optically at room temperature. We report on experimental progress towards coherent control and coupling of single spins in diamond. Using magneto-photoluminescence imaging and electron spin resonance measurements, we have directly imaged single electron spins and manipulated them at GHz frequencies [7], observed their coherent coupling to single nearby dopant spins (N) including controlled polarization and readout [8], and performed coherent control (Rabi oscillations) and spin echo lifetime measurements [9]. Finally, photonic bandgap structures from diamond films with Q-factors approaching 1000 suggest potential pathways for spin-based photonics in this system. These results pave the way towards room-temperature coherent control of coupled spin states in diamond and new quantum technologies.

The road to silicon spintronics.

R. Jansen

MESA+ Institute for Nanotechnology, University of Twente, Enschede, Netherlands

Semiconductor electronics has been the cornerstone of information technology for many decades. It is based on the manipulation, control and storage of electrical charge in circuits used for logic and memory applications, with the transistor as the central element. Semiconductor materials prevail because they allow power amplification, with silicon being by far the dominant material. However, as concerns are raised about the further advancements of semiconductor devices in future chip generations, alternative technologies are actively being explored. The field of spintronics aims to improve the performance and enhance the functionality of electronic circuits and systems by making use of the spin of electrons. While significant progress has been made in recent years in combining spin with III-V (GaAs) based semiconductor materials, silicon-based spintronics is still at its infancy.

While it is clear that implementing spin-functionality into silicon is potentially highly rewarding, it has turned out to be a major challenge. Amongst the key advances to be made are to develop robust and efficient ways to inject electron spins into Si, and to develop suitable (optical, electrical) methods to detect and manipulate the spin-polarization in the Si. However, perhaps the most challenging aspect is to design fully electrical silicon based spin-devices with useful functionality and large spin-signals in a simple and preferably two-terminal geometry. With respect to the latter, efforts have so far focused on devices such as the spin-MOSFET, a transistor with a Si channel and a ferromagnetic (FM) source and drain. It is now clear that this demands careful consideration of the requirements for the FM injector and detector contacts [1,2,3], going beyond the obvious need for a high spin polarization of the contacts. For example, it is found that Schottky barrier formation on Si can be detrimental to the magnetoresistance of such a device [3]. This is partly because of the resulting large resistance area (RA) product of the contacts and partly because of the potential energy landscape, which affects spin flow across the interface [4].

As a solution, novel approaches are developed [3] to control the Schottky barrier height and resistance-area (RA) product of spin tunnel contacts to Si, e.g. using low work function materials. These include ferromagnets as well as non-magnetic materials, inserted as ultrathin (sub-nm) interfacial layers into FM/Al₂O₃/Si spin-tunnel contacts on either side of the tunnel barrier. In this way, the RA product of FM/Al₂O₃/Si contacts can be tuned over 8 orders of magnitude (see fig. 1). Equally important, complementary tunnel magnetoresistance data (fig. 2) show that a reasonable tunnel spin-polarization is simultaneously maintained. Interestingly, the Schottky barrier can even be inverted, in which case an interfacial accumulation layer (i.e. a 2-dimensional electron gas) can be established, creating new device options. Such engineered spin-tunnel contacts with low work function materials therefore not only qualify as conductivity-matched source and drain electrodes for spin-transistors, but also open up new avenues to design spin devices based on Si quantum structures for application in silicon spintronics.

Spin Manipulation in Semiconductors and Metals.

H. Ohno

1. Laboratory for Nanoelectronics and Spintronics, Research Institute of Electrical Communication, Tohoku University, Sendai, Japan; 2. ERATO, JST, Sendai, Japan

Electrical manipulation of spins in semiconductors and metals is now an established branch of spintronics, through which we can learn about the origin of magnetism, electrically reverse the magnetization direction and generate microwave power. Here, I choose two topics that delineate the importance of such manipulation of spins in condensed matter. One is the domain wall manipulation by spin-polarized current in a ferromagnetic structure, which reveals rich physics involved in spin-transfer torque driven domain wall motion [1]. The other is the current-induced magnetization switching in magnetic tunnel junctions having a synthetic ferrimagnetic free layer [2]. The latter is one of the possibilities to satisfy both thermal stability and low threshold current density in current-induced switching. Finally, I will discuss about the future directions made possible by these developments.

Micromagnetic Model Analysis of a Single-Pole-Type Head for 1 – 2 Tbit/in²

Y. Kanai¹, K. Hirasawa¹, T. Tsukamoto¹, K. Yoshida², S. Greaves³, H. Muraoka³

1. Niigata Institute of Technology, Kashiwazaki, Japan; 2. Kogakuin University, Tokyo, Japan; 3. Tohoku University, Sendai, Japan

Introduction

The single-pole-type (SPT) head is one of the most important components needed to achieve a high areal density in perpendicular magnetic recording system. The switching speed of the SPT head, as well as the write field amplitude, is critical for recording at high data rates, especially when writing on a bit-patterned medium (BPM) [1]. In this paper, SPT heads, having an air bearing surface (ABS) area of 25 nm × 25 nm, were investigated using a Landau-Lifshitz-Gilbert (LLG) micromagnetic analysis. The recording performance, which includes field strength, adjacent track erasure field, switching speed, was discussed for 1 – 2 Tbit/in².

SPT head model

We consider the SPT head model whose main pole tip was tapered both in down-track and cross-track directions, for which the width of the main pole at ABS was 25 nm and its length was 25 nm. The side and trailing shields were located 20 nm and 30 nm from the main pole, respectively. The ABS – soft underlayer (SUL) spacing was 25.5 nm. The entire recording system, comprising the SPT head and the double-layered medium, was treated micromagnetically using the finite-difference method with cubic cells of 5 nm, giving a total cell count exceeding ten million. The material characteristics: saturation magnetization M_s , anisotropy energy K_u , and exchange constant A , are; 1910 emu/cm³, 3×10^4 erg/cm³, and 1×10^{-6} erg/cm for the head; 955 emu/cm³, 3×10^4 erg/cm³, and 1×10^{-6} erg/cm for the soft underlayer. A Gilbert damping factor of 0.2 was used. The recording layer was assumed to be air and the recording field distributions were observed in a plane 16.5 nm from the ABS.

Results and discussion

In Fig. 1, the temporal head field variation is shown for the ultra-fast current rise time of 1 ps (Current-A), together with the response to current rise times of 0.2 ns (Current-B) and 0.4 ns (Current-C), where the current rise time is defined as the time for the current to switch from the negative peak (-100%) to the positive peak (+100%). The delay before the head field begins to switch (i.e. the head field is between -100% and -90% of its maximum value), called the non-response period hereafter, and the head field rise times (the time for the head field to change from -90% to +90% of its maximum value) are shown in Fig. 2 for various driving currents. It was found that the non-response period could be shortened by reducing the current rise time, however, the head field rise time never became small. In addition, we assumed another two types of driving current; Current-D: rise time of 0.4 ns with 100% overshoot; Current-E: rise time of 0.2 ns with 100% overshoot, showing that only fast switching current with overshoot (Current-E) was effective.

For the head structure, the head field rise time was 0.28 ns for unshielded head, it was also 0.28 ns for the un-tapered, unshielded head with an ABS of 100 nm × 180 nm. From these results, it can be said that the head field response would never be worse if the ABS area were reduced.

With regard to the write synchronization, increasing the write head rise time was confirmed to have an unfavorable effect on the write margin in which bits can be correctly written, and the write margin narrowed rapidly for rise times of more than 0.70 ns (-90% to +90%) [2]. This timing window is quite narrow compared to the calculated head field rise times and the non-response periods.

Finally, micromagnetic simulation of media magnetization indicated that the written tracks were very poor for unshielded head because of the low head field gradient, meaning side and trailing

shields are indispensable even for BPM. For continuous media, 650 Gb/in² (70 nm track pitch × 1800 kfc) was obtained, however, media anisotropy energy of 3.6 erg/cm³ was too low for long-term thermal stability. When BPM having long-term thermal stability was assumed, the obtained smallest bit cell without adjacent track erasure (ATE) was 30 nm × 15 nm, giving an areal density of 1.43 Tbit/in².

1 Turn Solenoid PMR Writer Design for High Frequency Writing.

E. Kim, K. Sunwoo

HDD Core Tech TF, Samsung Advanced Institute of Technology, Yongin, South Korea

Recently HDD adapted PMR mechanism and keep increasing the areal density. Further increase of recording density, especially the linear density requires high frequency data writing. But, current PMR write head shows switching delays at high frequency and the head field rising time becomes a critical factor in recording performances for current high frequency data rate[1]. Head inductance and eddy current loss are main reasons for this head response delay and these can be reduced by increasing the resistivity of pole materials or decreasing the yoke length[2]. But changing the resistivity also changes other magnetic properties of pole material, such as saturation magnetization and coercivity. So, the more effective way to reduce the head inductance and eddy current effect is to decrease the yoke length of head. We suggested the 1 turn solenoid coil PMR head structure with very short yoke length which is less than 2.0 μm to improve the high frequency performances of head as shown in Fig 1. Because of this short yoke length, we can delete the sub yoke layer and this simple structure can reduce the number of masks and processes also. But, the static head field strength and field gradients are smaller than currents PMR write head of 10 μm yoke length with 3 coil turns because of reduced number of coil turns. So we do FEM simulation for our 1 turn solenoid head modeling with different main pole and return pole shape and thickness to improve write field strength and field gradients. Because of etching process, return yoke tip has wedged-type shape at gap area and we considered this real shape as shown in Fig 2. Increasing main pole thickness could increase the head field, but it also increases the skew effect and degrades the writing performance. So we kept the pole thickness at ABS constant and only increased at the region under coil as shown in Fig 3. The simulated perpendicular head field along down track direction. It shows that our optimized head design shows more than 20% increase of head field compared with original 1 turn solenoid coil head design and shows comparable static writability with current 3 turn solenoid coil head. We find that there are some critical current where the field strength become sensitive to main pole thickness, i.e. write head field strength doesn't changed with head design at 30mA current density, but it increased with increasing pole thickness over 40mA current density. Also simulated results show that our short yoke length head has more than 50% faster head field rising time than current PMR head as shown in Fig.5.

We suggested short yoke length 1 turn solenoid coil PMR head and simulation results show that our optimized head has comparable static performance with conventional head and better writability for high frequency. Also our simplified structure can reduce the making process.

Western Digital Corp, Fremont, CA

As areal densities of commercial magnetic recording progress beyond 300Gb/in²[1], the advantages of combining high sensitivity TuMR read head[2] and high writability PMR write head[3] becomes increasingly significant. In this regard, these two head technology breakthroughs are the key enablers to keep the current annual compound growth rate of areal density at 40% in the HDD industry.

Regarding to readers, the achievements of high dR/R(80-200%) and low RA(1-3 ohm*um²) has made TuMR the choice of read head material for high areal density recording applications at 1Tb/in²[4]. Furthermore, the CPP configuration of TuMR reader exhibit two additional advantages over conventional CIP reader configuration. The first is better linear resolution from read gaps that could be made as thin as the sensor stack. The second is reduced side-reading from more planar top shield geometry due to the absence of conductor leads at track-edges.

Regarding to writers, the combination of the perpendicular writer and the soft-underlayer provides much larger writability, sharper field gradient and lesser side-reading over conventional longitudinal writing. The drastic improvement of both writability and field gradient allows us to develop a higher coercivity disk; therefore it opens up the possibility for more aggressive magnetic grain size reduction in order to achieve higher areal density and lower disk noise without sacrificing thermal stability.

In this work, we first discuss the challenges of integrating high sensitivity TuMR reader and perpendicular writer. We explore its potentials and push the design limitations on continuous media. Then we will present the design and magnetic recording performance of integrated recording heads at high areal densities.

The read sensor comprised a bottom TuMR film with a synthetic reference layer and a synthetic free layer yielding a dR/R up to 160% and a low RA down to 1.5ohm*um². Track widths as narrow as 40nm were defined using optical lithography(Fig. 1). Magnetic stabilization was achieved by an insulated abutted-junction with CoPt-alloy hard magnets adjacent to the sensor track-edges. A narrow read gap of around 32 nm was achieved. After wafer fabrication, the read heads were lapped to stripe heights of 60-100 nm.

To achieve high areal density, various writer designs have been explored. We found that the trailing shield design provides high write field and field gradient. It also imposes less process requirement. The fabrication process and sigma control is one generation down when compared to other exotic writer schemes. The achievable higher write field and field gradient was further utilized to improve head&media matching, namely reduction of magnetic grain size in disks. Write gaps as small as 20nm and physical pole widths as small as 65nm were fabricated. After lapping, the write heads have nose lengths of 40 – 120 nm.

Parametric recording study of these TuMR perpendicular heads was performed on low noise perpendicular media with an areal moment of 0.6-0.7 memu/cm². Results indeed showed the write heads have strong write field yielding 35 to 45 dB reverse overwrite at narrow magnetic write widths of 85 – 115 nm. In addition, the read heads also showed large signal amplitude exhibiting high non-disk signal-to-noise ratios of around 24-28 dB over a wide bandwidth of 280MHz. Regarding to track resolution, microtrack profile showed magnetic read widths as narrow as 40 nm

were achieved. Regarding to linear resolution, T50 widths as low as 18 nm were achieved due to the narrow read gap as well as the sharp write field gradient. Moreover, our integrated heads showed on track error rate of 10⁻⁵ at a linear density 1420 kbp (Fig. 2). In conclusion, all the above results indeed indicated that our recording heads have the capability to achieve areal densities above 500Gb/in².

Introduction

Continuing growth of recording density will require using media with increasing anisotropy energy to maintain thermal stability of recorded signals. To meet this requirement, the write heads have to produce a large field in spite of extremely narrow track width of the main pole (MP). Since saturation magnetization of the main-pole material has reached to the practical maximum of 2.45T, design of pole tip structure to increase head field becomes more important. The tapered structure of the main pole was shown to exhibit higher head field than a conventional pole structure [1]. We proposed the shielded planar single-pole-head [2] where the multi-charged-surface MP [3] combined with a shield was employed. From the recording simulation this head revealed to have a potential for achieving recording densities of more than 1 Tbit/in² [4], and a moderate taper angle between 35 and 55 degrees seems to be practical in terms of avoiding adjacent track erasure [5]. However the main pole fabrication process using plating in the etch-pit on the Silicon template is complex and challenging that ordinary process, e.g., ion beam milling is preferable for fabrication, which has being few reports. In this work, a sufficient head field of 15 kOe and a very steep field gradient of 500 Oe/nm are demonstrated with a 20nm-trackwidth MP.

Main pole taper profile

A trace image of a main pole that fabricated by ion-beam etching taken from the cross-sectional transmitting electron microscopy (TEM) is shown in Fig. 1. The trace is a typical one by the ion milling among many profiles of the main pole tip that can be obtained with variation of mask and beam conditions. This typical profile can be characterized as a two-step-tapered structure in which outer portion (far from mask edge) of the etched area shows gradual taper profile.

Writing Performance

Perpendicular field as a function of down track position estimated from a 20nm-trackwidth MP profiles by the ion milling (refer to Fig. 1) and template [2] process is shown in Fig. 2. The inset shows the MP and shield structure. The MP is composed of a two-step-tapered structure with the inner (shown as angle 'A') and the outer (shown as angle 'B') tapers. The MP fabricated by ion milling or by template process is designed to have the inner (A) /outer (B) taper angles of 55 / 15 or 55 / 0 degrees, respectively. Regardless with the angle combination, maximum value of a set of the field strength and the gradient of about 15 kOe and 500 Oe/nm, respectively, which are capable for Tbps recording with a bit patterned media (BPM) [4] was obtained. Furthermore, tail part of the profile along the cross-track direction was suppressed considerably with outer taper angle (B) of 15 degree compared with that of 0 degree. The main reason of the suppression is due to the MP configuration with gradual outer taper which is character of ion milling process. This leads to have wider margin for MP and shield design in a planar head.

Conclusions

Writing potential of a shielded planar head with an ion milling processed MP was estimated. Magnetic field simulation revealed that the ion milling processed MP has enough writing potential in both field strength (15kOe) and field gradient (500 Oe/nm) for the Tbps recording. Furthermore, better characteristic in side writing performance compared with that of template method is clarified. The shielded planar head with the ion milling processed MP is one of the strong candidates

as a writer in the Tbps recording age. This work was supported in part by Research and Development for Next-Generation Information Technology of MEXT.

Thin film processing realities for Tbit/in² recording.

R. Fontana¹, N. Robertson¹, S. Hetzler²

1. Hitachi GST, San Jose, CA; 2. IBM Research Division, San Jose, CA

Magnetic recording has maintained a cost/bit advantage over solid state storage by using a single transducer to assemble bits with sub-lithographic dimensions on an unpatterned substrate. In particular, the bit cell length is a sub lithographic dimension determined by the distance the disk rotates during the time interval between current pulses applied to the write yoke. This paper explores the ability of magnetic recording to maintain this advantage by examining the process challenges associated with the fabrication of head structures at 1 Tbit/in². Today, magnetic disc products have areal densities of 200 Gbit/in², a bit cell size of 150 nm x 20 nm formed with a minimum feature, F = 75 nm, for the MR sensor. This feature is 35% larger than the present IC critical feature, F = 55 nm, for NAND equal line and space dimensions. Using the NAND minimum feature, today's recording bit has a cell size of 2.70F x 0.36F and an area of 0.98F². In comparison, the competing NAND cell, two bits per cell, has an area of 3F².

Assuming annual areal density growth rates of 40%, in 2012 the manufacture of 1 Tbit/in² recording heads will require processing of structures with minimum features in the 25 nm range. Table I lists the design points of three 1 Tbit/in² head proposals by Wood [1], Mallory [2], and Kryder [3] where the physical sensor and pole tip widths are estimated using processing assumptions from Fontana and Hetzler [4]. Figure 1 shows the geometries of a perpendicular head structure appropriate for Table I. Figure 2 shows the most recent semiconductor ITRS lithography projections [5]. In 2012 these data project the 3 σ control of critical dimensions (12% of DRAM half pitch) as 3.8 nm, the 3 σ control of overlay (20% of DRAM half pitch) as 7 nm, and the minimum dimension for fabricating isolated MR sensors (microprocessor MP gate resist) as 24 nm. These values suggest that in the 2012 time frame 24 nm MR sensor widths can be fabricated. However, achieving flare lengths of 20 nm is questionable since the flare length is determined by at least five process actions: overlay of the MR sensor to a reference point (3 σ ol), overlay of the flare to the same reference point (3 σ ol), dimension control of the back edge of the sensor (0.5 x 3 σ cd), dimension control of the x and y dimensions of the flare structure (3 σ cd), and the lapping tolerance for the final sensor height (3 σ cd). For this paper, the 3 σ lapping tolerance is assumed equivalent to the dimension control of the sensor width, i.e. 12%, so that the variation of the area of the sensor is less than 25%. These tolerances produce a flare height variation of +/- 12 nm or +/- 60% for a 20 nm target.

Several implications result for 1 Tbit/in² head design points. Critical head dimensions will require smaller features than NAND flash. Control of yoke length will be limited by overlay. Most critically, 1 Tbit/in² head structures will require state of the art lithography equipment rather than tooling that lags the ITRS roadmap by 2-3 years as is the case today. In addition to these issues, the process implications of moving minimum feature processing from the head to the disk will also be discussed in the paper.

I. INTRODUCTION

Since the discovery of long range oscillatory indirect magnetic exchanging coupling in ferromagnetic/non-magnetic/ferromagnetic (FM) sandwich structures [1], many important aspects have been understood and applications have been realized. The examples include early giant magnetoresistance (GMR) sensors [2] and synthetic antiferromagnetic (SAF) multilayers [3] as soft underlayer (SUL) in perpendicular recording. The exchange coupling between the FM layers depends on the thickness of the non-magnetic layer and is very sensitive to the structure defects and interface quality. This effect offers us an extra path to control the effective anisotropy of the layers as well as the magnetic configuration and switching sequence of the whole structure.

Soft magnetic films in write head are required to have well-defined in-plane anisotropy with proper magnitude to enable the usage of them in in-plane hard axis direction, in addition to the requirements of high saturation magnetization (M_s), low remanent magnetization (M_r) and low coercivity field (H_c). In this report, we demonstrate that the SAF multilayers with three layers of FM layers and two non-magnetic layers provides the control of effective anisotropy and switching sequence of each layer through the exchange coupling, which shows discrete steps of magnetization in the easy axis (E.A.) hysteresis loop. It is now possible to use the SAF multilayers in their E.A. direction and have a step function-like operation in write head. Bilinear and biquadratic exchange coupling constants [4, 5] were extracted from the measurements and compared..

II. EXPERIMENT

The SAF multilayers were deposited by sputtering. The film structure is shown in Fig. 1, which consist three ferromagnetic layers (M1, M2, and M3) separated by two Ru layers. The ferromagnetic material is FeCoN. M2 is twice as thick as M1 and M3. Two different underlayers (UL1 and UL2) were used to induce different interface roughness in the structure. Magnetic properties were measured by vibrating sample magnetometer (VSM).

III. RESULTS AND DISCUSSION

The hysteresis loops of SAF multilayers are shown in Fig. 2, A, B and E. Calculation of hysteresis loops assumed coherent rotation in three coupled single magnetic single domain thin films and were obtained by minimizing the energy per unit area (Fig. 3), where d_1 , d_2 and d_3 are thickness of each FeCoN layer, θ_1 , θ_2 , and θ_3 are angles between magnetization of FeCoN and its E.A., ϕ is the angle between the applied field and E.A. (Fig. 1B), J_{12} and J_{23} are the bilinear exchange coupling constants between M1 and M2, and M2 and M3, respectively. J_{q12} and J_{q23} are the biquadratic exchange coupling constants of these layers. The E.A. of the three FM layers were assumed to be aligned. By fitting the measured hysteresis, J and J_q were extracted and listed in Table 1. The different interface roughness induced by different ULs affects the both bilinear and biquadratic exchange coupling, though the bilinear exchange couplings are impacted more severely. Larger roughness at the interface corresponds to decreased exchange coupling.

Laminated high moment FeCo films for perpendicular magnetic recording.

B. Ocker, K. Schuller, J. Wrona, J. Langer, W. Maass

Singulus Nano Deposition Technologies GmbH, Kahl am Main, Germany

Since several years high moment FeCo compositions are of great interest for writing head applications in the magnetic recording industry. With the implementation of the perpendicular magnetic recording new challenges at the material properties came up. Sputter deposited high B_s materials offer more flexibility in optimizing magnetic film properties in order to achieve desired writer performance [1], [2]. Laminations of these films offers an additional wide range for optimization [3]. We investigated single $\text{Fe}_{70}\text{Co}_{30}$ films and laminated films with magnetic and nonmagnetic spacers. The magnetic alignment of these films is strongly influenced by the direction of the material flow during the deposition process. The linear dynamic DC magnetron sputter process provides films with a very good uniformity of the magnetic properties across the wafer and in particular a nearly perfect anisotropy with an excellent alignment of the easy axis. The remanence in the hard axis direction is lower than 4% for the single films and has been improved by the laminations to better than 1 %. The magnetic moment of the single $\text{Fe}_{70}\text{Co}_{30}$ films were > 2.4 T.

Comparison of Electrical and Magnetic Flux Rise Times in Tape Heads Using Impedance Measurements and High Speed Kerr Magnetometry.

A. Kaya^{1,3}, J. A. Bain¹, J. P. Nibarger², K. D. McKinstry²

1. Carnegie Mellon University, Pittsburgh, PA; 2. Sun Microsystems, Louisville, CO; 3. Hitachi Global Storage, San Jose, CA

Increasing frequency requirements in modern tape heads requires detailed knowledge of the relationship between input current and flux rise time. To further this understanding we have performed high frequency impedance measurements, time domain reflectometry, and high speed Kerr magnetometry of the pole tips of a commercial tape head. The results of these studies are combined with a complete electrical model of the head which reproduces all of the observed measurements in the low drive current regime.

Head measurements were performed at the chip level in order to minimize interconnect effects. Head inductance, at drive levels below saturation, was measured to be 50 nH, in series with 18 Ohms of resistance and in parallel with 1.3 pF of capacitance. The flux rise time at the pole tips as a function of drive current is shown in Figure 1. It should be noted that when the head is driven into saturation clipping effects create substantial improvements in rise time, decreasing the 10-90% rise time to 1.05 ns, as has been shown previously in disk heads.

A simulation of the current in the head is shown in Figure 2. The model results indicate that the current rise time of the inductor is 2.1 ns when driven with a 50 Ohm transmission line, in agreement with the observed flux rise time at the pole tips at low drive current. This agreement between flux rise time and calculated current rise time indicates that little phase lag occurs between current and flux in the pole tips at these frequencies (> 500 MHz).

An important consequence of these observations is that eddy currents are much less active in the pole materials than would be suggested by their sheet film properties. The pole material in these heads has a thickness of 4 microns, a sheet film relative permeability of 800, and an electrical resistivity of 100 micro-Ohm-cm. These numbers suggest eddy currents should create significant phase lag between flux and current at 80 MHz (i.e. skin depth = thickness/2). The lack of phase lag between magnetic response and current for a 2 ns rise time indicates that the skin depth must be greater than 2 microns at a frequency of 500 MHz.

This increase in eddy current frequency can only be explained by a decrease in relative permeability of the head poles to approximately 100. Internal demagnetizing fields within the heads cause this permeability reduction and permit the higher frequency performance. This work therefore indicates that for quantitative design of heads for high frequency, pole geometry is critical for determining frequency response of the complete head, and a significant increase in head frequency response can be possible if demagnetizing fields are present.

Figure 1: Measured flux rise time as determined by high speed kerr microscopy at the pole tips of the head under various levels of drive current.

Figure 2: Calculated current rise time on the coil of the head, when a perfect voltage step is delivered to the head by a 50 Ohm transmission line.

Crosstalk between write transducers.

P. Herget, R. G. Biskeborn
IBM Corporation, San Jose, CA

A trend for improving performance in tape recording systems has been the miniaturization of head magnetic transducers and arrays. Smaller transducers enable packing more into a given span in the head, and this in turn enables higher data rate. A smaller span enables higher areal densities by reducing sensitivity to miss-tracking caused by changes in tape dimensions. However, it is well known that writers brought very close together can interact with one another [1]. When this happens, current in one writer alters the signals written to tape by the nearest neighbors. This paper discusses this phenomenon using modern recording heads.

<P>

Experiments were conducted on heads built using HDD wafer processing. Accordingly, the write transducers studied have high moment iron alloy cores and conventional pancake coils, and the separation between the writers was limited by the coil dimensions. In the tests, an isolated pulse waveform is applied to one transducer, while DC current is applied to its adjacent neighbors. The signals recorded on both sets of written tracks are read back. A weak remnant of the isolated pulse pattern is observed in the DC written tracks over a narrow range of DC current. Coupling in the writer leads was ruled out, as observations with widely spaced heads having identical cabling showed no such signals. On the AC driven tracks, the recorded isolated pulses have a normal shape, but close inspection shows that their timing is slightly off.

<P>

In the absence of DC current, the distance between adjacent positive and negative peaks is precisely half the period. When DC current is applied to the nearest adjacent writers, the positive and negative peaks shift in opposite directions. The positive and negative peaks are found to shift by the same amount. This is shown schematically in Fig. 1.

<P>

The measured dependence of the single pulse transition shift on DC current is shown in Fig. 2. The data include shifts that are longer than the rise time for current in a modern head (1-2 nanoseconds). This suggests that the field created by the DC currents in the neighbors modulates the center transducer 'write bubble' field [2], thus producing a physical shift in the transition locations on tape. The shift directions depend on the relative current polarities, while their magnitude is a measure of the coupling strength. When the applied DC currents in the two neighbors are in opposite directions, the shift vanishes.

<P>

The optimal operating current for the head and tape combination used for these data is approximately 20 milliamperes, which is typical for present day tape recording devices. At the experimental tape speed of 3 meters/s, the transition displacement on tape is approximately 6 nanometers. This is related to transducer design specifics, as well as to writer-to-writer spacing in the head. As that spacing is increased, the magnetic flux coupling between writers and the transition shift diminishes. No effect is observed for heads built on the industry standard pitch of 166.5 micrometers.

2. Swiss Light Source, Paul Scherrer Institut, Villigen, Switzerland

In this work we study the interaction of vortex cores with either holes in domain walls of Landau structures or other vortices and antivortices, which are also interconnected through the adjacent domain walls of a single cross-tie structure.

During the last few years the investigation of magnetic vortices and their dynamic properties has attracted great attention due to the fundamental interest in the physics of solitons and since they might be used as non volatile memory devices in future applications, e. g. [1,2]. One striking feature of magnetic vortices is that the cores are attracted and can be trapped by artificial defects. If more than one of such defects are created a switching between different vortex core trapped states, which might serve as discrete levels in a multivalent memory device, can be achieved. We report the imaging of the magnetic excitation spectrum in presence of holes, fabricated by focused ion beam milling, in the magnetic domains and domain walls of Landau structures by means of x-ray magnetic circular dichroism photoemission electron microscopy (XMCD-PEEM). The vortex core in the center of the structure is not modified by ions, here we investigate the interaction of unmodified vortex cores with holes far away (> 1 Mikrometer) in the domain walls and the domains of Landau structures. Due to the very high lateral and temporal resolution the magnetization dynamics and the corresponding Eigen modes (Fig. 1), which are characteristic for the vortex-hole interaction, are investigated in detail [3]. Analyzing the vortex movement unravels an acceleration of the vortex gyrotropic mode if holes are present in the middle of domain walls. The presence of holes in the middle of domains has no significant influence on the vortex speed. The experimental results are compared to micromagnetic simulations.

Another fascinating property of micromagnetism comes from the possibility to control the domain and vortex configuration through the sample shape and size. For instance, in a rectangular platelet a configuration containing a stable combination of two vortices and an antivortex can be created. Such a single cross-tie wall can be understood as being a coupled micromagnetic system with three static solitons. Here we report on its magnetization dynamics including the vortex-antivortex interactions [4]. The spectrum of eigenmodes is investigated as well as the effect of different vortex core orientations. These are important for the magnetization dynamics because they determine the sense of rotation for the gyrotropic motion. Since three cores are present in total $2^3 = 8$ configurations are possible. In Fig. 2 a) micromagnetic simulations of the vortex (left, right) and antivortex displacements upon field pulse excitation are shown for the first 16 ns. It is clearly observed that different types of configurations lead to completely different dynamic behaviors. The origin is the dynamic coupling of the cores which is mediated by the exchange coupling through the adjacent domain walls. This coupling is significant and introduces unexpected effects, such as the quenching of gyrotropic motion for the antivortex in certain core configurations. Another consequence is the absence of simple eigen modes describing the vortex gyration. The experimental investigation of the vortex core dynamics allows to determine the actual core configuration although the lateral core size is below the spatial resolution of the photoemission microscope. This is done by comparing the experimentally determined core displacements with the micromagnetically simulated ones as shown in Fig. 2 b).

The concept of controlling magnetization on the nanoscale ferromagnetic structures by spin-polarized currents has constructed a new category in the field of the spin-tronics. The current-driven magnetic domain wall (DW) motion [1-4] in ferromagnetic nano-wires has been considered as one of the most promising candidates for realizing new spin-tronics devices, such as the magnetic race-track memory [5]. The underlying physics of the current-driven DW motion is the so-called spin transfer torque, described as an interaction between spin-polarized conduction electrons and local magnetic moments. However, the current-driven DW motion is affected by many manifold contributions such as increase of the joule heating, effect of edge roughness, deformation of domain wall structures, non-adiabatic current effect, and stochastic character. Fundamental understandings about the spin transfer effect on the magnetic domain structures are still required.

The current-induced resonant excitation of the magnetic vortex [6,7] is a promising path to study the spin-transfer torque[8-9]. The magnetic vortex core confined in a ferromagnetic circular disk has a characteristic excitation called translational mode that corresponds to the circular motion of the vortex core. The motion can be resonantly excited around the dot center using an ac current, and the radius of this circular motion is proportional to the excitation current density. The advantage of this system is free from the manifold contributions described above. Thus, exploring the magnetic vortex dynamics upon excitation by spin-polarized currents is a promising path to understand in general the impact of current effects on the dynamics of non-collinear spin structures on the nanoscale including the current-driven DW motion.

In this presentation, we will talk about the time-resolved soft X-ray microscopy with < 70 ps time resolution [10] used to image the dynamics of the magnetic vortex translational motion excited by an ac current. The sample was prepared on the 200 nm thick Si₃N₄ membrane substrate. The diameter and thickness of the permalloy disk were 1.5 μm and 40 nm, respectively. To achieve the time-resolved measurement by the pump-probe method, the phase of the excitation current should be synclonized with timing of the X-Ray pulse. Thereby, a pulse modulated ac voltage of 100 ns in duration was applied to excite the motion of the magnetic vortex core. Excitation frequencies were varied from 150 MHz to 250 MHz.

The motion of the vortex core was found for the excitation frequency (f) of 210 MHz $< f <$ 230 MHz which is close to the resonant frequency (218 MHz) estimated from the Landau-Lifschitz-Gilbert equation. This is direct evidence of the current-induced magnetic vortex translational motion. Detailed analysis with the micromagnetic simulation enables us to estimate the spin polarization of the conduction electron to be ~0.6.

Elementary Eigenmodes of Magnetic Vortex Gyrotropic Motions in Magnetic Nanoelements.

K. Lee, S. Kim, D. Jung, Y. Yu, Y. Choi

Research Center for Spin Dynamics and Spin-Wave Devices & Nanospintronics Laboratory,
Seoul National University, Seoul, South Korea

From both fundamental and technological points of view, a magnetic vortex (MV), which consist of in-plane curling magnetizations (\mathbf{M} s) and out-of-plane \mathbf{M} s at the center region (called the vortex core) in soft magnetic nanodots, has attracted much attention because of its nontrivial static and dynamic properties [1-3]. The nanometer-sized vortex core (VC) has the bistate \mathbf{M} orientations, either up or down. Owing to the bistate VC orientations with high thermal stability, the MVs can be used as information carrier for future information-storage devices such as vortex-based random access memory, so called VRAM [4]. For the sake of utilizing the vortex state as a memory unit, it is necessary to find the reliable low-power control of VC orientation switching. Recently, ultrafast VC switching by applying very small amplitude of linearly oscillating magnetic field pulse or spin-polarized current along a certain axis in the film plane, has been verified experimentally [1]. Such reliable low-power switching of VC is an important step for realizing VRAM. Using this linearly oscillating magnetic field or current, however, we can not switch VC to a desired orientation because the linearly oscillating magnetic field reverses both upward and downward VC orientations. Now, we solve this problem by using an asymmetric resonant character of vortex gyrotropic motion in response to circular rotating magnetic field or current [4]. In this presentation, we report the elementary circular eigenmodes of vortex gyrotropic motion and their asymmetric resonant character and how we can apply such resonant character to control the VC reversal.

Based on Thiele's equation of vortex motion [5], we derived a dynamic susceptibility tensor of the VC motion [6], which is a useful to represent quantitatively the vortex response to any polarized oscillating field. Through the diagonalization of this tensor, we obtained the clockwise (CW) and counter-clockwise (CCW) rotating circular eigenvector basis of the VC motion in response to the CW and CCW rotating fields ($\mathbf{H}_{\text{CW}}(\omega_{\text{H}})$ and $\mathbf{H}_{\text{CCW}}(\omega_{\text{H}})$) or currents ($\mathbf{I}_{\text{CW}}(\omega_{\text{I}})$ and $\mathbf{I}_{\text{CCW}}(\omega_{\text{I}})$). As a result, we found that the CW and CCW eigenmodes of the gyrotropic motion and each circular eigenmotion can be expressed analytically by $\mathbf{X}_{\text{CCW}} = \chi_{\text{CCW}} \mathbf{H}_{\text{CCW}}$ and $\mathbf{X}_{\text{CW}} = \chi_{\text{CW}} \mathbf{H}_{\text{CW}}$. From both analytical equations, we can numerically calculate the amplification and phase delay of the eigenmotion in response to \mathbf{H}_{CCW} and \mathbf{H}_{CW} as shown in Fig. 1(a). These analytical calculations (solid line) are in good agreement with the micromagnetic simulation results (symbols). Depending on the VC polarization, p , only one of either the CCW or CW eigenmode shows the resonance effect, the other one showing non-resonance (sharp peak line vs straight line).

Due to the distinctly different asymmetric resonance effect near the resonance frequency, ω_{D} , the \mathbf{H}_{CCW} and \mathbf{H}_{CW} can be used to selectively excite the large gyrotropic motion of either CCW or CW rotation for a given VC orientation. Since the velocity of the VC motion is proportional to the amplitude of the gyrotropic motion for a given frequency and the VC orientation switches when the velocity of the VC motion reaches its critical value, $v_{\text{cr}} \sim 350$ 20 m/sec [3], we can switch the VC orientation selectively using \mathbf{H}_{CCW} and \mathbf{H}_{CW} , i.e., the \mathbf{H}_{CCW} can selectively switch only the up-core, but the \mathbf{H}_{CW} can switch only the down-core. To verify these, we conducted micromagnetic simulations on a Permalloy (Py) nanodisk of $2R = 600$ nm diameter and $L = 20$ nm thickness with the up-core orientation. As shown in Fig. 1(b), the amplitude of the orbital motions for the CCW motion by \mathbf{H}_{CCW} is extremely large compared with those for the CW motion by \mathbf{H}_{CW} and the upward VC orientation is switched to the downward VC orientation by \mathbf{H}_{CCW} but not by \mathbf{H}_{CW} . These asymmet-

ric resonance effect and selective VC switching are also observed when we apply circular rotating currents, \mathbf{I}_{CCW} and \mathbf{I}_{CW} [See Fig. 1(c)].

This work offers a principal further step toward practical applications of vortex states for ultrafast information-storage, -recording and -readout in vortex-based random access memory (VRAM).

We report on experimental observations of selective switching of the vortex core polarisation in sub-micron sized ferromagnetic Landau structures by applying rotating magnetic fields. The vortex core can be switched in a unidirectional way either to its 'up' or 'down' position depending on the sense of rotation (CW or CCW) of the external field.

The magnetic vortex [1] is a well known configuration of a ground state in geometrically confined ferromagnetic elements. It consists of an in-plane curling magnetization which in the centre, in order to avoid a singularity, turns out-of-plane and forms the vortex core. This vortex core has a radius of about 10-20 nanometres [2] and plays a key role in the magnetization dynamics [3,4]. As the out-of-plane magnetisation of the vortex core polarization (p) can point in two directions, either 'up' or 'down' (p = 1 or -1), it could be regarded as memory element. The high stability of the vortex structure and its very low stray fields would offer distinct advantages for applications requiring high density integration. Switching of the vortex core can be achieved, for instance, by applying a magnetic field perpendicular to the sample plane. However, field strengths of about 0.5 T are reported to be necessary [5,6] to crash the vortex core in this way and to rebuild it on the opposite side. Such high fields are intricate to realize on the small length scales necessary in practical devices for data storage.

Recently we discovered a new way to switch the vortex core polarization [7]. It was shown experimentally by X-ray microscopy that short, low-amplitude bursts of an alternating linear magnetic field reverse the vortex core. Burst with lengths down to a single period (4 ns) and amplitudes down to 1.5 mT [7] could toggle the polarization state of the vortex core. Based on micromagnetic simulations we also suggested that this dynamic vortex core reversal is mediated by the creation and annihilation of vortex-antivortex (VA) pairs [7]. This VA mediated switching scheme is now generally accepted for dynamic vortex core switching not only with excitation by magnetic field pulses but also by spin torque.

So far experiments and most simulations were performed with linear field pulses or bursts which toggle the vortex core from 'up' to 'down' and vice versa. For data storage application an unequivocal switching direction would be highly desirable. This could be achieved by circular rotating excitation fields [8-9].

Experiments have been performed by scanning transmission X-ray microscopy (STXM) at the Advanced Light Source (ALS, beamline 11.0.2) at Berkeley, CA, on square shaped, 500 nm large and 50 nm thin Permalloy elements. In-plane rotating magnetic fields were produced by cross-shaped striplines below the samples. The CW or CCW rotating fields were generated by ac currents in horizontal and vertical direction with the same frequency but a +90° or -90° phase difference respectively.

We observed that we could only excite the vortex core movement with the correct sense of rotation (CW or CCW) of the external rotating field depending on the vortex core polarisation [10]. When the amplitude of the rotating field was increased above a distinct threshold the gyrotropic vortex motion stopped, indicating that the vortex core polarization has been switched. For re-switching an

external field with the opposite sense of rotation had to be applied. All these results are consistent with micromagnetic simulations showing that an unequivocal and unidirectional switching of the vortex core polarization can be achieved by circular field excitation. Switching of the vortex core could also be confirmed by applying a linear in-plane ac field of the same frequency, which excites the vortex gyration independently of the vortex core polarization. The sense of the gyrotropic vortex motion indicates the polarization of the vortex core.

Surprisingly, significant differences have been found in the ac field amplitudes needed for switching the vortex polarization from 'up' to 'down' and from 'down' to 'up'. These differences in the switching thresholds have been observed not only during excitation with circular but also with linear ac fields. Such differences were never observed so far in micromagnetic simulations of 'perfect' samples. Possible explanations for this 'symmetry breaking' will be discussed.

We use a novel frequency resolved magneto-optic Kerr effect (FR-MOKE) [1] technique to probe the spin-dynamics and mode structure in 50 to 200 nm diameter Permalloy nanodots from 3 to 10 nm in thickness. It is important to understand the high-frequency behavior of such structures for continued development of spintronic technologies. An important question is how scaling and processing in nanostructures affects the magnetic properties such as switching field distributions and switching rates.

In this work, arrays of circular and elliptical nanodots were fabricated from dc magnetron sputter deposited 3 nm Ta/ 10 nm Permalloy/ 4 nm Si₃N₄ layers on sapphire substrates. Electron beam lithography was then used to create a cross-linked PMMA mask. Ion milling was used to transfer the mask pattern to the deposited magnetic layer. The inset of Fig. 1 shows a secondary electron micrograph of a typical array of 50 nm diameter nanodots.

Uniform precession modes were studied using FR-MOKE, whereby the nanodot arrays is driven by a cw microwave field generated by a coplanar waveguide. The microwave dynamics are detected by focusing a low-noise cw laser beam on the array and analyzing the polarization-modulated reflected light with a polarizer and a 12 GHz broadband photo-diode. The details of this technique and the data analysis used for fitting is given in Ref. 1. Figure 1 shows a typical FR-MOKE spectrum for an array of 50 nm diameter nanodots.

For nanodots greater than 75 nm diameter, two modes are observed with FR-MOKE. The field dependence of the frequency of these two modes is given in Fig. 2(a) and 2(b) for 100 nm and 200 nm nanodots respectively. Micromagnetic simulations [2] for a single ellipsoidal shaped nanomagnet (see insets in Fig. 2) reveal that one mode is concentrated at the edge while the other is concentrated at the center (herein referred to as the “edge” and “center” modes, respectively). The field dependence of the simulated mode-frequency is included in Fig. 2 in fair agreement with the data. We speculate that the small shift in frequency is most likely due to the fact that simulations were done on perfect structures that do not take into account such things as irregular shape, side wall tapering, and dot-to-dot dipole interactions. Figure 3(b) also show an asymmetry in the peaks which is reproduced in the simulations shown in Fig. 3(a). This asymmetry is due to a phase difference between the two modes that occurs when they overlap.

Characterization of the linewidth of these two modes allows us to independently study the homogeneity at the edge and center regions of the nanostructures. Micromagnetic simulations indicate that the linewidths of the two modes should intrinsically be the same as shown in Fig. 3(a) for a perfect structure. However, Figs. 3(b) and 3(c) show that the linewidth for the “edge” mode is approximately a factor of 2 greater. One plausible explanation is that the edge mode frequency is more susceptible to defects at the edges of the nanodots. Such defects would be most likely due to fabrication-induced damage and edge roughness. Such a sensitive dependence of edge mode properties on edge structure has been observed for edge modes in long Permalloy wires. [3] Thus, FR-MOKE could be used to quantitatively measure the edge properties of magnetic nanostructures and ultimately correlate that with processing conditions.

Many fields of application of magnetic materials require a fundamental study of the switching mechanism of small (micro or nano) magnetic elements. Most studies are oriented to magnetic data storage technologies [1,2], either for solid-state devices (MRAM) or patterned media hard disks. We have another application purpose which is to combine magneto-optics and microwave micro/nano materials for detection of intense electromagnetic pulses (EMP), like the ones emitted by large range radars. For aeronautics applications, the availability of rf magnetic field sensors is crucial for the determination of surface current density in airframes. The technique presently used is based on thermo-emissive foils (e.g. thin conductive layers deposited of polymer films) and infrared detection [3]. This method is only sensitive to the electric field component of the microwaves.

We have developed a combination of time-resolved Kerr magnetometer and stationary Kerr microscope, coupled with static field electromagnets, microwave generators and strip-lines for the excitation of high permeability micro-elements.

Experimental details :

Permalloy thin films were grown by rf sputtering on oxidized silicon wafers. A 1 kOe static magnetic field was applied in the plane of the substrates in order to induce a magnetic easy axis. Thickness was set in the range 10 to 50 nm in order to keep the magnetization in plane and to have a sufficient response in Kerr effect. Several sets of photolithography masks, containing assemblies of rectangular elements with lateral shapes $W(\text{width}) \times L(\text{length})$ ranging from 10×10 up to 20×160 square microns were used for patterning wafers in sectors of 7×7 square mm. The deposition-induced magnetic easy axis was aligned along the length of the micro-elements. A subsequent 5 nm Si_3N_4 capping layer was rf-sputtered prior to dicing.

Each individual sample was studied by longitudinal Kerr effect (ac field and He :Ne polarized laser). These first measurements reveal low values for the coercive field of our samples (typically from 1 to 10 Oe), as one can expect from large size magnetic elements. Dynamic susceptibility of each sample was analyzed with in a inductive coil in reflexion mode on a vectorial network analyzer. The cutoff frequency of this set up is 2 GHz. Compared to a plain NiFe film which has a gyromagnetic resonance frequency of 0.84 GHz, patterned films exhibit gyromagnetic resonance at larger frequency : 1.28 to 1.31 GHz for $20 \times L$ elements ($L=20$ to 160 microns), more than 2 GHz for $10 \times L$ samples. Fitting to LLG equations of the permeability spectrum of the plain film yields an anisotropy field of 8 Oe and a damping coefficient of 0.012. Such model does not apply for patterned elements since it requires uniformly magnetized thin film samples.

We have used a Kerr microscope, equipped with a 300 W UV-filtered Xe:Hg lamp, a standard set of polarizer/analyzer and a wide field objective. Images are collected with a 12 bits CCD camera and are subsequently analyzed for background subtraction and subpixel corrections of spurious sample motion. The optical resolution of our microscope is better than 1 micrometer. The sample holder is equipped with two microwave ports and an adapted strip line with one optical window. Samples are mounted underneath the strip line. The observation window is located in the center of the strip line where the rf field is highly homogeneous. This configuration leads to a more homogeneous magnetic field than with the usual coplanar waveguide used by others. Its drawback is the relative difficulty of accessing to the magnetic elements.

Results :

Magnetization switching field (or coercive field) decreases monotonically from 3.5 Oe for the unexcited elements, down to 2 Oe for 20 W. This decrease, already reported by Nembach et al [1] and Woltersdorf et al [2], is characteristic of the excitation of the transverse magnetization of the elements that favors its reversal. We are presently studying in detail the dependence of coercivity vs. the element dimensions, the microwave power and density. These results will be accompanied with micromagnetic modeling.

Another alternative way we have investigated is the demagnetization of a saturated permalloy element when it is submitted to submicrosecond magnetic field pulses. NiFe square elements ($100 \times 100 \mu\text{m}^2$) were excited with several series of 25 ns magnetic pulses. The peak magnetic field H_{peak} was adjusted from 0.1 to 10 Oe. Above a threshold value of $H_{\text{peak}} = 2$ Oe, we observe a significant demagnetization of the patterned square with the growth of opposite or transverse domains.

In conclusion, we have demonstrated that it is possible to monitor either the intensity and the frequency of a CW microwave excitation or the intensity, width and number of electromagnetic pulses on magnetic micro elements by Kerr microscopy. The implementation of this technique for microwave metrology is presently in progress.

The fundamentals of fast magnetisation switching is one of the important problems in magnetism, related to technological applications. Among various possibilities, the microwave-assisted (mw) switching with linearly-polarized excitation could be implemented based, for example, on fast magneto-optic Kerr set-up, synchronized with a microwave field [1]. It has been shown that the mw-assisted switching requires smaller dc external field. The process of understanding the underlying physics is still on-going and several ideas which include fast precessional switching [2], nonlinear phenomena [3], enhanced nucleation or increased domain wall mobility [1,4] could be found in the literature.

In the present work and with the aim to understand the mw-assisted switching in large magnetic elements [1], we use a micromagnetic model to simulate a permalloy ellipsoid of $4\mu\text{m} \times 2\mu\text{m}$ by 25 nm dimensions with easy axis parallel to the large ellipsoid dimension (y-axis). Initially the ellipsoid is magnetised along this axis and the dc-applied field is also placed parallel to it. The ac field with large amplitude is directed perpendicular (x-axis). First of all, we notice that the largest effect of the coercivity reduction comes from the deviation of the magnetisation from y-axis, following the ac-field. Thus, the coercivity is reduced simply due to the fact that most of time the resulting field is applied at some angle to the easy axis. Consequently, we compare the mw-assisted switching with the situation when we substitute the ac-field with the dc-field of the same amplitude. Our results show that even in this case the mw-assisted switching requires less dc-field.

Figs.1 show the magnetisation configurations during the static and mw-assisted reversal. We clearly observe that in the second case the ellipsoid is dynamically divided into “domain” structures. The number of “domains” depends strongly on the mw frequency and may be related to the length of the spinwave mode, excited in the system. The division of the ellipsoid into domains during mw-assisted switching is experimentally confirmed by Kerr images in Ref.[5].

Furthermore, during this process the Néel type domain walls appear. The magnetic moments in the center of domain walls are precessing and their mobility may be incremented by mw following the precessional switching effect. Another effect may be related to mw-assisted vortices switching [6], whose multiple appearance is also detected in the system.

We have investigated the switching time for ellipsoid as a function of the mw amplitude and frequency. Since the main features of the nonlinear processes with large-amplitude excitation may resemble that of the parametric resonance ones, we present in Fig.2 our results as a function of the double FMR frequency (evaluated for different applied fields), ω_0 normalized to the ac-frequency ν . Our simulations clearly show the maximum of switching time corresponding to the resonance condition $2\omega_0/\nu \gg 2a$. The difference a could be attributed to the nonlinear shift of the precessional frequency due to large-angle motion. Secondly, next-order resonances are also observed. Surprisingly, the switching time appears to be large when the mw frequency coincides with that of the nonlinear FMR one. Having analysed in details the switching process, we observed strong precession of magnetic moments in this case. Consequently, due to the coupling of the mw to the precessional mode, the energy is transferred into this motion and not to the switching process [4]. Finally, we conclude that several of the effects described above coincide, making the overall process compli-

cated. However, our simulations clearly confirm the fact that the mw-assisted switching requires less external field and is faster.

The study of magnetization switching in thin magnetic films and small magnetic elements is of interest today with the advent of patterned recording media and of MRAM. In this work we present a combined experimental and theoretical study of precessional magnetization switching in thin Py films. We show the evidence for nonlinear processes occurring during large-angle switching [1] that can strongly decrease the coherency of reversal and decrease switching times [2]. We focus on the effect that varying the strength and direction of bias fields may have on the threshold for non-linearity.

A 10nm Permalloy film was switched by applying a bias field and then a short pulse field at 90 degrees to the bias, which causes the magnetization to precess. The dynamics were measured using a Magneto-Optical Kerr Effect (MOKE) set-up in longitudinal configuration [3]. The magnetization vector can be resolved in all three directions and at all times during its trajectory using this technique. However, recombining the three components of the magnetization vector, it can be seen that the vector length, $|M|$, is not conserved (see Fig.1.). This is evidence that there are spin waves being parametrically excited in the film that have wavelengths shorter than the laser spot-size used in the experiment.

To compare with experiment we have used a classical, perturbative theory in which we write the magnetic Hamiltonian for the thin film and then solve equations of motion to find analytically the parametric threshold [4]. This is a threshold for four-wave decay of the large-angle precession, induced by the pulse field.

In Fig.2 we plot the minimum value of $|M|/M=|m|$ measured during switching as a function of bias field for both easy and hard axis biasing. A pulsed field of 5.9 Oe (as inferred by macrospin simulations) is used, and there is a uniaxial anisotropy of 7.9 Oe, which is experimentally measured. It can be seen that while for the easy axis biasing the maximum decrease in $|M|$ is 2%, for the hard axis biasing the maximum decrease is a much larger 10%. Also, for both plots there is a smaller decrease in $|M|$ for larger bias fields.

These results can be explained with comparison to our theoretical results. In Fig.3 we have plotted on the left the threshold to see a reduction in $|M|$ (in terms of average angle of precession) for hard (dashed line) and easy (solid line) axis biasing. There is a lower threshold for the hard axis biasing so we would expect the reduction in $|M|$ to be higher in this geometry. This is not the whole story, however, because the “supercriticality” of the system (how far above threshold it is) will also determine the decrease in $|M|$. On the right of Fig.3 we have plotted the switching angle for hard (dashed line) and easy axis (solid line) biasing, which gives a qualitative description of the precession angles involved during switching. Again, for the hard axis biasing there is a larger switching angle, and so a higher level of supercriticality, and we would expect a much larger decrease in $|M|$. Also, for larger bias fields, the precession angle goes towards zero.

Although Permalloy has a small uniaxial anisotropy, it has been shown that the direction of biasing is very important in determining the dynamics during switching. There is a much larger nonlinearity for hard-axis biasing at low fields, which means switching will be less coherent but faster in this geometry.

Precessional magnetization reversal in composite patterned media: Dependence on applied field parameters.

B. Livshitz¹, H. N. Bertram^{2,3}, A. Inomata⁴, V. Lomakin¹

1. Department of Electrical and Computer Engineering, UCSD, San Diego, CA; 2. Center for Magnetic Recording Research, UCSD, San Diego, CA; 3. Research Center, Hitachi Global Storage, San Jose, CA; 4. Storage and Intelligent Systems Laboratories, Fujitsu Laboratories Ltd, Atsugi, Japan

Precessional reversal (PR) is a reversal mechanism allowing bypassing an energy barrier thus resulting in a low reversal field [1,2]. Recently, it was shown that compared to PR in homogeneous elements, PR in exchange coupled composite elements is characterized by several unique properties [2,3], including substantial reduction of the reversal field and increase of the critical rise time, viz. rise time required for PR to occur.

Here, we continue the investigation of PR in composite elements. Specifically, we study the dependence of PR parameters on the applied field parameters, including the magnitude, pulse duration, and element coverage. We consider exchange coupled dual-layer elements in Fig. 1. The layers have anisotropies of K_h (hard) and K_s (soft) and identical size of $w, w/2, w$ and they are coupled with surface energy J_s . The layers have a damping constant α , saturation magnetization M_s , and exchange length $l_{ex} = A^{1/2}/M_s$ (with A the exchange constant). A magnetic field $\mathbf{H}_{ext} = -H_a(1 - 2\exp(-2t/\tau))(x\sin\phi + y\cos\phi)$ is applied uniformly across the width and through the height of the element but only over a varying percentage of the length direction. Here, ϕ is the field angle, H_a is the field magnitude, and τ is the field rise time. Magnetization reversal occurs when H_a is above a certain reversal field H_r . The analysis is performed by numerically solving the Landau-Lifshitz equation. Figure 1(a) shows H_r vs. percentage of the applied field coverage for different rise times for the structure parameters shown in the insert. It is found that H_r increases with a decrease of the applied field coverage. The magnetization distribution behavior shows that the increase is associated with non-uniform reversal in horizontal direction. More interestingly, H_r is found to be substantially smaller for a small rise time ($\tau=20$ ps- full curve) than for a large rise time ($\tau=200$ ps- dashed curve). The H_r reduction for small τ is obtained because in this case reversal occurs in the precessional regime [3]. It also should be noted that the PR field reduction for composite elements is much more pronounced than for homogeneous elements [3,4].

A crucial parameter for PR is the critical rise time τ_{crit} [3]. For homogeneous elements $\tau_{crit} = \pi/\gamma H_k$ and it can be extremely small for large values of H_k , which are required for thermal stability in high-density media. The situation is different in the case of composite media. Figure 1(b) depicts τ_{crit} vs. percentage of applied field coverage. The obtained τ_{crit} is significantly (about 8 times) larger than τ_{crit} for homogeneous elements. The values of τ_{crit} can be even larger for other structure parameters. It is also observed that τ_{crit} noticeably decreases with a decrease of the applied field coverage. It follows that by carefully choosing the rise time, one can control the mechanism of reversal for different applied field coverage. This is demonstrated by the dotted curve in Fig. 1(a) that shows H_r for $\tau=45$ ps. It is evident that H_r is very low and almost equals the PR field when the entire element is under the applied field, whereas it is much higher and almost equals the damping reversal field when only a small part of the element is under the applied field. This increased reversal field contrast can have important applications to improve time margin errors in magnetic recording applications.

We also have studied the reversal field behavior for many other parameters of the structure and pulsed applied field, including the applied field magnitude, rise time, pulse duration, and pulse shape. These results will be presented during the conference.

We study the statics and ultra-fast dynamics of magnetic bubbles in finite geometries. We identify transient phenomena that dominate the dynamics and show a way to obtain magnetic bubbles of varying topology in magnetic elements. We also calculate an eigenfrequency, which can provide an easy link with experiment. While the magnetic vortex is well understood as a fundamental state for magnetically soft discs, the question arises as to the corresponding fundamental state in the presence of a strong symmetry breaking anisotropy and its dynamical behavior. Confined single magnetic bubbles have been identified as ground states in nanoscale elements with magnetocrystalline uniaxial perpendicular anisotropy [1-4]. The bubble state presents a magnetic circulation around the centre of the dot and should be viewed as the analogue of the vortex found in soft dots. We have recently shown experimental evidence for the existence of such bubble domains [4], termed the monobubble (Fig.1), and the three-ring state, in suitably designed high-quality circular FePt nanodots. Here, we present Magnetic Force Microscopy imaging of these magnetic states.

A numerical study confirms the range of stability of the observed magnetic states and predicts the phase diagram in parameter space where these states are energetically favourable. The complexity of these multidomain states can be quantified by a topological invariant called the “Skyrmion number”, N . While the monobubble is the simplest topologically non-trivial structure (N unity) in magnetically hard dots, the three-ring structure has vanishing N . The skyrmion number is important for bubble dynamics since it is proportional to the gyrocoupling vector which is directly linked to magnetization dynamics [5]. We perform here a full numerical study of the evolution of bubbles under an external magnetic field gradient in nanodots and describe the unusual dynamics they exhibit. We allow the bubble to evolve under the field and then switch off the field and let it evolve freely until it reaches a remanent state. We use a field which varies by the magnitude of the saturation magnetization along the dot’s diameter. The field used here is particularly strong but the underlying described phenomena should be generic. By calculating the moments of the center of mass and the topological density of the bubble we follow its motion and dynamical behaviour.

Surprisingly, the topological charge moves not across the gradient, but perpendicular to it; in just $t=45$ ps it has moved for $10 l_{ex}$. Interestingly, at $t=385$ ps we observe a switch to vanishing topological density. The magnetic configuration is allowed to evolve freely and it relaxes in the center of the dot indicating that this is a metastable state in our system. We thus illustrate a simple subnanosecond mechanism to switch from a bubble with skyrmion number unity to a bubble with a vanishing skyrmion number in a finite geometry. This state is not symmetric anymore and it has a slightly larger energy. The circular domain wall now includes a pair of Néel lines. The new configuration’s dynamical behaviour is different to the monobubble’s dynamics. Importantly, this is an ultra-fast mechanism, which should be of interest in devices. We also identify the mechanism to switch back to the original symmetric monobubble state by controlling the applied pulse. We study the monobubble behaviour under various magnetic gradients of different durations and strengths. For low enough fields, we observe a low drive of the bubble without distortion of the domain wall structure. In addition, a displaced bubble with unperturbed domain wall, left to evolve freely, performs a damped periodic motion towards the center of the dot (Fig.2). We thus calculate the corre-

sponding eigenfrequency, which for the specific geometrical characteristics, is approximately 1GHz.

a) The topography of a 500nm diameter FePt nanodot is shown. b) The magnetic image shows a bubble in the center.

The moments of the center of mass (X, Y) and of the topological density (X_1, Y_1) are shown. The switching from the bubble with $N=0$ back to the monobubble with $N=1$ is shown. After the switch the bubble is off-centered and it enters a periodic motion to the center of the dot.

Control of domain wall motion in Permalloy nanowires using magnetostatic interactions.

S. Basu, D. Allwood, T. Schrefl

Department of Engineering Materials, University of Sheffield, Sheffield, United Kingdom

Controlled pinning and depinning of domain walls (DWs) in ferromagnetic nanowires can be used to control the movement of DWs [1, 2]. This may provide additional functionality in DW devices. We have carried out micromagnetic simulations of pinning and depinning of transverse DWs by magnetostatic interactions between two or three Permalloy (Ni80Fe20) nanowires placed side-to-end (T and cross shapes). Figure 1 gives a schematic representation of the wire geometries and shapes used for the study. The wires consist of a 'propagation wire' that has an initialised DW on one side, and one or two 'control' wires placed close to the edge of the propagation wire. A linearly increasing applied field is used to move the DW in a nanowire. In order to pass through the junction region, the DW must overcome the magnetostatic interactions with the control wire(s). These may be attractive or repulsive interactions but either case results in an increased 'pass' field compared to propagation elsewhere in the wire. This interaction varies as a function of the wire separations and end shape of the control wire(s). The control wire ends had either flat-ended or of tapered geometries. The wires were 200 nm wide. The separation between the wires was varied from $d = 20 - 100$ nm.

The pass field is higher when the end shape of the pinning wire is flat compared to when the end shape is tapered. The relative magnetisation direction in the control wires and in the DW was varied. In T shapes, it was either parallel or antiparallel. In cross shapes, the magnetisation configurations in the two control wires with respect to the DW magnetisation was parallel, antiparallel, antiparallel-antiparallel or parallel-parallel as depicted in figure 2a, 2b, 2c and 2d respectively for flat-ended control wires.

The pass field increases with decreasing separation. For example, in T-shaped structures with the tapered end of the control wire close to the propagation wire a 200% increase in pass field is observed when $d = 20$ nm compared to $d = 100$ nm (Figure 3). Again, the pass field is nearly doubled to 4.2 mT when the flat end of the control wire is close (20nm separation) to the propagation wire compared to the tapered end of the control wire close (2.2 mT). Figure 4 shows the pass field of the DW as a function of separation between the propagation and the control wire, with the flat end close. The cross shaped geometry was better in pinning the DW for some of the magnetisation configuration for smaller separation. For example, in the configuration where the magnetisation in the control wires is antiparallel to the DW magnetisation, the switching field is double compared to the T-shape with the same separation. When the tapered end is used to pin the DW, the pass field is much lower, compared to when the flat end is used to pin and also comparable to the T-shapes of equal separation. Cross-shapes offer high level of control for DW propagation by changing the magnetisation geometry compared to the T-shapes where little control is possible.

Domain wall depinning from a notch under oscillating currents: the role of non-adiabaticity.

E. Martinez¹, L. Lopez-Diaz², O. Alejos³, L. Torres²

1. Ingenieria Electromecanica, University of Burgos, Burgos, Spain; 2. Fisica Aplicada, University of Salamanca, Salamanca, Spain; 3. Electricidad y Electronica, University of Valladolid, Valladolid, Spain

The position of a Domain Wall (DW) in a thin ferromagnetic wire can be manipulated by means of notches, which act as pinning potential wells by locally lowering its magnetostatic energy. The analysis of the current-induced DW depinning from a notch is not only of technological relevance for promising logic and storage devices [1]. It is also interesting from a fundamental point of view, because the comparison between theoretical predictions and experimental observations could be used to ascertain the magnitude of the non-adiabatic spin torque, which is difficult to compute from first principles.

In this talk, the interaction between oscillating spin-polarized electrical currents and a DW initially trapped on a notch in a thin Permalloy nanostrip is investigated by micromagnetic modeling as well as a one-dimensional model which considers the wall as a rigid object [2]. A systematic analysis of the depinning transition is carried out in the frequency domain for several static magnetic fields and AC currents, both at zero and at finite temperature [3].

As an example, we have computed the depinning field as a function of the frequency of the injected current. The results are depicted in Fig. 1 under a constant amplitude current $1\text{A}/\mu\text{m}^2$ at room temperature. Each dot represents the first field at which the DW is depinned with 100% of probability ($P_D=1$) for each frequency of the current. Solid line represents the fitting to the analytical deterministic field in the stationary regime [3]. A dip of the depinning field is observed at the frequency resonance [2].

We have also analyzed a similar pinning potential as experimentally studied by Bedau and coworkers [4]. Their experimental results can be also quantitatively described by the rigid approach if a non-adiabatic parameter in the order of 1 is considered. Such a high value of the non-adiabatic parameter could be related to the large magnetization gradient occurring in a vortex wall, where the magnetization changes by 180 degrees within a few nanometers. This noticeable issue, along with its theoretical implications and details of our model, will be extensively discussed in the presentation.

Spin-polarized current induced magnetization switching has drawn considerable attentions for the potential applications of high density magnetic random access memory (MRAM). [1] The spin polarized current flows through the magnetic tunnel junctions exerts a spin torque on the magnetic moment of the ferromagnetic layer which is used as the information storage layer (free layer) in MRAM. One of the most challenging targets of the spin torque switching architecture is the reduction of critical current of magnetization reversal while keep the thermal stability at a reasonable level in the mean time. In general, the reduction of critical currents requires a intrinsically softer ferromagnetic material as the free layer or reducing the thickness of free layer. Nevertheless, these approaches contradict the requirement of maintaining thermal stability.

In this work, we propose a composite free layer, which is a sandwiched structure, two ferromagnetic layers separated by a metal layer, and coupled by the RKKY interlayer exchange coupling in parallel. The macrospin models were used to study this structure. The lateral size of model structure is a ellipse with a long axis of 100nm and a short axis of 50nm. The stacks and corresponding parameters are as following: a top soft free layer (layer 1), with a saturation magnetization of 250 emu/c.c., an uniaxial anisotropy of 10 Oe, a thickness of 17.5 angstrom, and a bottom hard layer (layer 2), with a saturation magnetization of 400 emu/c.c., an uniaxial anisotropy of 30 Oe, a thickness of 12.5 angstrom. Assume both layers are experiencing the spin torque simultaneously, and have the same damping constant of 0.02 and polarization of 0.2.

We found that with a 10ns current pulse, a single layer 2 has a switching critical current density of 6.4×10^6 A/cm² and a single layer 1 has a switching critical current density of 4.0×10^6 A/cm². However, if these two layers are combined together and interlayer exchange coupled with a coupling strength of 0.01 erg/cm², the device requires only 4.2×10^6 A/cm² of critical current density to switch. These results suggest that the precession of magnetic moment in the soft layer (layer 1) may assist the precession of magnetic moment in the hard layer (layer 2) and make the layer 2 switchable at a much lower current density than the value on its own. In a word, this kind of free layer structure has the potential of existing low switching current density and high thermal stability at the same time. The influences of exchange coupling strength, relative hardness of ferromagnetic layers, spin-torque efficiencies in these two layers, and random thermal perturbations will be addressed by both macrospin and micromagnetism simulations.

The magnetization dynamics of vortex structures in patterned elements has received considerable attention during the last few years due to its possible applications in high-density magnetic storage devices [1-3]. Recently, it was found that the vortex core magnetization can be switched by applying a short magnetic field pulse with an appropriate strength and duration [3]. For practical applications, however, it is desirable to find a more convenient method, i.e., current-driven switching of the magnetization state of the vortex. Here we report detailed micromagnetic studies of the spin-transfer effect on the vortex magnetization in magnetic multilayer structures. Fig. 1(a) is a schematic of the multilayered structure used in our study. The diameter is 100 nm, and the fixed magnetic layer (Co) is separated from the free magnetic layer (Py) by a 4 nm thick Cu layer. The bottom panel of Fig. 1 shows the initial magnetization configurations in the Py (b) and Co (c) layers, respectively. Each layer contains a single vortex core located at the center of the disk, and M_{Py} and M_{Co} are aligned close to parallel forming a small angle between M_{Py} and M_{Co} . To study the dynamic response of the vortex magnetization to the spin-polarized current pulse, the equilibrium micromagnetic distributions of M_{Py} and M_{Co} are excited by injecting a short current pulse. The current direction is denoted positive when it flows from Py to Co layer. Fig. 2 shows a series of the non-equilibrium configurations of M_{Py} captured at selected times after a negative current pulse of 30 mA ($\approx 1 \times 10^8$ A/cm²) with the duration of 200 ps is applied. Following the temporal evolution of the micromagnetic configuration, one finds that individual M_{Py} undergoes the CW rotation, while the whole vortex configuration appears to circulate CCW around the disk center. The image (b), captured at 84 ps after the current pulse is applied, reveals that M_{Py} rotates by $\sim 90^\circ$, and with increasing time M_{Py} further rotates by $\sim 180^\circ$, as shown in (c) captured at 144 ps. Finally, the vorticity of M_{Py} switches to CW (d). M_{Py} of the switched vortex state, however, is still in a nonequilibrium state, and the dynamics of the energy dissipation after the initial vortex chirality switching involves a series of complex magnetization processes. The magnetization configuration in (d), for instance, reveals a high degree of complexity both due to the nonuniform distribution of M_{Py} and the creation of an additional vortex-antivortex pair. The pair is found to be a metastable micromagnetic state, and it vanishes without undergoing the annihilation process. As shown in Fig. 2(e), a full relaxation of M_{Py} is reached after about 2 ns after the excitation. By contrast, the micromagnetic distribution of M_{Co} is only slightly perturbed from the initial state through the entire process of the chirality switching of M_{Py} , and no switching of vortex chirality of M_{Co} occurs (f). After the reversal of the vortex chirality of M_{Py} is completed, the curling in-plane magnetizations of M_{Py} and M_{Co} remain aligned nearly antiparallel to each other, implying that the vortex configuration shown in (e) and (f) is an energetically stable micromagnetic state in the nanopillar. Finally, the switched vortex chirality is reversed back to the initial vortex configurations of M_{Py} and M_{Co} by applying a positive current pulse, 25 mA in amplitude and 200 ps in duration. The critical current density required for the back-switching is reduced to about 8×10^7 A/cm², which is about 20% lower than the value needed for the negative current pulse discussed in Fig. 2. In conclusion the switching of the vortex chirality of M_{Py} is understood in terms of the spin-transfer torque exerted on M_{Py} . The dynamics of the energy dissipation in the chirality switching involves a series of complex magnetization processes,

which includes the magnetization precession and creation of additional vortex and antivortex cores. From an application point of view, the results suggest opportunities to implement the novel switching mechanism to memory device applications, in which vortex states with opposite chiralities in the free layer of a magnetic multilayer may be used as memory bits.

In the present paper we evaluate the temperature dependent properties of the micromagnetic exchange constant in FePt, a material which has been intensively studied due to its potential application as ultra-high density recording media. We introduce different approaches to investigate the scaling of the exchange stiffness A with the magnetization M in a broad temperature range up to the Curie temperature T_c . This scaling behaviour is of interest due to its application for coarser scale micromagnetic simulations, e. g. within the framework of the Landau-Lifshitz-Bloch equation [1,2]. The exchange stiffness is also relevant for pump-probe type and heat assisted magnetic recording (HAMR) simulations [3].

We use a number of approaches to determine the exchange stiffness A within the atomistic resolution. Namely, we model bulk FePt in the chemically ordered phase using an effective classical spin Hamiltonian [4,5]. The layered structure of this phase is responsible for the fact that the interaction within the Fe planes are larger than between different Fe planes. The latter affects the domain wall width as well as its energies [4].

Within this model, we obtain thermodynamic averages, such as the internal energy, by integrating a classical Gilbert equation with Langevin thermal fields at atomic scale until the system reaches equilibrium. The free energy is obtained by integrating the internal energy over the inverse temperature. We force a domain wall in the system by means of boundary conditions. The wall width and the excess free energy yield the micromagnetic anisotropy constant and micromagnetic exchange stiffness [6]. The anisotropy is consistent with independent calculations [4]. The exchange stiffness is shown in the figure for two orientations, perpendicular as well as parallel, of the wall relative to the FePt planes.

Furthermore, for confirmation of this result, we use a generic Hamiltonian using material parameters largely comparable to the effective Hamiltonian described above. Here, we use a constrained Monte Carlo method [7] to force a spin spiral into the system in order to calculate the free energy difference between a system with and without it. This is equivalent to the evaluation of the micromagnetic exchange stiffness. Finally, our third method calculates the spin wave spectrum using Fourier transformation of magnetisation fluctuations [8] in a generic atomistic system. From the spectra we extract the spin wave stiffness, which, on the macroscopic scale, is equivalent to the micromagnetic exchange energy constant.

The comparison of values from the different methods is complicated given that the crossover is difficult to detect from numerical results. However, all these different approaches yield the same magnetisation scaling of the exchange stiffness for temperatures not close to T_c , with exponents close to 1.7. Furthermore, analytical calculation of the domain wall free energy based on mean-field approximation suggests that two different scaling laws exist, one for low temperatures and another one in the high temperature limit, with two different scaling exponents. The reason for the different regimes will be discussed.

An alternative finite element scheme for dynamic micromagnetic computations.

A. Manzin¹, O. Bottauscio¹, M. Chiampi²

1. Istituto Nazionale di Ricerca Metrologica, Torino, Italy; 2. Ingegneria Elettrica, Politecnico di Torino, Torino, Italy

Finite difference or finite element techniques are well established numerical methods for the spatial discretization of the Landau-Lifshitz (LL) equation [1]. The finite element method (FEM) enables the use of unstructured meshes, allowing a precise description of complex geometries, and the adaptive mesh refinement. With a 3-D FEM discretization, the unknowns are the three components of the magnetization on each grid node [2], or the projection of the magnetization on each edge of the tetrahedral mesh [3]. In both FEM approaches, the weak formulation reduces the spatial derivative order in the exchange term, but requires the enforcement of the nonconvex constraint. With nodal FEM a possible strategy is the normalization of the magnetization module after every time step [2], but no corrections are imposed on the magnetization direction. The edge FEM makes difficult the introduction of direct corrector schemes; in this case the nonconvex constraint can be approximated by a penalization strategy, which has the drawback of requiring the tune-up of the penalty and mesh parameters [4].

To overcome these difficulties, this paper proposes an alternative solution, which applies the weak formulation in the effective field expression, before solving the LL equation. The three components of the effective field are obtained by a nodal FEM approach, leading to a time-invariant stiffness matrix, which is computed once and for all at the beginning of the dynamic evolution. The instantaneous nodal values of the effective field are then introduced in the LL equation, and the magnetization is locally derived in each FEM node following a time stepping scheme able to preserve the constraint [5]. The magnetostatic field, expressed by the scalar potential, is calculated by solving the Poisson equation either with a hybrid finite element/boundary element method (FEM/BEM) or with an integral Green formulation.

The procedure is applied to the study of magnetization reversal in bulk objects and thin films with a spatially uniform distribution of the initial magnetization and subjected to a uniform and constant applied field. The method validation is obtained by comparison to analytical relationships describing the uniform magnetization state, in the case of spherical particles [6], and to the results performed with the NIST/OOMMF code, in the case of thin films.

Fig. 1 reports the magnetization time evolution in the case of precessional switching in a sphere (diameter of 250 nm) with a uniaxial anisotropy constant of 150 kJ/m³ and easy axis along x-direction. The reversal is produced by an external field applied along y-axis. The computations are made with a 3-D coarse mesh having a tetrahedron edge size equal to a tenth of the sphere diameter. Despite the rough discretization, the comparison evidences how the numerical results are in good agreement with the analytical solution when calculating the magnetostatic field through the FEM/BEM approach. The Green formulation introduces numerical errors, which are reduced by refining the mesh of a factor 4.

The precessional switching in a permalloy thin film is shown in Fig. 2. The film is discretized with a 3-D mesh having a tetrahedron edge size Δs comparable to the exchange length; the method converges to the reference solution, calculated with the NIST/OOMMF code, provided that the time step Δt is sufficiently small.

An innovative time integration scheme for solving the Landau-Lifschitz-Gilbert (LLG) equations based on the finite element method (FEM) was proposed by Alouges in 2006 [1]. In our paper, we generalize it by taking into account all the energy terms and evidence its robustness and reliability in strongly nonlinear dynamics.

The magnetization distribution corresponding to an equilibrium state of the ferromagnet can be obtained by minimizing the total energy E_{tot} with respect to the orientation of $\mathbf{m}(\mathbf{r})$ [2]. In the continuous medium approximation, this energy is the sum of several contributions:

$$E_{tot}[\mathbf{m}] = \int A_{ex} [\nabla \mathbf{m}]^2 dV + \int K_L [1 - (\mathbf{u}_K \cdot \mathbf{m})^2] dV - \int \mu_0 M_S \mathbf{m} \cdot \mathbf{H}_{app} dV - \int 1/2 \mu_0 M_S \mathbf{m} \cdot \mathbf{H}_m dV \quad (1).$$

This integral expression depends on the material parameters: A_{ex} the exchange constant, K_L and \mathbf{u}_K for the uniaxial anisotropy and M_S the spontaneous magnetization. \mathbf{H}_m is the magnetostatic field, solution of Maxwell's equations.

The method adopted here to relax the magnetic configuration to its equilibrium state consists in integrating the dynamic LLG equations:

$$\mathbf{v} = -\mu_0 \gamma (\mathbf{m} \times \mathbf{H}_{eff}) + \alpha (\mathbf{m} \times \mathbf{v}) \quad (2).$$

Here \mathbf{v} is $\partial \mathbf{m} / \partial t$ with the constraint $|\mathbf{m}|=1$, γ is the gyromagnetic factor, α is the damping constant and \mathbf{H}_{eff} is the effective field obtained by variational derivation of the total energy E_{tot} with respect to $\mathbf{m}(\mathbf{r})$. Following (1) the effective field can be written as the sum of four fields: exchange field \mathbf{H}_{ex} , anisotropy field \mathbf{H}_{ani} , magnetostatic field \mathbf{H}_m and applied field \mathbf{H}_{app} . Solving Equations (2) using FEM, as explained below, means deriving their weak form and integrating it using the most suitable integration method [3].

Usually, the weak form is obtained by projecting the physical equations onto basis test functions \mathbf{w} . These test functions can be piecewise linear or quadratic functions. Our FEM approach is based on an original weak formulation of the LLG equation [1]. Due to the fact that the vector fields (\mathbf{m}, \mathbf{v}) belong to mutually orthogonal subspaces, the projection method is adapted by choosing vector test functions only in the tangent space to \mathbf{m} . One possibility to do that is by building $\boldsymbol{\phi} = \mathbf{m} \times \mathbf{w}$ such as $\mathbf{m} \cdot \mathbf{w} = 0$ without loss of generality. Taking these into account the weak form obtained for the LLG equations reads as:

$$\alpha \int \mathbf{w} \cdot \mathbf{v} + \int \mathbf{w} \cdot (\mathbf{m} \times \mathbf{v}) + (2A_{ex}) / (\mu_0 M_S) \int \nabla \mathbf{w} \cdot \nabla \mathbf{m} - \int \mathbf{w} \cdot \mathbf{H}_{loc} = 0 \quad (3).$$

Note that for the exchange term the derivation order of unknowns and test functions has been equilibrated.

The time discretization in our approach looks like a classical θ scheme. It is obtained from the weak form (Eq. 3) by replacing $\mathbf{m}(t)$ by $\mathbf{m}_n + \theta \delta t \mathbf{v}_n$, where $0 \leq \theta \leq 1$. In particular, $\theta = 1/2$ corresponds to a Crank-Nicholson like scheme. Finally Equation 3 can be rewritten as:

$$\alpha \int \mathbf{w} \cdot \mathbf{v}_n + \int \mathbf{w} \cdot (\mathbf{m}_n \times \mathbf{v}_n) + (2A_{ex} \delta t) / (\mu_0 M_S) \int \nabla \mathbf{w} \cdot \nabla \mathbf{v}_n = -(2A_{ex}) / (\mu_0 M_S) \int \nabla \mathbf{w} \cdot \nabla \mathbf{m}_n + \int \mathbf{w} \cdot \mathbf{H} \{ \mathbf{m}_n \} \quad (4).$$

It is important to notice that the system to solve always remains linear, only a normalization of the magnetization is needed at each mesh node and for each iteration, even in the case $\theta = 1/2$. This implies that the accuracy of the $\theta = 1/2$ scheme is better than the implicit one ($\theta = 1$), but is not of order 2 in time.

A key step is to show that the Equation 4 describes a dissipation process. In other terms, one has to check if the energy difference between two consecutive time steps:

$$\delta E_n = E \{ \mathbf{m}_{n+1} \} - E \{ \mathbf{m}_n \} = E \{ \mathbf{m}_n + \theta \delta t \mathbf{v}_n \} - E \{ \mathbf{m}_n \} \quad (5)$$

is negative. For sake of simplicity, only the exchange term is kept in the following proof. In this context, the system's energy reads as $E \{ \mathbf{m}_n \} = \int A_{ex} (\nabla \mathbf{m}_n)^2$ at each time step n . Writing down the energy at time step $n+1$ and making use of the weak formulation we manage to obtain the expression of δE_n :

$$\delta E_n = -\alpha \delta t \int \mathbf{v}_n^2 - (\theta - 1/2) \delta t^2 (2A_{ex}) / (\mu_0 M_S) \int (\nabla \mathbf{v}_n)^2 \quad (6).$$

One remarks that the system's energy decreases in time only if $\theta \in [1/2, 1]$.

We present here an application of our finite element approach to magnetic thin films with perpendicular anisotropy of moderate strength. The equilibrium magnetization configuration of such systems consists in a periodic modulation of the perpendicular component of the magnetization leading to parallel stripe domains [4].

To test our approach the relaxation process to equilibrium calculated by FEM is compared with the one obtained by a finite difference (FD) approach implemented in the software GL_FFT (© Institut Néel).

By monitoring the time evolution of the total energy we check that the time integration scheme describes a dissipation process towards equilibrium. A small energy gap below 0.1% is observed at equilibrium between the FD and FEM calculations. This gap can be attributed to the different ways to evaluate the total energy: FD uses local estimations of the magnetization vector and the effective field, whereas in FEM the total energy expression (1) is applied to the magnetization field interpolated on each element. A very good agreement between the results is observed on a large range of time, proving the high accuracy of our original weak form for micromagnetism.

Thermal stability in submicron-sized ferromagnetic bodies is one of the crucial issues in magnetic storage technologies and spintronics.

In the last decades, this topic has received considerable attention both from the experimental and the theoretical point of view [1].

Thermally induced magnetization dynamics is usually studied by including appropriate white-noise terms into the classical magnetization dynamics equations, such as Landau-Lifshitz (LL) or Landau-Lifshitz-Gilbert (LLG) equations [2].

The resulting Langevin-type equation is, from the mathematical point of view, a stochastic and nonlinear differential equation driven by non-additive white noise.

The solutions of this stochastic equation can be found, in principle, by direct stochastic time integration methods. On the other hand, in many situations relevant to applications, ferromagnetic elements are designed to be relatively stable against thermal fluctuations. This means that stable magnetization states are separated by large energy barriers and thermally activated transitions between these states occur on very long time scales. In these conditions, magnetization dynamics has very different time scales of evolution: stochastically perturbed precessional dynamics occurs on the picosecond time scale while thermal activated dynamics may occur on the microsecond second time scale. Since a correct stochastic time integration requires an accurate description also of the fast time scale, direct numerical Langevin simulations may become unfeasible especially when spatially nonuniformities of magnetization have to be taken into account.

The study of thermally activated transitions in these weak noise conditions can be carried out by using appropriate asymptotic techniques, such as nudged elastic band method [3], string method [4] and action functional method [5]. These techniques provide estimates of the probability of certain transitions. The probability is estimated in terms of exponential factors which can be computed by determining the most probable path followed by the state of the system to realize the transition under investigation. In the present work, we use the action functional method which is based on the Freidlin-Wentzell theory [5]. This method is applicable to stochastic systems governed by a generic stochastic differential

equation and it is based on a rigorous mathematical theory. The method is obtained by applying a large deviation principle to the probability that the stochastic trajectories generated by the differential equation are inside a specified set of paths. This probability can be formally written in terms of a Wiener path integral. According to the large deviation principle, one can prove that the probability associated to this set of paths, in the limit of weak noise, is determined by the path in the set which minimize an appropriate action functional. This path is what is generally called an optimal path. In the case of switching between two stable states 'a' and 'b', the set of paths of interest is the one given by the paths starting from the point 'a' and finishing in an appropriate neighborhood of the point 'b'. In this case, the optimal path is also an optimal switching path.

In this work, we study systematically the accuracy, for small but finite noise, of the action functional method. This study is carried out by comparing results of direct stochastic simulations of Langevin LL with those obtained by minimization of the action functional associated to LL equation. To keep the numerical simulations feasible we have limited ourselves to the case of a uniformly magnetized anisotropic nanoparticle. Stochastic time integration is performed by using the mid-point stochastic scheme presented in Ref.[6]. In Fig.1 it is shown typical stochastic evolution of one component of magnetization obtained by stochastic time integration. On the other hand, action functional minimization is performed by a suitable numerical optimization technique. The detailed analysis of Langevin simulations allows one to carry out an 'empirical analysis' of stochastic switching paths and in this way to show how accurate is the estimate obtained by the action functional technique. The complete comparative study of these two techniques will be presented in details in the full paper.

NiMnGa, as an important kind of ferromagnetic shape memory alloy (FSMA), is currently receiving increasing attention due to its large magnetic-field-induced strain (MFIS) since their discovery by Ullakko et al in 1996. However, the effect of external mechanical input on the magnetic behavior in NiMnGa alloy received limited attention. Several authors studied reversible (pseudoelastic) stress-strain behavior of single crystal NiMnGa at a constant magnetic field. It is found that the pseudoelastic stress-strain behavior only take place when the applied magnetic field exceeds certain critical value. When the applied field is lower, the quasiplastic behavior appears.

In this work, a phase-field method [1] was used to study the transition from the quasiplastic to pseudoelastic behavior under applied mechanical and magnetic field. In our model, a state of FSMA is described by two fields: a local magnetization field $M(r)$ and a stress-free transformation strain field ϵ . Their evolution may be obtained by solving Landau-Lifshitz-Gilbert (LLG) equation and time-dependent Ginzburg-Landau (TDGL) equation respectively. The parameters of NiMnGa employed in our model are from the references [2].

With no magnetic and stress fields applied, the Domain structure (DS) and Martensitic Microstructure (MS) are generated simultaneously. Two kinds of martensite variants (A and B) were obtained and each martensitic plate contains anti-parallel magnetic domains. The 90 degree magnetic domain walls coincide with twin boundaries.

As shown in Fig 1, a stress was applied along the y axis gradually without an applied magnetic field. In the initial stage of loading process of the quasiplastic behavior, the strain changes a little with the applied stress and both of the DS and MS have no visible deformation. With the increase of the applied stress, the loading curve climbs up rapidly. The martensite variant B grows up continuously and the variant A shrinks simultaneously. In the corresponding magnetic domain structure, the 90 degree domain wall starts to move. When the applied stress is greater than 7Mpa, only a single martensite variant left and a corresponding stripe magnetic domain structure exists. When the stress unloaded, the martensite microstructure remains unchanged, the strain will not reverse, except for the elastic deformation originating from elasticity of the material itself. There is no obvious change in the magnetic domain structure throughout the unloading process. The stress-strain curve under $H=150\text{kA/m}$ along x axis is similar to that in Fig. 1.

The pseudoelastic curve under an applied magnetic field of 300kA/m along x is shown in Fig 2. We observed that in each variant, the original anti-parallel domain structure disappeared and were replaced by a single orient magnetic domain structure after applying the magnetic field. As a result, there is only 90 degree domain wall exists. During the loading process, the evolution of martensite microstructure is exactly the same as the case with no external applied field, except that larger applied stress needed to move the martensite twin boundary. During the unloading stage, firstly, with the decrease of the stress, the strain decrease slowly, the domain structure and the martensite microstructure have no obvious change. But when the applied stress is lower than 0.8Mpa , the strain descends rapidly following the reducing of the stress. As shown in Fig2, the x domain expanded under the external applied magnetic field and the martensite twin boundary also started to move through the magnetoelastic coupling effect, recovering strain to its original state. Also,

throughout the loading and unloading process, 90 degree domain wall and the twin boundary are matched. The magnetization-strain curve shows a narrow hysteresis.

From the observed phenomenon above, we can conclude that the 90 degree domain walls coincide with the martensite twin boundary. Pseudoelastic stress-strain behavior will appear when the external magnetic field is large enough to move the martensite twin boundary through magnetoelastic coupling.

Effects of nanowire roughness on spin wave propagation.

S. Bance, T. Schrefl, D. Allwood, G. Hrkac, A. Goncharov
University of Sheffield, Sheffield, United Kingdom

Spin waves are of interest as propagators of information in the field of spin wave logic [1]. Here it is beneficial for their behaviour to be orderly and predictable so that device behaviour is reliable. Reflections from the structural boundaries of the magnetic microstructure may cause interference that would disrupt the useful waves that the devices use. Or in turn, well defined microstructural features may be used to perform certain logic operations. Wire roughness and edge defects can introduce small reflective and diffractive effects that might affect the amplitude and coherence of spin waves propagating through the wire. This work assesses the effect of wire roughness and single notches using finite element micromagnetics.

We first consider the effect of a single, triangular notch on the propagation of spin waves through a nanowire. A permalloy nanowire of width 100 nm and thickness 10 nm has a notch of width 50 nm and depth 25 nm on one edge. An external field is applied in a locally confined region at a distance of 200 nm from the notch to generate spin waves that travel outwards along both directions of the wire. Fig. 1 shows the two spin wave packets travelling from the centre to the two ends of the wire. The notch on the right hand side of the wire decreases the spin wave amplitude but does not hinder spin wave propagation. A probe is placed after the notch at a distance of 150 nm from the centre of the notch. The Fourier transform of the transverse magnetization at the probe point shows a decay of the spin wave amplitude and a slight shift of the spin wave frequency if the spin wave packet passes the notch. However, this change is observed only for a notch of width 50 nm and depth 25 nm. For a notch of only half of this size no significant change in the Fourier spectrum is observed due to the presence of the notch (see Fig. 2).

The spin wave propagation across the wire depends on the local initial susceptibility of the transverse magnetization. The wire is split into regions each of length 100 nm in order to calculate the magnetic susceptibility in each region. The local susceptibility at probe points in the vicinity of the notch is similar to the susceptibility at other points along the wire. Whereas the existence of a notch does not perceptibly alter the susceptibility in the region around it, the initial susceptibility close to the two wire ends is about two times higher than in the rest of the wire.

Four nanowires with different types of roughness have spin waves generated at their centre, as above, and probes to measure the peak spin wave amplitude at different probe positions along the wire. The results (Fig. 3) show that introducing roughness into the wire can reduce the propagation amplitude of the spin waves.

We conclude that notches in a nanowire can reduce spin wave transmission through the nanowire and may be used to adjust the spin wave frequency. Since wire roughness can be modelled as a series of notches, roughness may also hinder spin wave propagation.

[1] A. Khitun & K. L. Wang, Superlattices and Microstructures 38 pp. 184-200 (2005)

Figure 1. Spin wave propagation from the centre of a 100 nm wide nanowire. The notch does not hinder the propagation of the spin wave packet but reduces the spin wave amplitude. The perpendicular magnetization component is colour coded at different times after perturbing the magnetisation in the wire centre.

Figure 2. Spin wave frequency plot for a probe positioned after the notch shows reduced transmission of the spin waves for increasing notch size. The Fourier transform of the transverse magnetization is plotted for wires with notch width 50 nm, 25 nm, and no notch.

Figure 3. Spin wave maximum amplitudes at positions along a permalloy nanowire. The spin wave amplitude can vary by around 15% depending on the type of roughness used. Shown here are two examples of triangular, periodic roughness of various size as well as realistic roughness taken from a micrograph image. These are compared to a wire with no roughness.

Effect of interface exchange coupling on the reversal of single antiferromagnetic grains in exchange bias systems.

J. Jackson, U. Nowak, R. Chantrell
Physics, University of York, York, United Kingdom

The exchange bias and coercivity increase observed in multilayer systems, consisting of an antiferromagnetic (AFM) layer exchange coupled to a ferromagnetic (FM) layer, are strongly affected by the characteristics of the AFM layer during field reversal. For a single grain in an exchange decoupled AFM film, the size, geometry and interface structure determine whether the AFM sublattice magnetisation reverses and, if reversal does occur, the mechanism of reversal.

Here, zero temperature atomistic simulations using the Landau-Lifshitz-Gilbert equation are presented, modelling the reversal of single antiferromagnetic grain due to the exchange field of an interfacial FM. The transition from collective reversal to incoherent reversal has been studied for systems with perfect interfaces; FM/AFM interfaces with a step like structure having varying proportions of each AFM sublattice coupled to the FM have also been examined.

For the case of perfectly uncompensated interfaces and in the small grain limit, reversal proceeds by coherent rotation analogous to Stoner-Wohlfarth switching. When the grain length is comparable with the material domain wall width, reversal occurs by the introduction and propagation of a domain wall in the AFM grain in accord with the Mauri model [1]. During such domain wall assisted reversal, a distortion of the magnetisation away from the easy axis is introduced into the grain at the interface. This is the minimum energy configuration for small deviations of the ferromagnet orientation from the antiferromagnet easy axis, but becomes metastable as the partial domain wall angle increases. This results in hysteresis in the reversal of the AFM which is considered to be a realistic dynamic effect having an energy barrier corresponding to the domain wall energy of the grain.

When the interface contains a step, AFM ordering is frustrated and a distinct surface domain forms for all orientations of the ferromagnet. This surface domain, which minimises exchange energy at the surface, prohibits coherent AFM magnetisation reversal for all film thicknesses by eliminating the energy barrier of establishing a domain wall within the grain. Because the axial symmetry of the system is broken by the surface step, reversal occurs by collective spin fluctuations out of the interface plane resulting in reversal hysteresis different to that observed for perfect interfaces.

Atomic resolution simulation shows that the dynamics for step-like interfaces cannot be simply described by a varying interface coupling because of the domain structure present at the interface. These simulations provide a framework for advancing micromagnetic simulation studies of the exchange bias effect; realistic reversal energy barriers together with a more accurate description of the importance of surface inhomogeneity and interface exchange coupling variation can substantially improve Fulcomer-Charap type approaches [2].

It has also been found that the domain wall energy in finite systems depends upon the crystallographic orientation of the major axis of the grain. For systems where the grain axis is aligned along the [111] direction, the energy barrier tends to the energy of a 90 degree domain wall in the limit of infinite film thickness. This effect, which is most pronounced as the aspect ratio of the grain is increased, is important for film thicknesses found in modern sensor devices.

Maximum uniaxial AFM anisotropy for coherent reversal for perfectly uncompensated FM/AFM interfaces. The dotted line shows the prediction of the 1-dimensional Heisenberg model.

Change in the AFM reversal energy barrier, dE , as a function of Length for different grain widths. For the [111] interface, the energy change is larger than that predicted by the 1-dimensional Heisenberg model. The different lines correspond to varying grain radius (lattice units).

Microtexture and Magnetic Microstructure of Sputtered NdFeB Thick Films Destined for Application in Micro-Electro-Mechanical Systems (MEMS).

T. G. Woodcock¹, K. Khlopkov¹, A. Walther², N. M. Dempsey², D. Givord², O. Gutfleisch¹

1. Institute for Metallic Materials, IFW Dresden, Dresden, Germany; 2. Institut Néel, CNRS, Grenoble, France

Thick films (5-300 μm) of NdFeB have excellent hard magnetic properties which make them attractive for applications in micro-electro-mechanical systems (MEMS) [1]. Such films have been prepared by a two step process consisting of triode sputtering followed by high temperature annealing of the as-deposited film [2,3,4]. Optimum magnetic properties were achieved for a substrate temperature of 500°C during deposition and an annealing temperature of 750°C for 10 min with a rapid heating rate [3,4]. In this digest, detailed characterisation of the local crystallographic texture and magnetic microstructure of the NdFeB layer are presented.

Triode sputtering was used to deposit {Ta (100 nm) / NdFeB (5 μm) / Ta (100 nm)} multilayers onto 100 mm diameter Si substrates at various temperatures. Details of the deposition procedure are given elsewhere [3,4]. The microtexture of the NdFeB layers was investigated in plan view by electron backscatter diffraction (EBSD) in a FEG-SEM. The magnetic microstructure of the NdFeB layers was investigated using magnetic force microscopy (MFM) using hard magnetic tips.

The misorientation of the NdFeB grains with respect to the ideal orientation [001]//film normal is shown for deposition at 300°C (fig. 1a) and 500°C (fig. 1b). Both films were annealed at 750°C for 10 min after deposition. The grains are coloured according to the misorientation angle given in the colour key. Grain boundaries are shown in black. The grey areas in fig. 1a and b correspond to those electron backscatter diffraction patterns which could not be indexed as the Nd₂Fe₁₄B phase. These points are due to imperfections or contamination on the polished surface. Although the proportion of these points is relatively high, significant microtexture information has still been obtained. Blue and dark green grains have a misorientation of < 20° and are therefore considered to be well oriented. Although the sample deposited at 300°C (fig. 1a) has a large fraction of well oriented grains, the sample at 500°C (fig. 1b) is entirely well oriented. This is also shown by the misorientation distribution above the colour key (fig. 1a and b) which is much sharper and has its maximum at a lower angle for the film deposited at 500°C. Sharper texture leads to higher out of plane magnetic anisotropy and therefore to an improved energy product (BH_{max}) [3].

The magnetic microstructure of the NdFeB films imaged by MFM is shown in fig. 2 for films in the as-deposited state. Bright areas correspond to domains directed out of the plane of the image and dark areas are domains oriented 180° to the bright ones. The films deposited without substrate heating (fig. 2a) and at 400°C (fig. 2b) have magnetic domains typical of amorphous materials. These films were reported to be amorphous in the as-deposited state [3]. The film deposited at 500°C was reported to be crystalline and to display hard magnetic properties [3] and this is reflected in the magnetic microstructure (fig. 2c) which is typical for crystalline materials with high magnetic anisotropy.

A comparison of MFM images of samples in their as-deposited and annealed states will be made. The evolution in the characteristics of the magnetic microstructure, with increasing deposition temperature, will be discussed. The application of EBSD to study microtexture in NdFeB films is a novel approach and is expected to become an important characterisation tool in these systems. A combination of high resolution characterisation techniques is vital for the development of MEMS.

Temperature dependent anisotropy in epitaxial Pr-Co films.

A. K. Patra¹, M. Eisterer², R. Biele^{1,3}, S. Fähler¹, L. Schultz¹, V. Neu¹

1. IFW Dresden, Dresden, Germany; 2. Atomic Institute of the Austrian Universities, Vienna, Austria; 3. University of Technology Dresden, Dresden, Germany

Recently, epitaxial Pr-Co films have been prepared on Cr buffered MgO(110) substrates with a single orientation of the c-axis along the MgO[001] and record values of M_s and energy density ($(BH)_{\max} = 310 \text{ kJ/m}^3$) [1]. In this work, we focus on the intrinsic properties of such a highly textured, epitaxial $\text{Pr}_{15.4}\text{Co}_{84.6}$ film, especially on the temperature dependent anisotropy including the spin reorientation transition (SRT).

The magnetic characterization was performed by measuring magnetization curves in a VSM with field applied along different angles with respect to the texture axis of the sample at various temperatures (Fig. 1). To determine the anisotropy constants a full range fitting procedure to the magnetization loops in a field range of 2 to 5 T is performed. The theoretical magnetization loops were calculated based on an energy minimization code including anisotropy energy up to second order (K_1 and K_2) and magnetostatic energy of the magnetization vector in an applied field. A realistic texture spread of 10° was implemented by averaging over a Gauss shaped c-axis distribution around the texture axis of the sample. For a given temperature, measurements at 5 different angles were fitted simultaneously to derive the first and second order anisotropy constant (K_1 and K_2). In Fig. 2 the measured magnetization loops at a temperature of 220 K are shown. For the applied field along the easy axis ($\alpha = 0^\circ$), the magnetization curve in the first quadrant reaches a constant value of M_s already at small fields. When the field is applied at an angle to the easy axis ($0 < \alpha \leq 90^\circ$), the field leads to a rotation of the magnetization vector away from the easy axis and consequently the remanent magnetization decreases and the slope of the magnetization loop increases. Fig. 3 shows the first quadrant magnetization curve measured at 100 K (open circle) together with the calculated curve (line) obtained from the minimization routine. It is worth noting, that at this temperature the $\text{Pr}_{15.4}\text{Co}_{84.6}$ film is below the SRT and the anisotropy energy is minimum in an easy cone configuration around the c-axis. This is apparent from the reduced slope of the magnetization curve at $\alpha = 90^\circ$, which would intersect the magnetization axis at a non-zero remanence value. The anisotropy constants K_1 and K_2 as a function of temperature are shown in Fig. 4. The measured value of $K_1 = 4.8 \text{ MJ/m}^3$ at room temperature is lower compared to the bulk single crystal value of $K_1 = 7.7 \text{ MJ/m}^3$ for PrCo_5 [2], whereas the value of $K_2 = 1.1 \text{ MJ/m}^3$ is higher. This discrepancy may be due to the high Cobalt content of this $\text{Pr}_{15.4}\text{Co}_{84.6}$ film, which is optimized for high saturation magnetization or due to the presence of a mixed phase. Nevertheless, the nature of the curves are similar to the bulk with a monotonic increase of K_2 and a decrease of K_1 with decrease in temperature, and a sign reversal of K_1 at about 120 K, which manifests the spin reorientation transition.

Sintered $\text{Sm}_2\text{Co}_{17}$ -based Magnets with Small Additions of Indium.

A. Gabay¹, M. Marinescu², J. Liu², G. C. Hadjipanayis¹

1. University of Delaware, Newark, DE; 2. Electron Energy Corporation, Landisville, PA

In the best currently used high-temperature Sm-Co permanent magnets, the coercivity is developed in the bulk state through a multiphase “cellular” nanostructure. To assure this some excess of Sm and 7 - 10 at. % of Cu and Zr must be added to the alloy, which decreases the amount of high-magnetization $\text{Sm}_2(\text{Co,Fe})_{17}$ phase. The earlier attempts to obtain “pure” 2:17 magnets were not very successful [1,2], though a maximum energy product of 28 MGOe has been reported for magnets containing Mn [3]. Coercivity of magnets fabricated via sintering of anisotropic micron-size powders critically depends on the state of their grain boundaries. In particular, the high performance of sintered Nd-Fe-B magnets is assured by the low-melting-temperature Nd-rich phase which magnetically insulates the $\text{Nd}_2\text{Fe}_{14}\text{B}$ grains and inhibits nucleation of reversed magnetic domains.

In this work, we analyzed the grain-boundary phases formed in the $\text{Sm}_2(\text{Co,Fe})_{17}$ sintered magnets due to small additions of several elements (Ag, C, Ga, In, Sn) and their combinations. Differential thermal analysis (DTA) indicates the appearance of a liquid phase at 1055 - 1070 °C in In-added $\text{Sm}_2\text{Co}_{17}$ and $\text{Sm}_2(\text{Co,Fe})_{17}$ alloys (Fig. 1). According to energy-dispersive spectrometry (EDS), the grain-boundary phase found in the In-added cast alloys and in sintered magnets is enriched in both Sm and In (Fig. 2). Virtually all the added In is concentrated in this phase, where its content reaches 18 - 20 at.%. Due to the lowered solidus temperature, the 2:17 magnets with only 0.5 at.% In exhibit a density of 0.98 times that of the ingot after sintering for 1 h at 1075 °C (Fig. 3a), which is more than 100 degrees lower than the usual sintering temperature of the 2:17 magnets.

The addition of In also led to a significant increase in the coercivity (Fig. 3b), though the reasonable values were obtained only for the $\text{Sm}_2(\text{Co,Fe,Mn})_{17}$ matrix phase known to have an enhanced magnetocrystalline anisotropy [3]. The coercivity was found to be very sensitive to the post-sintering heat treatment, as shown in Fig. 4, and it is dramatically reduced if the magnets have been quenched from a temperature lower than 1000 °C after annealing for 1 h at this temperature. This behavior resembles that of the SmCo_5 magnets, though the most usual explanation of the latter (the 1:5 phase supposedly decomposes into the 2:17 and 2:7 phases) is hardly applicable to the 2:17 magnets. The coercivity values of optimally annealed magnets with different Sm content are also shown in Fig. 4. In conclusion, the small In additions greatly facilitate sintering of the “pure” 2:17 magnets, but more effort is needed to obtain a high magnetic performance.

Prediction of temperature demagnetization of bonded rare earth magnets by finite element analysis.

T. Schliesch, T. Lindner

Max Baermann GmbH, Bergisch Gladbach, Germany

Often permanent magnets suffer irreversible losses of magnetic flux by changes of temperature or by external fields. This especially is of relevance for many sorts of bonded magnets on rare earth basis like NdFeB or SmFeN magnets. Mechanisms for magnetic weakening can be sought in mainly three effects: Passage of magnetization to minor hysteresis curves, change of operating points by magnetic viscosity and flux losses due to oxidation. In our paper we will deal with the analysis of the first two effects. The method we use is applied for homogeneously magnetized magnets as well as for specimen, which have non trivial shape of polarization. Predictions by FEM will be compared with experimental results.

Fig. 1a sketches the basic principle of magnetic losses in rare earth magnets due to the movement of operating points to minor hysteresis loops when temperature is changed. Here e.g. a point A changes to B when the magnet is exposed to a high temperature, and finally to C when the sample is cooled down again. In bonded NdFeB magnets such losses due to a movement to recoil curves even start at low magnetic loads, as the most materials show a bent demagnetization curve already at locations close to remanence. On the other hand also magnetic viscosity plays an important role for these sorts of magnets, which can be seen in Fig. 1b. by the flux loss of a bonded NdFeB sample as a function of time. In Fig. 1a. this effect can be described by a vertical movement e.g. of point B to point B' at high operating temperatures.

To perform a quantitative description of the irreversible losses of bonded magnets, especially after the exposition to high operating temperatures, we included both effects into the FEM analysis of the related systems. The recoil curve effect was treated by modeling temperature dependent demagnetization curves and by transferring the operating point locations to inner loops when temperature changes and irreversible parts of the demagnetization curve are occupied. The minor curves were modeled as unique curves for simplicity. This process was done for each finite element of the magnet due to the spatial spreading of magnetic loads, which takes place even for homogeneously magnetized magnets. The impact of viscosity was modeled by treating it as an additional, time dependent field, which generally is also different at different locations in the magnet. For non homogenous magnets which were magnetized by pulse magnetization, in addition the pulse magnetization process had to be modeled by coupling the coil model with that of the magnetizers circuit and by applying a simple hysteresis model. Fig. 2 shows the degree of saturation for such a non homogeneous magnet of rotational shape, which had a two pole bow shaped magnetization in axial direction. In Fig.2 the specimen is only partially saturated. This magnet was analyzed in regard to its losses after temperature exposition in saturated as well as in non saturated state to proof the accuracy of our method under different conditions. All predictions by finite elements were compared to experimental values by comparing computed fields outside the magnet with hall probe measurements.

One of our main results was that a neglect of magnetic viscosity always led to wrong predictions of magnetic losses with an error up to 50%, whereas the inclusion of viscosity resulted in good to adequate correspondences with experimental results. The predicted external fields always were a useful approximation of reality as long as magnetic loads were not to high and as long the upper temperature was within reasonable limits. Fig. 3 shows the change of the axial field maximum on

a circular path above the non homogenous magnet of Fig. 2 after different temperature expositions, at different distances to the magnets surface and for different magnetizing voltages.

New Dy-substituted Ba hexaferrites with high coercivity.

G. Litsardakis¹, I. Manolakis¹, A. Stergiou², C. Serletis², K. G. Efthimiadis²

1. Dept. of Electrical & Computer Engineering, Aristotle University, Thessaloniki, Greece; 2. Dept. of Physics, Aristotle University, Thessaloniki, Greece

Several rare earth additions have been tried recently in Ba and Sr hexaferrites after the preparation of Sr-La-Co sintered magnets with improved magnetic properties [1]. Addition of Sm, Nd and Pr has resulted in coercivity enhancement which is generally attributed to microstructural effects [2-4]. Single-phase rare-earth substituted hexaferrites have been obtained only with Nd by the chemical coprecipitation method [3] and with Gd by both the classical ceramic [5] and the coprecipitation methods [6]. In this report we present for the first time the synthesis and properties of a new series of Ba-Dy hexaferrites with enhanced coercivity.

Samples with nominal chemical formula $(\text{Ba}_{1-x}\text{Dy}_x)\text{O} \times 5.25\text{Fe}_2\text{O}_3$ ($x=0-0.30$) were prepared by the chemical coprecipitation method from nitrate salts and then heated at $T_h = 900-1200^\circ\text{C}$ for 2 h. Phase formation and crystal structure have been examined by x-ray powder diffraction with $\text{CuK}\alpha$ radiation. The recorded diffraction patterns have been analyzed by the Rietveld method. Magnetization measurements were performed by VSM at room temperature with maximum field 1.8 T. Diffraction patterns of samples heated at 1000°C are presented in Fig. 1. All samples present the M-type hexaferrite structure (s.g. $\text{P6}_3/\text{mmc}$, $a \approx 5.88\text{\AA}$, $c \approx 23.2\text{\AA}$) and are single-phase up to $x=0.15$ for $T_h=900^\circ\text{C}$ and $x=0.10$ for $T_h=1000^\circ\text{C}$. Beyond this substitution range, Fe_2O_3 is present as the only secondary phase in small amounts $\sim 1-10\%$. Formation of $\alpha\text{-Fe}_2\text{O}_3$ is also favored by the increase of the heating temperature.

The absence of other phases suggests that Dy is incorporated in the hexaferrite structure in the whole substitution range. This has not been observed in other rare earth substituted hexaferrites, except for Gd [6].

The hysteresis loop of sample $x=0.25$ at $T_h=1000^\circ\text{C}$, presenting a coercive field $H_c = 441\text{ kA/m}$ (5.6 kOe) is shown in Fig. 2. In Fig. 3 the variation of specific saturation magnetization σ_{sat} and coercivity H_c with substitution x are traced for $T_h=1000^\circ\text{C}$. Coercivity is high ($\sim 365-410\text{ kA/m}$), and increases significantly up to $\sim 440\text{ kA/m}$ for $x=0.15-0.25$, at $T_h=1000^\circ\text{C}$, while it decreases for $x=0.30$. Magnetization decreases slightly with substitution and ranges between $65-62\text{ Am}^2/\text{kg}$ up to $x=0.25$. The decrease of magnetization is related to the presence of $\alpha\text{-Fe}_2\text{O}_3$. The variation of coercivity may be attributed mainly to the influence of Dy on grain growth, according to the studies of the analogous Gd series, $(\text{Ba}_{1-x}\text{Gd}_x)\text{O} \times 5.25\text{Fe}_2\text{O}_3$ [6]. A similar behaviour is observed in Sr-Dy hexaferrites which are currently under study.

Strain-induced exchange bias effects in chemically ordered Pt₃Fe single crystal.

S. Kobayashi, S. Takahashi, Y. Kamada, H. Kikuchi
Faculty of Engineering, Iwate University, Morioka, Japan

The chemically long-range ordered Pt₃Fe alloy has L1₂-type superlattice structure and exhibits paramagnetic-antiferromagnetic phase transition at $T_1 = 170$ K, associated with magnetic structure characterized by propagation vector $\mathbf{q}=(1/2 \ 1/2 \ 0)$. [1] With decreasing temperature, Pt₃Fe alloy shows another antiferromagnetic phase transition at $T_2 = 100$ K below which two types of magnetic structures with $\mathbf{q}=(1/2 \ 1/2 \ 0)$ and $(1/2 \ 0 \ 0)$ coexist.

Plastic deformation on such chemically ordered alloy drastically changes the magnetic property, because it strongly depends on the atomic arrangement and/or the configuration of atom-atom pairs. It was shown that plastic deformation on Pt₃Fe single crystal results in superlattice dislocations with burgers vector of $(a/2)\langle 110 \rangle$ and glide plane of $\{111\}$, and large spontaneous magnetization shows up even at room temperature after very small plastic deformation by 1.3% strain. [2] The appearance of the large ferromagnetism was explained as due to ferromagnetic domains produced around slip planes where strong ferromagnetic exchange coupling between Fe atoms plays a crucial role. In spite of the understanding of formation mechanism of ferromagnetic domains, however, the coupling between the ferromagnetic domains and antiferromagnetic structure in L1₂ matrix has not been studied. In this paper, we report the results of magnetic hysteresis loop measurements on chemically ordered Pt₃Fe single crystals after tensile deformation up to 29.8% strain.

Measurements of magnetic hysteresis loops for lightly deformed Pt₃Fe single crystals were performed using a commercial Quantum Design SQUID magnetometer with magnetic fields up to 50 kOe in the temperature range from 5 to 300 K. We confirmed that ferromagnetism, associated with magnetic hysteresis, appears for all deformed samples in all temperature range below 300 K and found that the loop area and coercive field increase with decreasing temperature. However, when the samples were field-cooled at $H = 20$ kOe from 300 K, observed magnetic hysteresis loops were found to be shifted toward the negative field, unlike normal hysteresis loops centered at origin obtained after zero-field cooling. Figure 1 shows temperature dependence of field shift toward a negative field i.e. exchange bias H_{eb} , obtained after field cooling at 20 kOe. For all deformed samples, exchange bias effect shows up below T_1 and H_{eb} rapidly increases with decreasing temperature. Increasing the level of deformation first makes H_{eb} increase at each temperature but further deformation rather makes it decrease. Such behavior of H_{eb} was also observed after field cooling at $H = 10$ kOe, though a decrease of cooling field enhances the exchange bias effect. These observations reflect strong coupling between antiferromagnetic matrix and ferromagnetic domains formed around superlattice dislocations in plastically deformed Pt₃Fe single crystal.

Fe-Pt thick film magnets prepared by high-speed PLD method.

S. Shibata, M. Nakano, T. Yanai, H. Fukunaga

Electronics and Electrical Engineering, Nagasaki University, Nagasaki, Japan

In order to apply Fe-Pt film magnets for dental attachment[1] and medical micro-machines, the films with high energy product and thickness of several tens of microns are needed. A dominant method for obtaining Fe-Pt thick films is a sputtering method. For example, Aoyama et al. reported a 129 micron-thick film with $H_c = 580$ kA/m and $(BH)_{max} = 104$ kJ/m³, and a 7 micron-thick Fe-Pt film was reported by Liu et al. to have magnetic properties with $H_c = 446$ kA/m and $(BH)_{max} = 124$ kJ/m³ [2][3]. The sputtering method, however, includes the difficulty of deposition speed for a mass-production of the above-mentioned miniaturized devices. This contribution reports PLD(Pulsed Laser Deposition)-fabricated Fe₅₀Pt₅₀ films thicker than 10 microns under the high deposition rate up to approximately 40 microns/h. A Fe-Pt target was ablated with a Nd-YAG pulse laser at the repetition rate of 30 Hz, and the films were deposited on Ta substrates. Before the ablation, the chamber was evacuated down to approximately 0.1 mPa with a molecular turbo pump. The distance between a target and a substrate was fixed at 10 mm. The deposition rate was varied by controlling the laser power between 1 and 9 W at the irradiation exit of a Nd-YAG laser system. The composition of all the obtained films was approximately Fe₅₀Pt₅₀. After an as-deposited sample was magnetized up to 7 T with a pulse magnetizer, magnetic properties were measured with a vibrating sample magnetometer which could apply a magnetic field up to approximately 1800 kA/m reversibly. All films were magnetically isotropic and, therefore, in-plane magnetic properties were shown in this abstract. Figure 1 shows the thickness of Fe-Pt film magnets as a function of the laser power. The deposition rate was proportional to a laser power. The wide deposition rate ranging 10 times as large as that reported by Aoyama[2]. Although the surface roughness increased with increasing the laser power and the deposition rate, the peeling phenomenon was not observed in all the films. Figure 2 shows the relationship between the laser power and coercivity for the films. The coercivity values of the as-deposited films prepared by the laser power higher than 5.0 W reached approximately 400 kA/m without a post annealing process. An observation of X-ray diffraction patterns for the same samples showed that order and disorder phase transformation occurred with increasing the laser power. We also confirmed that the substrate temperature became higher than 573 K at the laser power of 5 W without a substrate heating system. Figure 3 shows a M-H loop of an as-deposited Fe-Pt film prepared at the laser power of 8 W. The values of coercivity, remanence and $(BH)_{max}$ were 442 kA/m, 0.69 T and 68 kJ/m³, respectively. It was clarified that further improvements in remanence and $(BH)_{max}$ are required for PLD-fabricated Fe-Pt thick film magnets.

Coercivity generation of surface Nd₂Fe₁₄B grains and mechanism of fcc-phase formation at Nd/Nd₂Fe₁₄B interface in Nd-sputtered Nd-Fe-B sintered magnets.

T. Fukagawa, S. Hirose

Magnetic Materials Research Laboratory NEOMAX Company, Hitachi Metals, Ltd., 2-15-17, Egawa, Shimamoto-cho, Mishima-gun, Japan

Introduction

Coercivity of surface grains of an Nd-Fe-B sintered magnet can be measured unequivocally when the magnet is a thin slab with its orientation of the c-axis is parallel to the largest surface. Because of losing a part of a neodymium-rich grain boundary phase, the surface Nd₂Fe₁₄B grains have low coercivity after machining. Importantly, the coercivity of the surface grains can be regenerated when the specimen is appropriately annealed after a layer of Nd metal has been sputter deposited on the surface. This observation suggested that HcJ of the surface grains are sensitively dependent on the interface properties near the boundary between the surface of Nd₂Fe₁₄B grains and deposited Nd layer. The purpose of the present study is to obtain the microstructure-property relationship describing the regeneration of coercivity of the surface Nd₂Fe₁₄B grains.

Experimental method

Thin slices of 4mm-6mm-0.35mm size were prepared from a block of an Nd-Fe-B ternary sintered magnet block. The magnetic field orientation direction was parallel to the 4mm edge. Then the slices were mechanically polished down to a thickness of 0.3mm. Metallic Nd layers of about 2μm thickness were deposited on both 4mm-6mm surfaces (Fig. 1). These samples were annealed in vacuum of about 5×10⁻³ Pa and quenched in a stream of Ar. The magnetic properties were measured with a vibrating sample magnetometer (VSM) after magnetizing the specimens in a pulsed magnetic field of 3200 kA/m. The microstructures of the Nd film were observed with a transmission electron microscope (TEM) and the selected electron diffraction patterns (SADP) were taken and analyzed.

Experimental result and discussion

When an Nd metallic layer was sputter-deposited on the surface and annealed in the temperature range from 500°C to 675°C, the surface coercivity recovered to its full value identical to the coercivity of the bulk magnet from which the slab was cut out (Fig. 2).

TEM investigations identified phases observed in the Nd films in specimens before (Specimen A) and after (Specimen B) the surface coercivity was recovered. SADPs of these specimens are shown in Fig.3. The whole layer of Nd film was composed of only double hexagonal closed packed (dhcp) phase (metallic Nd) in the specimen A whose surface coercivity wasn't recovered (Fig.3 (a) and (b)). Whereas an fcc phase with the lattice constant of 0.548nm was formed only near the surface Nd₂Fe₁₄B grains in the specimen B whose surface coercivity was recovered (Fig.3(c)). The fcc phase is very similar to fcc Nd-O phases that were observed at triple grain boundary junctions in sintered Nd-Fe-B magnets. On the other hand, not only a dhcp but also A-type Nd₂O₃ (Fig.3 (d)) was observed in the inner layer of the Nd film apart from the interface in the specimen B. A-type Nd₂O₃ having hexagonal structure of *a* = 0.382 nm and *c* = 0.598 nm is the most stable phase among different types of neodymium oxides of the 2:3 stoichiometry. Since the fcc phase is derived from metastable C-type Nd₂O₃ having cubic structure of *a* = 1.108 nm, the fcc phase is also a metastable phase. Therefore, it is considered that the formation of the fcc phase results from the interfacial energy with the Nd₂Fe₁₄B grains.

Wettability and interfacial microstructure between Nd₂Fe₁₄B and Nd-rich phases in Nd-Fe-B alloys.

R. Goto, S. Nishio, M. Matsuura, N. Tezuka, S. Sugimoto

Department of Materials Science, Tohoku University, Sendai, Japan

[Introduction] Nd-Fe-B sintered magnets are well known as permanent magnets with the highest energy products ($(BH)_{\max}$) and have been started to use in motors in hybrid electric vehicles (HEV). As high heat resistance and high coercivity are strongly required in HEVs, some amount of Dy is added to Nd-Fe-B magnets. However, the natural abundance of Dy is quite low and the producing country is limited. Therefore, the development of Dy-free or -less Nd-Fe-B sintered magnets with high coercivity is strongly demanded.

The coercivity mechanism is important for increasing coercivity and several candidates of the mechanism have been proposed [1-3]. Although the mechanism has been still discussed, it is generally accepted that Nd-rich phase plays an important role at the interface between Nd₂Fe₁₄B and Nd-rich phases to achieve high coercivity. Consequently, the wettability and interfacial reaction between these two phases are considered to be important. However, there are very few reports related to the wettability besides the report by Knoch *et al.* [4], in which the wettability was measured by the sessile drop method and both Al and Ga addition improve the wettability.

In this study, we investigated the wettability between Nd₂Fe₁₄B and Nd-rich phases to evaluate the reaction process by measuring the change of contact angles under isothermal condition. The wettability was measured by the sessile drop method and a contact angle was adopted as a parameter of the wettability.

[Experimental procedures] Stoichiometric Nd₂Fe₁₄B ingot and two Nd-rich ingots such as Nd_{72.0}Fe_{26.1}B_{1.9} (ternary) and Nd_{72.0}Fe_{22.4}Cu_{3.7}B_{1.9} (Cu-added) were prepared. Nd₂Fe₁₄B ingots were sliced into the plate of 20 x 20 x 1.5 mm³ and polished by SiC emery papers and oil diamonds. Nd-rich ingots were cut into the block of 2 x 2 x 2 mm³ and polished in inert gas atmosphere. After polishing, the block of Nd-rich ingot was set on the plate of Nd₂Fe₁₄B ingot on the stage of an infrared image furnace. The samples were heated to 560-720°C at a rate of 50 °C/min, and then kept for 1 h in Ar atmosphere. Time dependence of contact angle between Nd₂Fe₁₄B and Nd-rich ingots was observed by a CCD camera. The angle and time when the contact angle became constant were defined as the saturated angle (θ_s) and completion time (t_{comp}), respectively. Microstructure of the interface between the Nd₂Fe₁₄B and Nd-rich ingots is also observed by a scanning electron microscope (SEM).

[Result] Figure 1 shows the time dependence of contact angles between Nd₂Fe₁₄B and ternary Nd-rich ingots heat-treated at 640-720°C. For the ternary Nd-rich ingots, θ_s and t_{comp} tend to decrease with increasing heat treatment temperature. Although tendency of the change in contact angle is similar for both ternary and Cu-added Nd-rich ingots, the θ_s values for Cu-added Nd-rich ingots are smaller than those for ternary Nd-rich ingots. The activation energies that the wetting achieves equilibrium were estimated from the Arrhenius plot using t_{comp} and temperature. The result is shown in Figure 2. From the figure, the activation energy is estimated to be 196.8 kJ/mol and 162.6 kJ/mol for ternary and Cu-added Nd-rich ingots, respectively.

Therefore, it is concluded that Cu addition improves the wettability of Nd-rich phase to the Nd₂Fe₁₄B phase and the effect is related to the decrease in the activation energy.

1. National Institute for Materials Science, Tsukuba, Japan; 2. CREST, JST, Japan; 3. Tohoku University, Sendai, Japan

1. Introduction

It is well known that the coercivities of Nd-Fe-B based sintered magnets are strongly influenced by the aging treatment at around 773K after sintering. This coercivity enhancement by aging can be seen in the sintered magnets that contain approximately 0.5 at.% of Cu [1]. The increase of coercivity should be due to a microstructure effect, since the anisotropy field hardly decreases [2]. Although the previous investigation[3] reported the formation of continuous Nd-rich thin layers surrounding grain boundaries during aging, how Cu is involved in these thin grain boundary phases as well as chemical distribution within Nd-rich grains are not well understood. In this work, we have studied the microstructure differences between the samples with and without Cu addition systematically. Focuses have been put on the distribution of Nd-rich phase and the segregation of Cu, which are thought to be the dominant factor on the coercivity of sintered Nd-Fe-B magnets.

2. Experimental details

The nominal compositions of the sintered magnets studied in this investigation were Nd_{14.5}Fe_{79.4}B_{6.1} and Nd_{14.5}Fe_{79.3}B_{6.1}Cu_{0.1}. The sintered magnets were annealed under magnetic field of 140 kOe at 823K. For microstructure investigation, FEG-SEM LEO 1550,1540 EsB cross beam system, TECNAI G2 F30 TEM equipped with GIF and EDX, and Femtosecond laser assisted 3D atom probe (3DAP) were employed.

3. Result and discussion

The coercivities of the Cu-free and Cu-containing samples were 3.6 and 13.6 kOe, respectively, after the magnetic annealing. SEM EsB images of the Cu-containing sample showed thin bright contrast along grain boundaries, while no such contrast was observed from the Cu-free sample (Fig. 1). We have obtained 3D tomography of the brightly imaged Nd-rich phase by sequentially observing BSE images with continuous removal of thin volume of samples by FIB as shown in Fig. 2. In the Cu-containing sample, the grain boundary phase continuously envelope Nd₂Fe₁₄B grains, while in the Cu-free sample, grain boundary phase form only in localized regions near triple junctions. This means that the Nd-rich phase was trapped into the grain boundary junction regions and did not penetrate into the grain boundaries between the Nd₂Fe₁₄B phase grains in the Cu-free sample.

Energy filter mapping, and HRTEM images, can further confirmed that the Nd-rich phases in the Cu-containing magnet form a shell around the Nd₂Fe₁₄B grains, resulting in decoupling of hard magnetic phases.

Figure 3 shows 3DAP concentration depth profile across a Nd-rich phase/Nd₂Fe₁₄B grain interface. The composition within the Nd-rich phase is approximately Nd₃₅Fe₃₀Cu₁₀O₂₅. There is Cu depleted and Cu enriched layers near the interface.

4. Conclusion

With a small amount of Cu addition (0.13 at.%), the coercivity of sintered magnet is significantly increased from 3.6kOe to 13.6kOe after magnetic annealing at 823K. It was found that by Cu addition Nd-rich phases in the magnet form a shell around Nd₂Fe₁₄B grains resulting in decoupling of hard magnetic phases, thereby enhancing coercivity. The better wettability of Nd-rich phase around the surface of Nd₂Fe₁₄B is originated from the Cu incorporation due to lowered melting point. 3DAP investigation revealed a thin Cu-enriched layer at the interface of Nd-rich phase/Nd₂Fe₁₄B phase.

SmCo hard magnetic films have been extensively studied in the last years due to their applications in microelectromechanical systems (MEMS) [1,2] and recording media [3,4]. Depending on the Sm content of the films, microstructure and magnetic properties change [5]. Sm content is not the only parameter these properties depend on. The Argon pressure and the underlayers used, are also important factors to take into account. Amongst all the possible SmCo phases present in bulk magnets as well as in thin films, SmCo₅ has been the most studied. However SmCo present other interesting phases such as SmCo₇, Sm₂Co₇ and Sm₂Co₁₇. In this work, we study the dependence of the thin film composition and the crystalline phases on the working pressure and the presence of a Mo underlayer for different annealing processes trying to get a hard magnetic material with an out-of-plane easy axis..

SmCo layers were grown both with and without a 100nm thick Mo underlayer onto Si (100) substrates at different working pressures. Commercial Sm₂Co₁₇ sintered targets were used as sputter targets. The base pressure in the chamber was below 5×10^{-7} mbar and the working pressures were 3.5×10^{-3} mbar and 2.5×10^{-2} mbar. The thickness of the SmCo layers was between 550 and 650 nm. All samples were covered with a 30 nm thick Mo layer in order to avoid the sample oxidation. The samples were annealed with three different thermal treatments, two of them without applied magnetic field and the last one with a 2 T magnetic field applied perpendicular to the surface of the sample in order to induce an out-of-plan anisotropy. The two first thermal treatments were carried out in a tubular furnace with a controlled and constant Argon flux at 600°C for an hour. The difference between them is that in the second one, when the temperature is decreasing, there was one step more where the temperature was maintained at 400°C for another hour. The annealing with the applied magnetic field was carried out in a small tubular furnace which is part of a VSM. This annealing had not the 400°C step.

Sputtered SmCo and Mo/SmCo samples are amorphous. Both set of films obtained with the lower working pressure, which have less percentage of Sm [5], present a clearly defined in-plane anisotropy. On the other hand, films obtained using the higher working pressure, which more Sm content [5], present an anisotropy with an out-of plane contribution. X-ray measurements developed for the samples grown with the different working pressures after the annealing process, demonstrated the presence of Sm₂Co₇ and Sm₂Co₁₇ crystalline phases for the samples with Mo underlayer and the presence of SmCo₅ and SmCo₇ phases for the samples without it. Regarding the desired magnetic properties, we have that coercivity field and remanence increase considerably after annealing in both SmCo and Mo/SmCo samples although the variation is higher in the SmCo thin films. These samples present coercivity values of 0.26 T in-plane and 0.35 T out-of-plane after annealing while Mo/SmCo samples present coercivity values around 0.1 T in-plane and 0.15 T out-of-plane. SmCo samples without Mo underlayer become isotropic, with no well defined anisotropy, whereas Mo/SmCo samples anisotropy remain showing just an out-of-plane contribution. Besides, the remanence of the SmCo samples is also higher than in the samples with Mo underlayer (Fig. 1 and Fig. 2). The heat treatment carried out with an applied magnetic field reported no better results

because the coercivities and remanence fields are smaller than those obtained by using the first heat treatment.

To summarize we can conclude that we have got thin film SmCo samples that do not present a dominant in-plane crystalline anisotropy with remanences and coercive fields high enough to be used as hard magnetic thin films with out-of-plane magnetization.

Nowadays, one of the most important goals in material science is to develop new materials at the nanometric scale. Magnetic materials have their physical properties strongly dependent on the size and on local structure of the grains. This has allowed to develop new application in areas such as catalysis, magnetism, optoelectronics and medicine [1]. The cobalt ferrite CoFe_2O_4 , for instance, was found to be an important magnetic material because of its application in magnetic fluids, in magnetic recording media and also in magnetic resonance imaging. It presents high magneto-crystalline anisotropy, moderate saturation magnetization, remarkable chemical stability and mechanical hardness. CoFe_2 , in turn, is an important soft-ferromagnetic material with unique properties such as large magnetic permeability and very high saturation magnetization (above 230 emu/g). The nanocomposites CoFe_2O_4 - CoFe_2 , on the other hand, have attracted great attention due to their potential use in developing magnetoresistive devices [2]. Besides, they are suitable to investigate the phenomena of the exchange-coupling in soft-hard ferro-ferrimagnetic composite material which is less studied and it is not completely elucidated yet. The ferrimagnetic and the ferromagnetic phases are expected to couple their magnetic moments at the interface between the phases. It is expected that the exchange spring mechanism would allow one to obtain nanocomposite hard magnetic materials combining the hard (high anisotropy) and soft (high magnetization) magnetic properties in such way that the soft phase becomes harder and its high magnetization enhances the energy product $(\text{BH})_{\text{max}}$ [3].

In this work we report a detailed studying of the magnetic properties of powders made of nanoparticles composed by a solid-solution of CoFe_2O_4 - CoFe_2 . Powders with different relative volume fraction of this two phases were obtained by heat treatments of single phase cobalt ferrite CoFe_2O_4 into a flux of high purity hydrogen gas. The composition of the resulting powders presented nano-sized particles with a relative volume fraction of the oxide CoFe_2O_4 and of the metallic CoFe_2 phases. The amount of CoFe_2 in the composite was increased up to 90% vol. by this process. The volume fraction of the two phases were controlled by the hydrogen flux and by the amount of time and temperature which the samples were exposed during the reduction process. The composition, the structure and the morphology of the particles were characterized by using X-ray diffraction and electron microscopy while the magnetic properties were investigated by using a vibrating sample magnetometer. It was found that the saturation magnetization of the nanocomposite powders increase with the volume fraction of the ferromagnetic CoFe_2 phase while their coercivity decrease. A maximum at the remanence M_r ($= 49,3$ emu/g) was observed for the composite containing 90 % vol. of CoFe_2 while the maximum energy product $(\text{BH})_{\text{max}}$ was found to be 0.62 MGOe. This is 19% higher than the value obtained for single phase CoFe_2O_4 . The coercive field H_c for this composition was found to be 539 Oe. Moreover, for all the range of volume fractions investigated the powders behaved as magnetic single phase-like showing smooth magnetic field variation at the magnetization hysteresis curves. This result indicate that the ferrimagnetic CoFe_2O_4 and ferromagnetic CoFe_2 are effectively exchange coupled and that magnetization of both CoFe_2O_4 and CoFe_2 reverses cooperatively.

Bimodal use of maghemite nanoparticles as contrast agents for magnetic resonance imaging (T1 and T2 CA's) through modulation of their stabilizing coating.

In biomedicine, magnetic materials have been used for long time in diagnosis as well as in therapy; some of its applications are found in magnetic resonance imaging (MRI), hyperthermia or magnetic separation. For biomedical use, magnetic nanoparticles are generally preserved as aqueous colloidal dispersions which must fulfill some important requirements: superparamagnetic (SPM) behaviour at room temperature (RT), high saturation magnetization, biocompatibility and stability in physiological media. The SPM behaviour of the particles assures that they will be only magnetized in the presence of an external magnetic field. Lack of toxicity is a fundamental concern as particles are internalized in the patient body or used with cell culture. Finally, stability in physiological media must be guaranteed avoiding the aggregation and precipitation of the particles, since their magnetic properties and biodistribution depend significantly on their size.

Our work has been directed towards the material's aspect of the problem; in particular on the synthesis and characterization of new materials suitable to act as contrast agents for magnetic resonance imaging (CA's for MRI). Based upon on our earlier work (1), dual MRI nanoparticles have been synthesized. On the one hand maghemite nanoparticles (γ -Fe₂O₃ NPs) of 5 nm of diameter stabilized in water with sodium citrate (γ -Fe₂O₃-citrate) that act as positive contrast agents (T1-CAs) and on the other hand, maghemite NPs embedded in silica aerogel resulting in negative contrast agents (T2-CA) (γ -Fe₂O₃-silica aerogel) (see enclosed figure).

The synthesis of maghemite nanoparticles was carried out in organic media by thermal decomposition of iron pentacarbonyl in presence of oleic acid (2). The particles were afterwards dispersed in hexane. The organic colloidal-dispersion, γ -Fe₂O₃-oleic, is the starting material for our dual system. It is remarkable the narrow particle size distribution achieved by this synthetic route allowing the control over the magnetic properties of the system.

The γ -Fe₂O₃-citrate aqueous colloidal dispersions were obtained by displacement of the oleic acid adsorbed onto the surface of the particles by the electrolyte sodium citrate. The γ -Fe₂O₃-citrate NPs are superparamagnetic at RT, with high saturation magnetization (68 emu/g γ -Fe₂O₃), very close to the maghemite bulk value (76 emu/g γ -Fe₂O₃) and large considering the small size of the particles.

The γ -Fe₂O₃-silica aerogel is a composite material formed of sub-micrometric size particles, dispersible in water. The synthesis of the porous silica is done under supercritical conditions of acetone ($T > 250^\circ\text{C}$, $P > 200$ bar) in the presence of the γ -Fe₂O₃-oleic particles. The composite particles have a final mean size around 100-200 nm, with big magnetic cores (30-70 nm diameter) built up of non-contacting maghemite NP's and silica aerogel shells. The composite also shows SPM behaviour at RT.

Both γ -Fe₂O₃-citrate and γ -Fe₂O₃-silica aerogel, were evaluated as contrast agents for MRI. This is a medical technique able to enhance contrast differences between healthy and pathological tissues. It measures the longitudinal and transversal magnetic relaxation times of the protons. Contrast agents (CA's) are magnetic materials that increase the relaxation rates, enhancing the contrast between tissues. Positive CA's (or T1) increase the longitudinal relaxation rates (r_1) and negative CA's (or T2) increase the transversal ones (r_2). The r_1 value directly depends on the magnetization

of the CA and the accessibility of the protons to the CA. On the other side, r_2 magnitude is directly dependent on the magnetization of the CA and the ability to produce local magnetic inhomogeneities.

We will show that the relaxation mechanism is hugely dependent on the coating of the maghemite NP's. The values of r_1 and r_2 values obtained for γ -Fe₂O₃-citrate give an $r_2/r_1 \approx 1$, indicating a positive CA while for γ -Fe₂O₃-silica aerogel an $r_2/r_1 > 1000$ was found indicating a negative CA. Which is the reason for this different relaxometric behavior when both materials contain the same magnetic NP's? The main explanation resides in the clustering of the nanoparticles in the silica matrix. The r_2/r_1 value for γ -Fe₂O₃-citrate is near 1 due mainly to the small size of the nanoparticles as well as its very homogeneous dispersion in the medium. In contrast, γ -Fe₂O₃-silica nanoparticles act as T2-CAs mostly because its big magnetic cores induce large local magnetic inhomogeneities and high increase of the r_2 values.

To sum up, we have synthesized and characterized two different magnetic colloidal dispersions with the same magnetic material but with different relaxometric properties. Thus, it has been demonstrated that in view of their final application in life sciences, the coating of magnetic nanoparticles is as relevant as their inherent magnetic properties.

Magnetic hyperthermia (MH) is a developing strategy in biomedical research fields, by which the temperature of a target cell or tissue containing ferromagnetic particles can be raised remotely through radio-waves of 100 to 1000 kHz.[1] In this frequency range the heating effects on living tissues, related to electric coupling of dipolar moments and E-component of the waves, are negligible. On the other hand, if magnetic particles are loaded into the target tissue, their magnetic moment interacts with the B-component of these radio waves, releasing the absorbed power as heat. The origin of the energy dissipation when a ferromagnetic nanoparticle is placed on an ac magnetic field is related to magnetic losses through domain wall displacements (in multi-domain particles), and/or Néel relaxation in single domain particles. Energy loss from mechanical rotation of the particles, acting against viscous forces of the liquid medium (Brownian losses) could also contribute at low (< 50 kHz) frequencies. The dominant process will depend on the specific particles used and the applied frequency range. The heating efficiency of a magnetic colloid is measured by the heating power of a given mass m_{NP} of the constituent nanoparticles diluted in a mass m_H of ferrofluid, through the Specific Absorption Rate

$$SAR = C_S(m_H/m_{NP})(\Delta T/\Delta t) \quad (I)$$

in W/g, where C_S is the specific heat of the colloid, and $\Delta T/\Delta t$ is obtained from the heating curves of the material. Although SAR values are often given without any further specification,[2,3] it is known that the rate of temperature increase $\Delta T/\Delta t$ is time-dependent. Therefore the values reported in the literature are difficult to compare and evaluate in terms of their actual heating capacity.

In this work we analyze the effect of particle size on SAR values in a series of Fe₃O₄ NPs with increasing mean particle size from 3 to 30 nm, and good control of size dispersion.

Experiments of power absorption as a function of particle size revealed the existence of a sharp increase in SAR values near the single- to multi-domain structure, irrespective of magnetization values, as displayed in figure 1. The largest value obtained was 130 W/g, corresponding to a bimodal particle distribution with average size values of 17 and 25 nm. We discuss the correlation of this behavior with magnetic parameters such as crystalline state of the particles, magnetic anisotropy and coercivity values.

When measured against NP concentration, the SAR values were not constant as expected from eq.(I). We present evidence of other effects such as dipolar interactions among particles, and also the non-adiabaticity effects of experimental protocols used for measurements in ferrofluids, aiming a useful determination of SAR values.

Figure1. Saturation magnetization values, M_s , at room temperature (left axis) and the corresponding Specific Absorption Rate values (right axis) for magnetite particles with different mean particle diameters, d . It can be observed a jump in M_s values for the larger particles, in a smaller d range than the observed increase of SAR.

Synthesis and Cellular Uptake of Folate-Conjugated Hydrophobic Superparamagnetic Iron Oxide Nanoparticles.

K. Woo¹, J. Moon^{1,2}, K. Choi³, K. Yoon³, T. Seong²

1. Nano-Materials Research Center, KIST, Seoul, South Korea; 2. Department of Materials Science and Engineering, Korea University, Seoul, South Korea; 3. Institute for Radiological Imaging Science, Wonkwang University School of Medicine, Iksan, South Korea

Recent advances [1-3] in preparation of monodisperse superparamagnetic iron oxide nanoparticles (SPIONs) in organic medium have accelerated the emergence of surface modification chemistry. However, most of the surface modification chemistry has been focused on the preparation of water-dispersible functional SPIONs. On the other hand, the surface modification study for hydrophobic functional SPIONs has been quite rare and few reports are found. Though not injectable alone, hydrophobic functional SPIONs can have some potential applications as implantable targeting probes [4] or inclusion probe materials in a polymer utilized micelle [5], together with drug delivery. The best advantage of hydrophobic functional SPIONs over hydrophilic ones could be an aggregation-free behavior.

In this investigation, we prepared foliate-conjugated hydrophobic SPIONs and investigated their cellular uptake by KB cell (human epidermoid carcinoma cell), which is one of the representative foliate receptor over-expressed cells, using magnetic resonance (MR) imaging. Folate-conjugation to imaging probes has been known to target and image breast cancer since some of the breast cancer cells over-express foliate receptors.

Our foliate-conjugated hydrophobic SPIONs were prepared as following. The oleic acid protected SPION (5.5 nm and 11 nm SPION-OA) was prepared according to the published method [1]. To this crude solution at 100°C, 10 mol % iron pentacarbonyl was added with stirring and then heated to reflux. The protecting ligand OA was substituted by decanoic acid (DA) to yield SPION-DA, which was treated with 5 equivalents of mercaptoundecanoic acid (MUA) to produce SPION(-DA)ex(-MUA)5. The carboxylic acid end groups of SPION(-DA)ex(-MUA)5 were conjugated to folic acid (FA) through ethylenediamine bridge, yielding the final product SPION(-DA)ex(-MUA-FA)5.

SPION(-DA)ex(-MUA-FA)5 was hydrophobic and soluble in non-polar solvents such as hexane, toluene, and chloroform. The TEM image analysis implied that each SPION(-DA)ex(-MUA-FA)5 was aggregation-free without its size change in both cases. The cellular tests with/without folic acid and their MR imaging showed efficient uptake of functional hydrophobic SPION(-DA)ex(-MUA-FA)5 to KB cells and about 10% decrease under the inhibition of excess folic acid.

The interest in using core/shell magnetic nanoparticles (NPs) for biomedical and bioengineering applications has been increasing over the last few years. These magnetic NPs can be widely used for in-vitro as well as in-vivo applications such as magnetic biosensing, cell separation and contrast enhancement in magnetic resonance imaging. Possible future applications are being developed such as tissue repair, magnetic hyperthermia treatment and targeted drug delivery. The size, shape and biochemical coating of these nanoparticles are of critical importance and must be controlled accurately. They must also be thermally and chemically stable and have large magnetic moments. It is therefore very important to optimize these parameters, and to characterize the magnetic properties so that the performance of the final pharmaceutical product can be evaluated. For specific applications such as magnetic inductive hyperthermia (MIH), the rheological properties of the colloids and the efficiency for absorbing RF power on NPs are also major issues that require optimization [1].

In this work core/shell magnetic nanoparticles have been obtained for further use in hyperthermia studies. Magnetite NPs of three different sizes of 30 nm, 50 nm and 110 nm have been prepared, labeled as ASi, BSi and CSi respectively. These magnetic NPs have been furthermore coated with a silica layer of 1 nm (ASi), 4.5 nm (BSi) and 15 nm (CSi). Fig.1 shows TEM images of one of these samples. Colloidal stability has been measured for all samples as a function of pH and surface charge. Silica has several advantages over organic coatings. It is very resistant against biodegradation and avoids unwanted interactions by preventing direct contact of the magnetic cores with other additional agents that might be linked to the silica surface [2]. Furthermore, silica coatings are very stable under aqueous conditions in a very wide range of pH. Through the silica coating it is relatively easy to control the interactions between particles in solution.

Hysteresis loops of magnetite and silica coated magnetite samples at room temperature have been obtained and compared, Fig.2. A slight increase in the coercivity, a clear increase in the squareness and in the area of the hysteresis loop is observed for coated samples compared to pure magnetite samples. Also, zero-field-cooled (ZFC) and field-cooled (FC) magnetisation measurements have been carried out in all samples. The samples were dispersed and stabilized in water and their power absorption efficiency at a frequency of 260 kHz and peak field of 150 Oe was determined in adiabatic experiments from the initial temperature increase of the Temperature vs. time curves. The slope of the curves reached their maximum values within the first five minutes for the 30 nm and 50 nm coated samples. We found that the 30 nm-magnetite NPs have the largest values of specific power absorption (82 W/g of magnetite), whereas for the largest particles (CSi sample) no power absorption was observed within experimental, Fig.3. Since in the largest particles (CSi, size 150 nm) the power absorption is dominated by domain wall displacements, our findings suggest that the optimal nanoparticle for power absorption should be designed to be close to its multi- to single-domain size.

The enhancement of χ_{AF} below T_N in antiferromagnetic nanoparticles compared to bulk was predicted by Néel and estimated to decrease with temperature [1]. The extra susceptibility (χ_a) is a finite size effect termed superantiferromagnetism arising from the coupling between the external field and the AF easy axis, corresponding to a progressive rotation of the AF axis from surface to surface across the particle, in particles with even number of ferromagnetic spin planes. Finding experimental evidence of superantiferromagnetism is not straightforward as it is necessary to have magnetic particles with small grains with controlled size distribution, and it is necessary to overcome the influence from the uncompensated magnetic moment μ_{un} . In the case of high field measurements, the influence of μ_{un} is related to the non-saturation of the magnetization associated to μ_{un} (M_u) at the typical applied fields (50 kOe) and temperatures. The absence of a reliable model of the field dependence of M_u , neither of its approach to saturation, makes the separation between the contribution of χ_{AF} and μ_{un} to the total magnetisation (and the subsequent determination of $\chi_{AF}(T)$) quite difficult.

In previous reports (see, for instance Ref. [2]), $\chi_{AF}(T)$ was found to decrease with temperature based on magnetisation curves measured up to 5×10^4 Oe and analysed without taking into account anisotropy effects. In Ref. [3], it was highlighted that a spurious contribution to $\chi_{AF}(T)$ arise when modelling $M_{mu}(H)$ without considering anisotropy. This spurious contribution decreases with temperature towards zero as anisotropy energy becomes small compared to $k_B T$ and $\mu_{un} H$. Given this scenario, a better insight on $\chi_{AF}(T)$ depends on measurements of the susceptibility at fields higher than those used up to now. With this aim, we present measurements taken up to different maximum fields and different techniques of measuring magnetisation in ferritin, a model system for nanoparticles with AF interactions, where many previous studies were performed.

Ferritin consists of a hollow spherical shell composed of 24 protein subunits surrounding a ferrihydrite-like core. The diameter of the cavity is of the order of 7-8 nm and the average size of the core is 5 nm. Ferritin samples used in the experiments here reported were obtained from Sigma Chemical Company and prepared in powder samples by evaporation of the solvent at room temperature. Magnetisation was determined as a function of field i) up to 9×10^4 Oe at different temperatures using a PPMS system (Quantum Design) with a vibrating sample magnetometer (VSM) option, ii) up to 30×10^4 Oe at different temperatures using an extraction magnetometer in a Bitter magnet (HFML facility, Nijmegen), and iii) up to 50×10^4 Oe at 4.2 K using pick up coils and a pulsed field (LNCMP facility, Toulouse).

From the magnetisation isotherm curves, it is possible to observe the different evolutions of χ_{AF} with temperature when χ_{AF} is estimated at different fields as the derivative of the magnetisation as a function of field dM/dH . To distinguish from the real χ_{AF} obtained for complete μ_{un} saturation, we term the susceptibilities obtained from dM/dH at different (high) fields as high field susceptibility χ_{hf} . In Fig. (1) it is possible to observe that χ_{hf} decreases with temperature when taken at 5×10^4 Oe, in accordance with previous results (see, for instance Ref. [2, 4]). When taken at 9×10^4 Oe, χ_{hf} has a non-monotonic behaviour, increasing and then decreasing with temperature. For

$H=30 \times 10^4$ Oe, χ_{hf} is reduced about 3 times compared to the values at 5×10^4 Oe and increases with temperature from 4.2 to 190 K. This clearly shows that the temperature dependence of the estimated χ_{AF} depends on the field at which is calculated, with the trend to increase with temperature being more evident as the field increases. This effect is associated to the non-saturation of μ_{un} at lower temperatures due to anisotropy.

The value of χ_{hf} found at 50×10^4 Oe and 4.2 K agrees quite well with $\chi_{AF}(0)$ estimated from mean field: 4.68×10^{-5} emu/Oe g_{Fe} , and thus superantiferromagnetism does not play a significant role in ferritin.

Magnetic nanoparticles (NPs) with tailored surface chemistry have been widely studied and mainly due to their strongly potential in vivo biomedical applications such as magnetic resonance imaging, tissue repair, immunoassay, drug delivery, biological fluids detoxification, hyperthermia, and cell separation.¹⁻³ However, all applications impose requirements on the magnetic nanoparticles properties as chemical composition, biocompatible surface and crystal structures, adsorption, solubility, low own toxicity, high magnetization and small size with narrow particle size distribution. These features improve tissular diffusion, sedimentation times, magnetic response, and allow a targetable delivery in a local specific area of the body.³ Magnetic iron oxide NPs, such as magnetite (Fe_3O_4), with magnetic moment of 300-400 emu/cc is currently used for this purpose, and there is significant interest in developing high magnetic moment materials closed to $\alpha\text{-Fe}$ (~1000 emu/cc). However, disadvantages of metallic NPs uses reside in their toxicity, highly sensitive to oxidation, and limited biocompatible molecules that could be used to functionalize the metallic surface.³ In this work, the synthesis and properties of the high magnetic moment Fe_3O_4 -coated FePt NPs in a core/shell structure with improved magnetic properties and controlled oxide surface thickness were reported. Recently, we reported a modified polyol process to produce 4 nm- $\text{Fe}_{55}\text{Pt}_{45}$ ferromagnetic NPs.⁴ Combining this process with the seed-mediated growth method, $\text{Fe}_{55}\text{Pt}_{45}@\text{Fe}_3\text{O}_4$ nanoparticles were prepared as follows: for coating of 2 nm- Fe_3O_4 shell thickness, oleic acid (1 mmol), oleylamine (1 mmol), $\text{Fe}(\text{acac})_3$ (1 mmol), and 1,2-hexadecanediol (5 mmol) in octyl ether were mixed under nitrogen flow in a three-necked round-bottom flask. Then, 4 nm- $\text{Fe}_{55}\text{Pt}_{45}$ NPs dispersed in hexane (50 mg in 5 mL) were added, the mixture heated at 100 °C for 1 hour, and the temperature raised to reflux (298 °C) under a blanket of nitrogen for 30 min. The suspension was then cooled down to room temperature and the NP separated by ethanol addition and centrifuging. In absence of seeds, 6 nm- Fe_3O_4 NPs were obtained (Fig. 1a), and in presence of FePt seeds the core-shell nanostructure was observed as showed in Fig. 1b for $\text{Fe}_{55}\text{Pt}_{45}@\text{Fe}_3\text{O}_4$ with 4 nm core and 2 nm shell. By controlling the ratio of $\text{Fe}(\text{acac})_3$ to FePt seeds, the oxide shell thickness can be readily tuned. XRD and EDX analysis show the Fe_3O_4 formation with Fe contents increasing with the increase of the shell thickness. Magnetic measurements show that saturation magnetization (M_s) of the as-synthesized NPs increases from 316 emu/cc to 830 emu/cc, respectively for Fe_3O_4 and core/shell nanostructure (Fig. 1c). Also, core/shell present coercive field (H_C) of only 90 Oe, closed to the superparamagnetic (SPM) behavior with magnetization directions of both core and shell switch coherently. Annealing the core/shell NPs leads to H_C and M_s values of 14.2 kOe and 1045 emu/cc, respectively, for 0.5 nm of shell thickness (Fig. 1d). This magnetization value is close to $\alpha\text{-Fe}$ and higher than that annealed pure $\text{Fe}_{55}\text{Pt}_{45}$ suggesting the presence of a higher moment iron-rich species in a thin layer on NP surface. H_C value increases by transformation of the FePt from fcc to fct phase, which increases the magnetocrystalline anisotropy. Hysteresis loop shape and the remanence ratio (~0.73) indicate effective exchange coupling between hard and soft phases, promoted by existence of a slightly iron oxide thin shell in the annealed composite (HRTEM, Fig. 1b inset). On the other hand, annealing of the 2 nm shell thickness coated-NPs (Fig. 1e) results in a coupled system presenting the exchange bias effect as evidenced by shift of the hysteresis curve

and showed in the Fig 1f detail due to a hard and soft magnetic phase formation. This coupling leads a strong decreases in the coercivity value (130 Oe) closed to the SPM behavior, but maintain the high magnetization close to $\alpha\text{-Fe}$. Results infer strong enhancement in the structural and magnetic properties of the core/shell NPs combined with the surface functionalization facility due to presence of the surface oxide layer suggesting potential biomedical applications.

Superparamagnetic iron oxide nanoparticles (SPIONs) are good candidates for various biomedical applications, such as magnetic resonance (MR) contrast agents, magnetic targeted drug/gene delivery, and hyperthermia. *In vivo* applications, which require stable colloid under physiological condition and further conjugation with bioactive molecules depending on individual purpose, remain a challenge. Since bare SPIONs tend to form agglomerations and it has barely any functional groups for attachment of bioactive molecules. So dextran and its derivatives have been attractive coating materials due to their biocompatible and hydrophilic characteristics. [1] Dextran stabilized SPIONs are readily commercially available. However, conjugation of bioactive molecules still strongly relies on generation of additional functional groups such as amine and carboxyl groups. Tat peptide conjugation to ammonia soaked dextran coated SPIONs was reported, but the amine activation is very unstable. [2] Carboxymethyl dextran (CMD) is of particular interests as iron oxide coating substances, due to their good biocompatibility and ability to conjugate with bio-molecules. CMD coating has been through physical adsorption and a 19-mer oligonucleotide has been attached to such CMD coated magnetic particles through carbodiimide conjugation.[3] However it has shown that long-term storage of CMD nanoparticles eliminates the functionality of such particles, since physically absorbed CMD may dissociate from particles and result in exposure of iron oxide into the environment.

In this work, carboxymethyl activated crosslinked superparamagnetic iron oxide nanoparticles (CM-CL-SPIONs) are developed. CM-CL-SPIONs as backbone nanocarriers have enormous potential in biomedical applications such as MR contrast agent and targeted drug delivery system. The CM-CL-SPIONs have two major advantages as nanocarriers: (1) carboxylic groups of CMD serve as functional groups for attachment of versatile bioactive molecules. (2) CMD coating is continuous and stable. Briefly, dextran coated SPIONs (D-SPIONs) are synthesized by alkaline coprecipitation of Fe³⁺ and Fe²⁺ in the presence of dextran, and subsequently crosslinker epichlorohydrin is applied to the colloids. CL-SPIONs were further modified to generate carboxymethyl groups by monochloroacetic acid.

The as-prepared CM-CL-SPIONs were characterized by TEM, FTIR, TGA, DSC and zeta-potential. The particles are spherical in shape, 3-9 nm in diameter, with some degree of agglomeration. (Fig. 1) FTIR spectra confirm the existence of dextran coating; the new peak at 1598 cm⁻¹ on CM-CL-SPIONs is due to carboxylate stretching, indicating the successful carboxymethylation. (Fig. 2) The stability of CM-CL-SPIONs with varied amount of crosslinking degree was investigated. Terminal sterilization (e.g. heat stress, 121 °C, 30 min) is legally required to for pharmaceutical products. However, heat stress cause severe dextran dissociation that is very undesirable and may cause exposures of SPION cores to the environment and subsequent aggregation. Estimation of dextran loss upon heat stress sterilization is very essential, if the product is used *in vivo*. With increased epichlorohydrin amount, the dissociation was suppressed, when reached a certain amount of crosslinking agent (10 %), the dextran lost is at the same level after heat stress (around 4 %), no matter further amount of crosslinker is added.

In conclusion, a versatile and novel magnetic nanocarrier CM-CL-SPIONs for biomedical applications is developed. Attributed to its good stability in water, and ability of conjugation of further biomolecules, CM-CL-SPIONs can be a backbone nanocarrier in biomedical applications.

Introduction

Magnetic nanoparticles (MP) are widely used in biomedical fields such as MRI and targeted drug delivery due to the high saturation magnetization, superparamagnetism, high magnetic susceptibility and low toxicity.[1-4] Among different carrier, silica is a promising material with good biocompatibility. The magnetic hollow silica nanospheres with a character of superparamagnetism are considered to be the proper carriers for magnetically guided targeted delivery and controlled release. In this paper, we report a novel synthetic method for magnetic porous hollow silica nanospheres (MPHSNs), using tetraethoxysilane (TEOS) as precursor, and sacrificed $\text{CaCO}_3/\text{Fe}_3\text{O}_4$ composite nanoparticles and cationic surfactant double templates. The product is potentially capable in bio-medicine applications.

Experiment

At room temperature, 3g $\text{Fe}_3\text{O}_4/\text{CaCO}_3$ composite particles was dispersed ultrasonically into a mixture of 60 ml ethanol and 40 ml H_2O for 30min and then stirred for 30 min. Then add 0.74g CTAB/mixed CTAB&Octane and dispersed ultrasonically for 20 min. [5-7] Add 34 ml ammonia, 3.7 ml TEOS into the reaction mixture to reach 11 of pH. The system was stirred at 500 rpm for 2 h and aged for 6h then filtrated. The cake was dried at 50°C for 6 h and calcined at 550°C for 5 h then immersed in acetic acid solution ($\text{HAc}:\text{H}_2\text{O} = 1:15$) for 5 h, then washed with H_2O and alcohol, and dried at 75°C for 18 h to yield the MPHSNs. The samples were investigated by Carl Zeiss 1530 VP FESEM, JEOL 2010 TEM, EDS, XRD, ASAP2010 Surface Area Analyzer, Quantum Design MPMS-5S SQUID magnetometer and controlled release test.

Magnetic nanoparticles (MP) are widely used in biomedical fields such as MRI and targeted drug delivery due to the high saturation magnetization, superparamagnetism, high magnetic susceptibility and low toxicity.[1-4] Among different carrier, silica is a promising material with good biocompatibility. The magnetic hollow silica nanospheres with a character of superparamagnetism are considered to be the proper carriers for magnetically guided targeted delivery and controlled release. In this paper, we report a novel synthetic method for magnetic porous hollow silica nanospheres (MPHSNs), using tetraethoxysilane (TEOS) as precursor, and sacrificed $\text{CaCO}_3/\text{Fe}_3\text{O}_4$ composite nanoparticles and cationic surfactant double templates. The product is potentially capable in bio-medicine applications.

Result and discussion

The obtained MPHSNs are shown in Fig.1. MPs are embedded in the cores and EDS analysis implies there is no Ca exists. Fig.2a shows ZFC and FC magnetization data of MPHSN in the temperature range of 10 to 300K. In ZFC, the sample was cooled from 300K to 5K in a zero field, then heated from 5 to 300 K in a field of 100 Oe and the magnetization was measured. In FC, the sample was cooled from 300 K to 5 K in a field of 100 Oe and the magnetization was measured as heated from 5 to 300 K in the field. The MPHSNs exhibit superparamagnetism and ferromagnetism above and below the blocking temperature, as shown in the field-dependent hysteresis loops of MPHSNs in Fig.2b. Fig.3 shows the vitro release behavior of MPHSNs using ibuprofen. MPHSNs using CTAB and Octane as surfactant have the best controlled release effect, indicating the potential capability in bio-medicine.

Hysteresis power loss heating of ferromagnetic nano-particles designed for magnetic thermoablation.

E. Kita¹, H. Yanagihara¹, S. Hashimoto², K. Yamada², T. Oda², M. Kishimoto³, A. Tasaki¹

1. Institute of Applied Physics, University of Tsukuba, Tsukuba, Japan; 2. Institute of Clinical Medicine, University of Tsukuba, Tsukuba, Japan; 3. Hitachi Maxell, Ltd., Oyamazaki, Japan

Magnetic hyperthermia and thermoablation using small magnetic particles have been a new approach to apply heat power on cancerous cells without surgical operations[1]. Most of researches have been carried out using magnetic fluids which consist of Fe oxides particles basically of superparamagnetic at room temperature. Additionally there are reports using ferromagnetic MgFe_2O_4 particles with small coercive force around 20 Oe. In both cases, AC magnetic fields around 100 kHz are widely used. The advantage of superparamagnetic relaxation heating is that particle aggregation due to the magnetic interaction between particles is small. It can be a realistic advantage for the actual medical use, however it has a difficulty in fitting their size properly to the driving frequency. On the other hand, ferromagnetic hysteresis loss heating is free from such condition to the driving frequency and size distribution has less effect on the heating performance. To use this hysteresis loss, it is necessary to apply higher magnetic field than those applied in usual methods with a frequency of 100 kHz. The use of hysteresis loss for heating at lower frequency and high magnetic fields is expected to be another solution to thermoablation. We have tested heating capacity of ferromagnetic nano-particles for thermoablation with rather high coercive force under an AC magnetic field of 10 kHz and 500 Oe.

Co-contained Fe_3O_4 particles were produced by heating the coprecipitants containing Co^{2+} , Fe^{2+} and Fe^{3+} ions in alkaline solution at 130 °C for 5 hours using hydrothermal method. The coercivity was controlled from 80 Oe to 320 Oe by changing the content of Co. Sizes of nano-particles were about 20 nm for all samples. Magnetic dc hysteresis loops were measured at room temperature with a vibrating sample magnetometer (VSM). AC magnetic fields were produced in a gap of a ferrite core. AC currents at 10 kHz were provided by a commercial high power audio amplifier. Oxide nano-particles of 50 mg were formed into a cylindrical shape and set at the center of a gap of the ferrite core. Temperature of the sample was recorded by an infrared optical thermometer.

Figure 1 shows an electron micrograph of typical Co-contained Fe_3O_4 particles and well dispersed nano-particles were observed. Magnetic hysteresis loops of Fe oxides particles were recorded under the magnetic field between -2000 Oe and 2000 Oe where the loop represents its major hysteresis loop and coercive force was about 160 Oe. A minor loop was recorded at the field between -500 and 500 Oe as shown in Fig. 2. Temperature variation of the same sample under the application of 500 Oe (peak) AC field at 10kHz was shown in the Fig. 3.

From the initial slope of the curve, heating power was derived to be 4 W /g. Power loss is expected to be the product of frequency and the area of DC hysteresis. From the 500 Oe minor loop shown in Fig. 2, the loss is estimated to be 6.7 W/g. These results conclude that loss at 10 kHz is fairly well understood by the DC minor loop recorded at the same magnetic field. By choosing magnetic fields strength and elevating the frequency, ferromagnetic hysteresis loss in nano-particles will be another candidate of the heating system.

The local atomic Joule magnetostriction of $\text{Fe}_{81}\text{Ga}_{19}$

M. P. Ruffoni¹, S. Pascarelli¹, R. Grössinger², R. Sato-Turtelli², R. F. Pettifer³

1. European Synchrotron Radiation Facility, Grenoble, France; 2. Technical University of Vienna, Vienna, Austria; 3. Department of Physics, University of Warwick, Coventry, United Kingdom

Using X-ray Absorption Spectroscopy (XAS) in differential mode (DiffXAS), the magnetostriction of a $\text{Fe}_{81}\text{Ga}_{19}$ splat cooled ribbon has been measured and the strain coefficients quantified. Due to the local atomic nature of XAS, this represents the first microscopic analysis of such a system, and was made possible only by recent advances in synchrotron radiation based techniques, capable of detecting atomic strains on the scale of femtometres [1].

Previously, magnetostriction measurements have relied on macroscopic techniques, commonly via strain gauges. However, such measurements on thin films and ribbons, which tend to be of the greatest importance from a technical perspective, are notoriously difficult. This is in part due to the measured strains being extremely small over a sample thickness of a few tens of microns, but also due to the practicalities of coupling such a sample to a sensor. Consequently, published magnetostriction coefficients vary immensely. In some cases, giant magnetostrictions have been reported for $\text{Fe}_{(1-x)}\text{Ga}_x$ ribbons [2][3] although doubt has recently been cast upon their validity [4]. This serves to assert a need for a more fundamental approach to measuring magnetostrictive strains. A need which is satisfied by DiffXAS.

Being based upon XAS, DiffXAS probes changes in local atomic structures and is just dependent upon the short-range order of the first one or two atomic shells surrounding an absorbing atom. However, whilst even giant magnetostrictive strains exhibited by a number of rare-earth based Fe alloys are on the very limits of detection by conventional XAS techniques, DiffXAS offers an increase in sensitivity of two orders of magnitude and so makes such strains easily measurable. Direct detection of strains on the scale of tens or hundreds of ppm then becomes possible. Furthermore, in principle, this is true for any type of strain that is reproducible upon the modulation of some external sample property [5].

Additionally, since x-ray absorption is chemically selective, these structural changes may be viewed from different positions within the crystal lattice, and so the underlying significance of different atomic species in the overall process elucidated. Contributions from different types of bonds within the structure may then be decoupled and analysed. Such information has immense value when trying to obtain fundamental knowledge of atomic strains, and particularly when attempting to verify theoretical models. Concerning $\text{Fe}_{(1-x)}\text{Ga}_x$, a theory for the observed strain enhancement was first put forward by Wu [6] in 2002, which has more recently been developed by Cullen et al. [7] after modelling the behaviour of the material's magnetocrystalline anisotropy. Experimental verification of these proposals has yet to be presented, but is something that DiffXAS has the potential to provide.

Using this technique, we have focused on the problem of enhanced magnetostriction observed in the $\text{Fe}_{(1-x)}\text{Ga}_x$ system. Such systems have attracted significant interest from a technological and device applications perspective since, although they do not possess truly giant magnetostrictions, they are both absent of expensive rare-earth elements and have desirable mechanical properties. They also show appreciable low-field magnetostriction, saturating at fields of only several hundred Oersteds. Working within these saturation conditions, DiffXAS detects the changes in photoelectron scattering path length induced by structural distortions that occur when the sample's magnetisation vector is modulated between two states – parallel and perpendicular to the x-ray polarisation vector.

Subsequent data analysis uses a framework of Cartesian tensors to model the structural properties of the sample, and *ab initio* XAS theory to model the observed perturbations. From this, the atomic strain tensor may be derived and related to the sample magnetisation vector in order to find the coefficients of the Joule magnetostriction tensor [8]. These coefficients may then be reduced to the more familiar macroscopic λ^{100} and λ^{111} coefficients by exploiting the crystal symmetry elements [8].

Working on a splat cooled foil of $\text{Fe}_{81}\text{Ga}_{19}$, preliminary analyses performed with this technique have yielded a magnetostriction coefficient of $(3/2)\lambda^{100} = 250 \pm 20 \text{ ppm}$ (λ^{111} coefficient is approximately zero for this composition), based upon a disordered A2 structure determined from analysis of the sample's conventional XAS signal. This analysis failed to detect the D0_3 structure reported by some authors for this composition. Further experiments are planned to examine the full range of compositions over which magnetostriction enhancement is observed in this system.

The Effect of Tempering on the Magnetostriction of Fe-Ga Alloys.

T. A. Lograsso^{1,2}, M. Huang¹

1. Institute for Physical Research and Technology, Iowa State University, Ames, IA; 2. Materials and Engineering Physics, Ames Laboratory, Ames, IA

It is well known that the magnetostriction in Fe-Ga alloys depends significantly on thermal history^{1,2}. While most studies have investigated properties of Fe-Ga alloys in terms of the cooling rate (quenched vs. slow cooling)^{1,2}, little attention has been given to the influence of tempering temperature on the magnetostriction. In this paper we report on single crystalline magnetostriction measurements of Fe_{100-x}Ga_x alloys to examine the affect of tempering temperature and time on the tetragonal magnetostrictive constant λ_{100} . These measurements were conducted on the same single crystal to minimize any effect of sample to sample variations in chemistry, misorientation or other sample to sample variations that can have significant influence on the measured strain. We have examined two different compositions; one far from the solubility limit ($x=10$) where formation of D0₃ on cooling is not expected, and the other near the first maximum in magnetostriction ($x=18.4$) where thermal history is known to have a significant impact on the structure of the alloy^{1,2}.

All samples were quenched from 1000 °C into water, tempered at various temperatures for 1 hr and then water quenched. Tempering temperatures started at 250 °C because according to Differential Scanning Calorimetry (DSC) analyses of quenched alloys³, the formation of D0₃ phase begins at around this temperature. It can be seen in Fig. 1, for Fe-10 at% Ga alloy, the magnetostriction is invariant with temperature within experimental error, ± 3 ppm. This result is consistent with the Fe-Ga phase equilibria⁴ where D0₃ formation is not expected as this composition is well within the A2 single phase region, from room temperature to 1500 °C. In contrast, as shown in Fig. 2, magnetostriction decreases dramatically with tempering temperature above 300 °C for a composition of Fe-18.4 at% Ga. This decrease in strain occurs unexpectedly at higher temperatures than the observed exothermal peak at around 250 °C in the DSC results³.

In order to confirm that D0₃ formation in the annealed samples leads to the observed decreases in $(3/2)\lambda_{100}$, X-ray diffraction measurements were carried out. Standard θ -2 θ X-ray spectra were used to examine the phase evolution with annealing time for the Fe-18.4 at. % Ga crystal, tempered at 350 °C up to 4 hours. A Si internal standard was used to account for any misalignment of the single crystal. It can be seen in Fig. 3a that D0₃ was not observed in the water quenched sample and a strong reflection at $\sim 64^\circ$ is from the (200) reflection of the A2 phase^{1,3}. After tempering for 1 hour, a small peak at around 30.5° was observed which corresponds to the superlattice (100)_{A2} reflection of the D0₃ phase. This peak increases in intensity with longer annealing times as seen in Fig. 3c and Fig. 3d, indicating larger fraction of D0₃ phase is formed. These X-ray results are consistent with previous studies¹ in that quenching from high temperature prevents the formation of the D0₃ phase resulting in maximum magnetostriction. Further the presents results confirms that D0₃ formation result in a decrease in magnetostriction.

Magnetic field and stress dependence of FeGa 3-D shaped polycrystalline magnetostrictive materials properties.

N. Lupu, H. Chiriac

Magnetic Materials and Devices, National Institute of Research and Development for Technical Physics, Iasi, Romania

Magnetostrictive materials can be obtained in desirable shapes depending on their final application. The fabrication in variable shapes strongly depends on the method of preparation. Fe–Rare Earth base giant magnetostrictive materials (Terfenol, Sm-Dy-Fe, Fe-Dy, etc.) are generally prepared as rods or bars especially due to the specific conditions to be assured to get the single crystal phase, but also because of their fragility in other shapes (thin films, melt-spun amorphous or polycrystalline ribbons). Despite of their no fragility under mechanical stress conditions, the obtaining of the single phase in Fe-Ga/Fe-Al base alloys which gives the large magnetostriction on preferred direction, impose limitations on preparation, and thus the bulk shapes (rods, bars) are preferred.

In this work, alloy ingots of $\text{Fe}_{1-x}\text{Ga}_x$ ($x = 0.15, 0.175, 0.195, 0.21, 0.225, 0.28$) were prepared by arc-melting high purity ($> 99.9\%$) constituent elements multiple times to insure homogeneity. Bulk cast samples as rods of 6 mm in diameter and 40 mm in length, and respectively bars of $3 \times 3 \times 10 \text{ mm}^3$ have been prepared by ejecting the molten alloy in Cu moulds using an ejection pressure of 4 atm. Bulk shaped samples were sealed in quartz tubes with approximately 1 atm. of Ar. Isothermal heat treatments were performed at 1000°C for 72 hours and then the samples were slow quenched to RT or slow quenched to 800°C then water quenched.

No texture was evidenced by XRD measurements. In addition to the primary reflections at $\sim 44^\circ$ (110) and $\sim 64^\circ$ (200), none reflections corresponding to the DO_3 phase were observed. The thermomagnetic measurements confirmed the existence of bcc Fe (A_2 phase), with an additional magnetic transition at around 500°C for $\text{Fe}_{79}\text{Ga}_{21}$ melt-spun ribbons. Additionally, the samples are magnetically very soft, which is also confirmed by the λ -H measurements shown below for $\text{Fe}_{82.5}\text{Ga}_{17.5}$ and $\text{Fe}_{80.5}\text{Ga}_{19.5}$ cast bars of $3 \times 3 \times 10 \text{ mm}^3$.

The magnetostriction of the 3-D shaped polycrystalline Fe-Ga bulk samples is dependent on the magnitude of the applied stresses during measurements, because of the stored magnetoelastic energy, as shown in Fig. 2. The same behavior is observed for all composition, but the increase of the magnetostriction is smaller for higher Ga contents. Additionally, depending on the composition, applied field direction and the treatment conditions (but mainly on the cooling history) the magnetostriction behaves differently for 21 and 28 at. % Ga, respectively. Such a different behavior is mainly caused by the specific microstructure developed in each polycrystalline Fe-Ga cast sample as a function of composition and annealing conditions (relaxation of internal stresses, presence of microstresses and microstrains, etc.).

All these aspects will be discussed in detail, being extremely important in what concerns the potential applications of such cast 3-D shaped polycrystalline magnetostrictive materials.

Magnetostriiction of Fe-X (X = B, Al, Ga, Si, Ge) intermetallic alloys.

G. Roland, S. Reiko, M. Nasir

Inst. of Solid State Physics, Techn. Univ. Vienna, Vienna, Austria

Metallic iron exhibits a rather low magnetostriction of $\lambda(100) = 20$ ppm and $\lambda(111) = -21$ ppm. However substituting Fe by nonmagnetic elements, such as Ga, Al, ... leads very often to a remarkable enhancement of the magnetostriction [1,2].

Table 1 shows the change of the magnetostriction due to substitution in Fe-X systems.

In single crystalline Fe_{100-x}Ga_x a maximum magnetostriction between 17 and at 19% Ga was found which can reach values of less than 400 ppm ($3/2 \lambda(100)$) at room temperature.

It should be noted that the phase diagram on the Fe-rich side is very similar for substituting Si, Al or Ga. First a statistical substitution of the bcc α -Fe occurs which leads to the A2 structure. For higher amounts of the substituting element the more ordered B2 or even the DO₃ structure can occur. Figure 1 shows the structural situation for the Fe-Ga system:

Due to the fact that in polycrystalline materials the relative amount of the different structure types plays a very important role, the production influences the achievable magnetostriction. Comparing Fe-Ga, Fe-Si and Fe-Ge binary systems, all three systems in the Fe-rich region present disordered solid solution in the A2 structure and ordered phases B2 and DO₃ for higher concentrations. So recently the magnetostriction was investigated on bulk annealed Fe_{100-x}Ga_x (x = 8, 12, 15, 20). Depending on the composition different crystallographic phases occur. For annealed Fe₈₀Ge₂₀ (T = 600°C) a maximum magnetostriction of -30×10^{-6} was found [7], which is significantly smaller than that of polycrystalline Fe-Ga.

In the last years a large number of papers appeared reporting large and even "giant" magnetostriction values obtained on rapidly quenched Fe-Ga ribbons. The reported "giant" values range from -1100 ppm for a Fe₈₅Ga₁₅ stacked ribbon sample [8], to even larger values such as -2100 ppm in Fe₈₃Ga₁₇ ribbon [9]. However due to careful investigations on the bending problem – depending on the field direction with respect to the ribbon axis - which may occur in such ribbons, doubts exist concerning the reliability of these data [10].

In the present paper an overview of actual achieved magnetostriction data on systems Fe-X (X = Al, Ga, Si, Ge) will be given. Of great importance is the applied measuring method. The samples are measured using either a strain gauge method or a capacitance dilatometer. The used geometry (e.g. field direction with respect to ribbon axis) is of large importance. Additionally is the structural situation, which can be influenced by the production method, important with respect to the local degree of disorder. The effect of the local surrounding, the symmetry as well as the microstructure will be discussed.

Magnetic and magnetoelastic properties of electrodeposited FeGa/CoFeB multilayered films and nanowires arrays.

N. Lupu, P. Pascariu, C. Gherasim, H. Chiriac

Magnetic Materials and Devices, National Institute of Research and Development for Technical Physics, Iasi, Romania

Recently, hybrid structures consisting of a combination of magnetostrictive alloys and soft magnetic materials have been proposed [1]. The multilayered thin films, prepared by conventional sputtering methods, were designed on the basis of “exchange spring” magnets, which consist of two materials with different magnetic properties, exchange coupled in a multilayer system. This behavior is called “exchange magnetostriction” and depends strongly on the thickness of the different layers forming the multilayered structure [2].

This work is focusing on the fabrication and characterization of Fe-Ga/Co-Fe-B multilayered thin films (MTF) and nanowires (MN). Multilayered films 3-4 μm thick have been obtained by electrodepositing 50 consecutive sequences of amorphous Co-Fe-B (20 nm or 60 nm) and Fe-Ga (60 or 20 nm) successive layers. 200 to 300 sequences multilayered nanowires were electrodeposited into commercially available Synkera[®] nanoporous alumina membranes with pore diameters ranging from 17 to 97 nm, and lengths of 50 μm . CoFeB amorphous alloy has been chosen for its magnetic softness [3], which favors the rotation of the magnetic moments, thus contributing to the appearance and magnitude of the “exchange magnetostriction” effect in the coupled FeGa/CoFeB structures. $[\text{Fe}_{1-x}\text{Ga}_x/\text{Co}_{60}\text{Fe}_{20}\text{B}_{20}] \times n$ ($x = 0.1 \div 0.3$) multilayered nanowires were electrochemically deposited into the nanopores from a Watts-type bath, changing the electrochemical potential in the range 0.75 (CoFeB) to 1.7 V (FeGa). The composition of the successive Fe-Ga and Co-Fe-B layers was controlled through optimizing deposition parameters such as ion concentration, buffer acids, and applied voltage. The bath consisted in a single mixed solution of iron(II) sulfate heptahydrate, cobalt(II) sulfate heptahydrate, gallium(III) sulfate hydrate and $\text{C}_2\text{H}_{10}\text{BN}$ combined with boric acid as a pH buffer and small amounts of sodium citrate as complexing agent to keep the ferrous iron and cobalt from oxidizing. Energy dispersive spectroscopy (EDS) was used to check the composition of the electrodeposited nanowires. In order to select only the most suitable conditions for multilayered nanowires preparation, separate thin films of Fe-Ga and Ni-Fe as well as multilayered thin films have been electrodeposited first, using brass substrates.

SEM micrographs of FeGa/CoFeB nanowires show that the multilayered structure is formed. The X-ray diffraction patterns indicates the coexistence of (Fe,Ga) solid-solution phase and amorphous CoFeB in multilayered thin films and nanowires. The coexistence of these phases is evidenced also by the thermomagnetic measurements shown in Fig. 1. The Curie temperature of the amorphous CoFeB is about 430^oC, whereas the second transition at about 700^oC is the ferromagnetic-paramagnetic transition of $\text{Fe}_{70}\text{Ga}_{30}$ [4].

The combination of $\text{Fe}_{1-x}\text{Ga}_x$ magnetostrictive material and $\text{Co}_{60}\text{Fe}_{20}\text{B}_{20}$ amorphous soft magnetic material shows good magnetic softness (H_c does not exceed 20 Gs) and gives novel magnetostrictive behavior caused by the formation of twisted spin structures. The coercive field values are smaller than those reported up to now for Fe-Ga single nanowires [5] and Fe-Ga/Py multilayered nanowires [6], and the reason for keeping such reduced coercivities might be again the softness of amorphous Co-Fe-B layer, which allows the rotation of the magnetic moment much faster than if using other interface layers. The intrinsic mechanisms governing the magnetic and magnetoelastic behavior of such “twisted” structures will be discussed in detail considering the magnetic domains structure of the component layers as well as the interlayer phenomena.

Modelling and experimental analysis of magnetostrictive devices: from the material characterisation to their dynamic behaviour.

O. Bottauscio¹, R. Bonin¹, A. Lovisolo¹, P. Roccatò², C. Sasso¹, M. Zucca¹

1. Electromagnetics, Istituto Nazionale di Ricerca Metrologica, Torino, Italy; 2. Dip. Ingegneria Elettrica, Politecnico di Torino, Torino, Italy

The prediction of the dynamic behaviour of magnetostrictive (MST) devices is fundamental for their use as active compensators of mechanical vibrations. To this aim, computational tools able to modelling the device response are useful both for the development of fast and reliable control algorithms and in the design of new multipurpose devices [1-2]. These tools have to couple the electromagnetic field equations with the supply circuits, accounting for the magnetoelastic properties of the magnetostrictive rod through the use of physical-based models [3,4].

A first approach coupling electromagnetic field analysis and magnetostrictive models has been proposed in [5], limiting the analysis to the MST rod section. Here the model has been extended to account for the entire device geometry.

The model is based on a finite element (FEM) solution of electromagnetic field equations within a domain describing the MST rod, the enclosure and the supply coil, including eddy currents in the rod. The magnetoelastic properties of the rod are modelled through a Preisach hysteresis model, introducing an effective field, which account for the magnetoelastic interaction [4]. FEM formulation is coupled with the magnetostrictive hysteresis model (MM) using the iterative Fixed Point technique.

MM is identified starting from static magnetoelastic characterisations carried out using a 30 kN dynamometer where an iron yoke was embedded under the moving crossbar to provide magnetic field and stress on a cylindrical Terfenol-D sample. The characterization has been performed under constant stress; the control logic of the dynamometer keeps the mechanical load constant under any change of shape of the sample and therefore compensates the mechanical load yield by the magnetized sample itself and the force due to the poles attraction. Magnetostriction (λ) has been measured by two electric strain gauges, along and transversally to the applied field respectively. Magnetization has been measured by a pick-up coil wound on the sample whereas field was measured by a hall probe placed close to the sample surface such to measure internal field. This set up has allowed the measurement of static hysteresis and magnetostriction loops under the effect of compressive stresses up to 32.5 MPa. The quasi-static measured and reconstructed B-H and λ -H cycles are reported in Fig. 1.

The coupled FEM-MM is applied to the simulation of a device having a bulk Terfenol-D rod. The analysis is extended up to 100 Hz evaluating the device response in terms of magnetic (magnetic flux in the rod) and mechanical properties (rod strain). Both quantities have been compared with measurements performed on the device, equipped with sensors for its complete magneto-mechanical characterisation [6].

Fig. 2 shows the magnetic flux flowing in the rod mid-section as a function of the coil current, comparing computed and measured values. The agreement between experiments and computations is encouraging, and it increases with frequency. The presence of eddy currents inside the magnetostrictive rod determines an enlargement of the hysteresis cycle, even if the same maximum value of the magnetic flux is reached. The corresponding global rod strain at 100 Hz is also shown, in comparison with the curve at 1 Hz.

The numerical implementation and the application to the analysis of the magnetostrictive actuator, comparing the results with experiments, will be shown in the full paper.

Design of a multipurpose magnetostrictive device.

O. Bottauscio¹, A. Lovisolo¹, P. Roccato², M. Zucca¹

1. Electromagnetics, INRIM, Torino, Italy; 2. Dip. Ing. Elettrica, Politecnico di Torino, Torino, Italy

The performances and the use of non-linear actuators, in the micropositioning applications and as active vibration compensators, could be limited by a non proper design of the magnetic circuit and by the approximation, necessarily introduced, in modelling their behaviour for the control environment. Therefore, the use of such devices often requires a specific design, which should take into account two aspects.

First, an effective design implies the availability of modelling tools coupling the electromagnetic field equations with the supply circuits and taking into account the magnetoelastic properties of the magnetostrictive(MST)rod through the use of physical-based models.

Second, an accurate verification of the actual dynamic behaviour of a MST device requires a measurement system able to assess the dynamic magnetic and dynamic electro mechanical characteristics: stress-current (ϵ -I) and magnetostriction (strain)-current (λ -I), at various frequencies and applied preloads. To this purpose, a measurement device has been proposed in [1].

In this paper, starting from the experience described in [1] and from approach proposed in [2], coupling electromagnetic field analysis and magnetostrictive models, a suitable Finite element – magnetostrictive approach (FEM-MM) has been employed in the design of a MST multipurpose device. This appliance has to be able to assess the magnetic and mechanical characteristics of the magnetoelastic rod housed inside and, thus, to perform the applications in presence of a significant applied load of thousands of Newton.

The work proposes a device configuration shown in Fig.1, where the magnetic circuit has been studied taking into account the presence of different measurement elements (load cell, strain gauges, pick up coils, ...) and the need of an higher magnitude and uniformity in magnetic flux density inside the MST rod. The device has been designed with an external case, constituted of magnetic commercial steel C45 which limits the stray field and guarantees a sufficient mechanical strength. Moreover, there is an internal magnetic circuit able to concentrate the magnetic flux inside the rod that, as it is known, has weak magnetic properties. The same C45 material can be used to build the magnetic circuit. The paper discusses, through the FEM-MM results, the effects in using different materials in the frequency range 1 Hz - 100 Hz. As an example, the stray field, the rod magnetization and strain are shown in the following for two different magnetic materials, the already mentioned C45 steel and the Somaloy provided by Hoganas. Fig. 1 evidences how, at the frequency of 10 Hz, Somaloy provides lower stray field whilst Fig. 2 put in evidence how the magnetic configuration guarantees a satisfactory magnetization and uniformity along the rod both at lower and higher frequencies and how the Somaloy circuit suffers a lower demagnetization increasing frequency. Fig. 3 shows how the lower dynamic effects in Somaloy reduce the derating in the time varying strain characteristics. In the full paper a complete analysis also employing other materials, including the effect of permanent magnets, will be provided.

1. Wolfson Centre for Magnetics, Cardiff University, Cardiff, United Kingdom; 2. Materials Science and Engineering Department, Iowa State University, Ames, IA

Cobalt ferrite based materials have potential for non-contact magnetostrictive sensor applications due to their low cost, high magnetostriction coefficient λ and high sensitivity to field $d\lambda/dH$ [1]. In the past, substitution of Cr^{3+} , Mn^{3+} or Ga^{3+} for Fe^{3+} has been used to vary the magnetic and magnetoelastic properties [2]. These properties are greatly affected by the site occupancy of the various ions in the cubic spinel structure. In the current study, the effect of $\text{Ge}^{4+}/\text{Co}^{2+}$ co-substitution is investigated, which is expected to show different effects than previous trivalent substitutions.

A series of polycrystalline Ge-substituted cobalt ferrite samples, $\text{Co}_{1+x}\text{Ge}_x\text{Fe}_{2-2x}\text{O}_4$ ($x=0, 0.3, 0.6$) were prepared by standard powder ceramic techniques [1, 2]. Curie temperatures determined by vibrating sample magnetometry were seen to fall steeply with increasing Ge content (780K, 558K and 407K for $x=0, 0.3$ and 0.6 respectively). The magnetostriction was measured with a strain gauge setup between temperatures of 250 – 400K at 50K intervals. As an example, Fig. 1 shows magnetostriction curves for all samples at 300 K.

Over the range 250 – 400K, three shapes of magnetostriction curves were observed and classified as shown in Fig. 2. (a). These shapes are due to presence of the two magnetostriction coefficients, λ_{100} and λ_{111} , having opposing signs in cobalt ferrite [5]. Shape-A was obtained when the contribution of λ_{100} to strain, negative in sign, initially increased faster with field than the contribution from λ_{111} . This continued until complete alignment of domains with easy $\langle 100 \rangle$ axes. After that the contribution from λ_{111} , opposite in sign, increased faster causing the magnetostriction to decrease in magnitude. This shape was observed for samples with Ge-content $x=0$ at all temperatures and for $x=0.3$ at 250 and 300K. Shape-B was observed for samples with $x=0.3$ at 350 and 400K. With this substitution of Ge/Co the contribution of λ_{100} to field induced strain has become dominant and that of λ_{111} appears negligible. Shape-C was an inverted form of Shape-B, observed for $x=0.6$ at all temperatures. Apparently either λ_{111} contributions have become dominant or λ_{100} has reversed sign. Field induced strain amplitude for the initial high-sensitivity linear region of each curve, $|\lambda|_{\text{max, linear}}$, was determined. For Shape-A, the maxima at the end of linear region were chosen as the $|\lambda|_{\text{max, linear}}$. For Shape-B or C, the end of linear region was chosen as the point where $|d\lambda/dH(H)|$ has decreased to 10% of $|d\lambda/dH|_{\text{max}}$ (see Fig. 2. (b)). Fig. 3 shows the temperature dependence of these $|\lambda|_{\text{max, linear}}$ and the amplitude of magnetostrictive strain sensitivity $|d\lambda/dH|_{\text{max}}$. At 250 K, the magnetostrictive strain amplitude for pure cobalt ferrite is the same as that of $\text{Co}_{1.3}\text{Ge}_{0.3}\text{Fe}_{1.4}\text{O}_4$. However, at this temperature, the field at which $\text{Co}_{1.3}\text{Ge}_{0.3}\text{Fe}_{1.4}\text{O}_4$ reaches maximum magnetostriction is only 70% of the field at which pure cobalt ferrite attains its maximum. In the design of device applications for this material, this translates to a power saving of 50% over pure cobalt ferrite. Due to its low Curie temperature, $\text{Co}_{1.3}\text{Ge}_{0.3}\text{Fe}_{1.4}\text{O}_4$ exhibits less hysteresis at low temperatures, which again is an important consideration for sensor design.

Magnetostriction studies on antiferromagnetic $\text{Mn}_x\text{Fe}_{100-x}$ ($30 \leq x \leq 55$) alloys.

M. Yan, T. Ma, J. Zhang, Y. Xu

Department of Materials Science and Engineering, Zhejiang University, Hangzhou, China

Introduction

In the past few decades, giant magnetostriction has been obtained in many magnetic materials, including both ferromagnets and antiferromagnets. Most magnetostrictive materials are ferromagnets, such as TbDyFe and NiMnGa alloys, which have been studied extensively and stepped into practical applications [1-2]. However, researches on magnetostrictive antiferromagnets are still very limited, since they only possess giant magnetostriction at cryogenic temperatures or in relatively strong magnetic fields [3]. Much more recently, at room temperature and in a relatively low magnetic field of 1 T, Peng et al found that antiferromagnetic Mn₄₂Fe₅₈ alloy possesses a magnetostriction up to 169 ppm [4], which can be comparable to that of textured ferromagnetic Fe-Ga alloys [5]. This makes it a promising candidate in magnetostrictive applications in addition to its low cost. Meanwhile, the magnetostriction mechanism of antiferromagnetic Mn-Fe alloys remains unclear up to now. This work presents a systemic study on the magnetostriction of antiferromagnetic $\text{Mn}_x\text{Fe}_{100-x}$ ($30 \leq x \leq 55$) alloys.

Microstructure

$\text{Mn}_x\text{Fe}_{100-x}$ ($x = 30, 35, 40, 50$ and 55) alloys were prepared by induction melting method, followed by homogenization for 24h at 1273K, then furnace cooled to room temperature. Fig.1 shows the x-ray diffraction spectra of the $\text{Mn}_x\text{Fe}_{100-x}$ samples. It can be seen that when x was less than 40, the diffraction peaks can be indexed as two phases. One was the face-centered-cubic (fcc) γ phase, the other was the hexagonal-close-packed (hcp) ϵ phase. The optical micrograph of Mn₃₀Fe₇₀ alloy also shows the mixed structure of two phases. When x was higher than 40, only γ phase remained in $\text{Mn}_x\text{Fe}_{100-x}$ alloys.

Magnetostriction

Fig.2 shows the magnetostriction curves of $\text{Mn}_x\text{Fe}_{100-x}$ ($30 \leq x \leq 55$) alloys up to 1.9 T. It can be seen that the magnetostriction value showed an obvious composition dependence. When Mn content x was less than 40, the magnetostriction at 1.9 T, $\lambda_{1.9T}$ was below 100×10^{-6} . At $x = 40$, $\lambda_{1.9T}$ increased to 209×10^{-6} . When x was further increased to 50 and 55, $\lambda_{1.9T}$ reached 875×10^{-6} and 665×10^{-6} , respectively. The 1.9 T field was not high enough to saturate the magnetostriction, thus higher values can be expectable when the magnetic field was further increased. It can be concluded that the MnFe alloys of single γ phase possessed higher magnetostriction than those containing both γ and ϵ phases.

To understand whether the magnetic-field-induced structural transformation occurred in Mn-Fe alloy, the Mn₅₀Fe₅₀ sample was magnetized by increasing the magnetic field to 1.9 T and then removing the field. The XRD spectrum of the as-magnetized sample is shown in Fig.3. As can be seen, the Mn₅₀Fe₅₀ alloy changed from single γ phase to a mixture of $\gamma + \epsilon$ phases after magnetizing. That means a magnetic-field-induced phase transformation from γ to ϵ occurred in Mn₅₀Fe₅₀ alloy. Thus, the large magnetostriction in Mn-Fe alloys of high Mn content should be attributed to the magnetic-field-induced structural transformation.

In this work we present an innovative method to optimize the magnetic properties of magnetostrictive thin films. For set deposition parameters we are able to reduce the coercivity and to control the magnetic anisotropy, while keeping the total magnetostriction.

The trend for the miniaturization of magnetostrictive sensors and actuators and the promising opportunities of magnetic MEMS produce a constraint in the maximum field that can be applied to activate the magnetostrictive material. These new trends require new materials with high magnetostriction and soft magnetic properties at the same time[1].

Our proposal consists of combining multilayers with crossed magnetic anisotropies. $(\text{Fe}_{80}\text{Co}_{20})_{80}\text{B}_{20}$ magnetostrictive amorphous thin films have been sputtered with 70 W power and 6 mTorr Ar pressure on 2×1.5 mm thermal oxide Si substrates lithographically defined. The magnetic anisotropy in every growing layer is induced by the oblique incidence of the plasma, due to the stress induced during the deposition[2].

In order to vary the magnetic anisotropy direction of the layers during the deposition process, we rotate the sample 90° with respect to the plasma incidence from layer to layer within the multilayers. We have deposited several multilayers, consisting of five identical bilayers composed of two layers with crossed magnetic anisotropies and different thickness ($X-9$ nm), X ranging from 16 to 30 nm. Note that all the layers have the same composition and therefore they are exchange coupled, being the overall direction of anisotropy the one of the thicker layers[3]. The multilayers are compared with a set of single layer samples with the same total thickness. Figure 1 shows a schematic picture of the samples under study.

The magnetic properties of the samples were measured with a VSM and the magnetostriction of some of them was measured as well through the optical detection of the deflection of cantilevers. All the samples present one well defined anisotropy axis. Figure 2 represents the anisotropy and the coercive field of all the samples of the study along the hard axis of magnetization, as well as the saturation magnetostriction of some of them.

The results show that the multilayers present a much lower magnetic anisotropy than the single layer samples and, though growing with the total thickness of the layer in both kind of samples, the variation of the $X/9$ thickness ratio in multilayers ensures an almost linear increase of the anisotropy field. Interestingly, the coercive field is observed to decrease in all the multilayer samples respect to their single layer counterparts. Although the coercive plot follows a slightly scattered trend, we have repeated this measurement several times, confirming the reduction of coercivity. In addition, the magnetostriction measurements of some selected multilayers show that multilayering does not affect the magnetostriction of the films.

Furthermore, the magnetic anisotropy is less dispersed in multilayers than in single layer samples, so that the hard axis hysteresis loops of multilayers are much more linear. Figure 3 shows the loops along the easy and the hard axis of magnetization of a multilayer and its single layer counterpart with the same thickness. The loops along the easy axis of magnetization are very similar. However, while the hard axis hysteresis loop of the multilayer sample is very linear in the low field region, it shows a little widening in the single layer, corresponding to domain wall movement.

The origin of these differences seems to lie in the mechanical energy accumulated in each layer. Indeed, Bitter images (not included) show very low mobile Bloch domain walls in multilayers and Neel domain walls in single layers.

Fine structure observation near critical temperature in $\text{Gd}_5\text{Si}_{1.95}\text{Ge}_{2.05}$

R. L. Hadimani, Y. Melikhov, J. E. Snyder, D. C. Jiles
 Wolfson Centre for Magnetism, Cardiff University, Cardiff, United Kingdom

$\text{Gd}_5(\text{Si}_x\text{Ge}_{1-x})_4$ exhibits the largest known room temperature giant magnetocaloric effect near its coupled first order magnetic-structural phase transition. This effect can be utilised for energy efficient refrigeration. The energy conversion efficiency of these refrigerators can reach as high as 60% of Carnot efficiency, which is much larger than the 30% achieved in conventional liquid/vapour cycle refrigeration. This first order magnetic-structural phase transition also involves a colossal magnetostriction of the order of 10,000 ppm [1].

$\text{Gd}_5(\text{Si}_x\text{Ge}_{1-x})_4$ has a complex magnetic-structural phase diagram which can be divided into three distinct regions. In the silicon rich region ($0.575 \leq x \leq 1.0$) there is a second order magnetic phase transition with no associated structural transition. In the germanium rich region ($0 \leq x \leq 0.3$) there is a first order magnetic-structural transition from Gd_5Si_4 -type orthorhombic ferromagnetic phase to Sm_5Ge_4 -type orthorhombic antiferromagnetic phase [2]. In the middle region ($0.4 \leq x \leq 0.503$) there is a first order magnetic-structural phase transition exhibiting the highest magnetocaloric effect [3]. We have carried out a series of measurements on single crystal and polycrystalline $\text{Gd}_5\text{Si}_{1.95}\text{Ge}_{2.05}$ and single crystal $\text{Gd}_5\text{Si}_2\text{Ge}_2$ samples showing magnetostrictive strain as a function of temperature at various magnetic field strengths and magnetostrictive strain as a function of magnetic field at various temperatures with a magnetic field of up to 7 Tesla.

In single crystal $\text{Gd}_5\text{Si}_{1.95}\text{Ge}_{2.05}$, there was fine structure observed in the magnetostriction curve λ (strain) vs. H (field strength) near the critical temperature (Fig 1 and 2). The magnetostriction measurements show that close to the critical temperature, there is a sudden increase in the magnetostrictive strain of about 200-300 ppm (positive) just before the field induced first order phase transition of about 900-1000 ppm (negative). This anomaly was observed for both strain vs. magnetic field at various temperatures and for measurements of strain vs. temperature at various magnetic field strengths. For the polycrystalline $\text{Gd}_5\text{Si}_{1.95}\text{Ge}_{2.05}$ sample the fine structure was not as strong as in the single crystal. The sudden change in the magnetostrictive strain just before the field induced first order phase transition was about 40 ppm (Fig 3).

Measurements of strain as a function of magnetic field strength and temperature were also made on a single crystal $\text{Gd}_5\text{Si}_2\text{Ge}_2$ sample using the same equipment. No sudden change in the strain below the critical temperature was observed (Fig.4).

From these results we conclude that the magnetoelastic behaviour of the $\text{Gd}_5(\text{Si}_x\text{Ge}_{1-x})_4$ can show significant levels of fine structure in the approach to the transition. This fine structure could be indicative of differences in switching field strength for different regions of the material which could be due to the presence of two phases.

The family of compounds $\text{Gd}_5(\text{Si}_x\text{Ge}_{1-x})_4$ is well known for showing giant magnetocaloric effect [1,3]. The interplay between the crystallographic and magnetic structures present in these materials configures a rich and complex scenario not yet completely understood, specially in the edge compound Gd_5Ge_4 [4, 5]. In this alloy, a second-order paramagnetic (PM)-to-antiferromagnetic (AFM) transition occurs at the Néel temperature $T_N \approx 130$ K. The nature of the AFM phase is complex, with competing AFM (between layers) and ferromagnetic (FM) interactions (within layers). The magnetic ordering remains AFM after zero-field-cooling down to 2 K. The application of a certain magnetic field, whose value depends on the temperature, induces a first-order AFM-to-FM magnetostructural transition, which is irreversible at temperatures below ~ 10 K, partially reversible from ~ 10 to ~ 20 K and fully reversible above ~ 20 K [5]. Here, we study Gd_5Ge_4 alloy with ac magnetic susceptibility and high field magnetization curves. The samples were prepared with high purity (99.99%) Gd and special attention was paid to the temperature stability and ramping rate during the measurements. An anomalous behavior is observed in the real and imaginary parts of the ac susceptibility through a peak around 225 K. This points out to the occurrence of spin clustering due to short-range correlations (SRC) in the PM phase, that is, a Griffiths-like phase behavior [2]. Gradually increasing the applied dc field causes this anomaly at $T_G \approx 225$ K to weaken and finally disappear at 200 Oe. Variation of the ac frequency from 0.1 Hz to 1 kHz shows a shift of T_G to higher temperatures. High magnetic field measurements (isothermal and isofield magnetization curves) were performed in the Grenoble High Magnetic Field Laboratory, with fields up to 23 T within 5 and 300 K. Isothermal magnetization up to 20 K shows gradual reduction of the hysteresis with increasing temperature, associated with the irreversible low-temperature transition [5]. Above 20 K, the transition becomes reversible and shifts to higher fields with increasing temperature. Above 90 K the hysteresis is no longer observable in the investigated field range. At about 80 K, a change in the slope of the magnetization curve is evident. Zero Field Cooled-Field Cooled (ZFC-FC) protocol in isofield curves do not show any difference between the ZFC and FC processes when data are acquired on increasing the temperature. In contrast, in a Field Cooling-Field Heating experiment, a remarkable hysteresis is observed in the first-order transition and, surprisingly enough, in the PM state. All the foregoing sheds some light on the nature of the Griffiths-like phase and evidences that SRC occur both at low and high magnetic fields. Consequently, it is likely that the interplay between the AFM and FM SRC, and the actual nature of the dominant ones, changes with temperature and magnetic field.

The theoretical description of several spintronics phenomena, is surrounded by several subtle challenging issues. Standing as a major challenge in the description of various phenomena such as current-induced magnetization reversal(2-5) and domain-wall motion(6-12), is their inherent non-equilibrium character. Besides the intrinsic non-equilibrium dynamics of the the magnetization degree of freedom, the nonequilibrium behavior manifests itself in the quasi-particle degrees of freedom that are driven out of equilibrium by the nonzero bias voltage. Due to this, the fluctuation-dissipation theorem cannot be applied to the quasi-particles. This, in part, has led to controversy surrounding the theory of current-induced domain wall motion (7-8). We consider the dynamics of single-domain nanomagnet that is subjected to non-equilibrium conditions. This system is modeled as a quantum spin coupled to two ferromagnetic leads. Starting from this model, and building upon previous work (1), we derive an effective stochastic equation for the dynamics of the magnetization direction using the functional-integral description of the Keldysh-Kadanoff-Baym nonequilibrium theory. We implement a microscopic derivation of the Langevin equation for the magnetization direction degree of freedom. In the limit of adiabatic changes in the magnetization direction it takes on the form of the stochastic Landau-Lifschitz-Gilbert equation. The effect of the ferromagnetic leads is displayed in the form of a spin-transfer-torque term (2-5). We are able to provide microscopic expressions for the Gilbert damping parameter and the strength of the fluctuations, including their bias-voltage dependence. Far from equilibrium it can be expected that the strength of the fluctuations and damping parameter are not related by the fluctuation-dissipation theorem. Our main finding is that in the low-frequency limit it is possible to introduce a voltage-dependent effective temperature that characterizes the fluctuations of the magnetization direction and its transport-steady-state probability distribution function.

In the situation that eV is substantially larger than $k_B T$, which is usually approached in experiments, we have that:

$$k_B T_{\text{eff}} = eV/4 + k_B T/2.$$

An effective temperature for magnetization dynamics has been introduced before on phenomenological grounds. Interestingly, the phenomenological expression of Urazhdin et al.(9), found by experimentally studying thermal activation of current-driven magnetization reversal in magnetic trilayers, has the same form as our expression for the effective temperature in the large bias-voltage limit that we derived microscopically. We believe that spin current shot noise may be observable in future experiments and that it may become important for applications as technological progress enables further miniaturization of magnetic materials. Moreover, the formalism presented here is an important step in understanding magnetization noise from a microscopic viewpoint as its generalization to more complicated models is in principle straightforward.

Race track memories seen from an ab-initio point of view.

P. Weinberger

1. Center for Computational Nanoscience, Vienna, Austria; 2. Department of Physics, New York University, New York, NY

Magnetic domains and domain walls and their resistivities have become important features of magnetism at the nanoscale (including thin wires or spin valve type arrangements), especially since the discovery of the giant magnetoresistance effect. Here, using the fully relativistic versions of the Screened Korringa-Kohn-Rostoker method and of the Kubo-Greenwood equation equilibrium domain wall widths and corresponding domain wall resistivities are calculated for Co-cFe-(1-c), Co-cNi-(1-c) and Fe-cNi-(1-c) and making use of a multi-scale approach (*). It is found that in Co-cFe-(1-c) the domain wall width becomes rather large at about $c=0.4$, but does not show an obvious singularity in the vicinity of the bcc to fcc phasetransition. In Co-cNi-(1-c) the domain wall width varies much less in size with respect to the concentration. In particular, it is demonstrated (**) that as compared to the homogeneous infinite systems the anisotropic magnetoresistance is reduced in the presence of a domain wall. This reduction is very small for Co-cFe-(1-c), rather moderate for Co-cNi-(1-c), while for Fe-cNi-(1-c) it is about 15%! The results clearly indicate that besides Fe-cNi-(1-c), Co-cNi-(1-c) might be a useful candidate for race track memories.

DETECTION OF CURRENT-INDUCED OSCILLATIONS OF PINNED DOMAIN WALLS.

M. Kläui¹, D. Bedau¹, S. Krzyk¹, G. Faini², L. Vila², U. Rüdiger¹

1. Physics, University of Konstanz, Konstanz, Germany; 2. LPN-CNRS, Marcoussis, France

When combining transport with magnetic materials on the nanoscale, a range of exciting and novel phenomena emerge. Due to the interaction of the current with the magnetization, the spin transfer torque effect leads to current-induced domain wall motion (CIDM) [1-3], which we study in detail. In CIDM, electrons transfer angular momentum and thereby push a domain wall [1-3]. We have comprehensively investigated this effect and observed that this interaction is strongly dependent on the temperature [3] and the wall spin structure [2]. So far, primarily current pulses have been employed to investigate domain wall displacements and strongly stochastic behaviour has been observed.

More reproducible behaviour is found if AC currents are used to excite domain wall oscillations, which are inherently reproducible. To generate a domain wall oscillator a restoring force is necessary, which can be provided by a constriction that generates an attractive potential well for a domain wall, which then acts as a quasiparticle [4]. The depth of the potential well, was found to increase with decreasing constriction width, and the well width was found to extend far beyond the physical size of the constriction [4].

To fully characterize the pinning potential, the curvature has to be determined in addition to the width and the depth. To study the curvature, the resonance frequency of the domain wall has to be ascertained and to this end, we inject AC currents with variable frequency into the structure shown in Fig. 1 (a) [5]. We then measure the depinning field as a function of the injected microwave frequency as shown in Fig. 2 (a) (blue squares) for a transverse wall (Fig. 1 (b)). We observe a dip of the depinning field at a resonance frequency of about 1.3 GHz even for low current densities of 10^{10} A/m² and the eigenmode consists of the whole wall moving. Next we consider a pinned vortex wall (Fig. 1 (c)) and a strong dip in the depinning field is observed at around 800 MHz (Fig. 2 (b), blue squares). Here the eigenmode consists of the vortex core oscillation. To obtain the resonance frequencies at variable fields we employ a DC homodyne detection scheme:

As the domain wall oscillates, the resistance of the magnetic structure is modulated due to the anisotropic magnetoresistance in phase with the domain wall position. If the quasiparticle happens to be excited at the resonance frequency, the varying resistance will rectify the injected high frequency current and a DC voltage is developed across the structure. We plot the DC response for the vortex wall pinned at the constriction in Fig. 2 (b) (red line). We see a dispersion-like signal with a change in the sign exactly at the resonance frequency, which allows us to determine the resonance from the DC signal. For the transverse wall the expected signal is much weaker since the oscillation has a smaller amplitude, as visible from the smaller change in the depinning field compared to the vortex wall and this is also reflected in the smaller DC signal (Fig. 2 (a) (red line)).

The domain wall resonance frequency was measured for different external magnetic fields and was found to increase with increasing field so that we can conclude that the potential well curvature can be engineered by varying the external field [5].

To directly determine the potential $U(x)$ we can use the power dependence of the resonance frequency [5]. From the resonance frequency as a function of the power, we obtain the oscillation period and, since the energy of an oscillator is proportional to the square of the driving force, also as a function of the energy in the system. From the energy dependence of the oscillation period we can for the first time directly determine $U(x)$ as shown in Fig. 2 (c) with the absolute width of the poten-

tial well determined as described in [4]. The blue dots are calculated from the measured oscillator periods and the red line indicates the parabolic part of the potential well. As expected the domain wall potential flattens far away from the origin, indicating a non-harmonic (non-linear) contribution [5].

The magnetic vortex structure [1] observed in ferromagnetic circular dot has been intensively studied recently because of its potential applications to high-density and non-volatile storage media. To realize a magnetic vortex memory, control of the polarity of the vortex core is a key issue. Recently, it has been reported that the polarity can be reversed via the translational motion excited by an ac magnetic field [2]. Here, we demonstrate the reversal of vortex core polarity by an ac excitation current [3,4]. Samples were fabricated by the lift-off method in combination with electron beam lithography onto Si substrates. The diameter and thickness of the Permalloy dot were 1 μm and 50 nm, respectively. The motion was excited by using an ac excitation current generated from arbitrary functional generator (AFG), and the current density was estimated from the reflection signal by using standing wave ratio (SWR) bridge, as shown in Figure 1. The polarity reversal in the vortex core was observed by using magnetic force microscopy (MFM), as shown in Figure 2. The magnetization reversal was observed when the current density (j) exceeds $3 \times 10^{11} \text{ A/m}^2$ and the frequency of the excitation current (f) is $280 \text{ MHz} < f < 300 \text{ MHz}$. Numerical simulations and theoretical studies revealed the critical role of the dynamical magnetic field induced by the motion of the vortex core [5]. Also, the studies indicate the existence of the threshold velocity. The dynamical magnetic field at the threshold velocity that corresponds to $\sim 2 \text{ kOe}$ is sufficient to reverse the vortex polarity.

The above scenario gives a way to control the polarity of the vortex core, not only by an ac current but also by a pulsed current. Recently, we succeeded in reversing the polarity by a pulsed current with a duration of 1 ns.

Figure 1. Schematic illustration of the measurement setup used in the experiment. The current is supplied from the AFG to the sample. The current reflected from the sample is measured in the oscilloscope via SWR bridge. The dot shown in the illustration is Scanning Electron Microscopy (SEM) image of the sample. Two wide Au electrodes with 70 nm thickness, through which an ac excitation current is supplied, are also seen.

Figure 2. (a) MFM image before the application of the excitation current. A dark spot at the center of the disk (inside the white circle) indicates that the core magnetization points upwards with respect to the paper plane. (b) MFM image after the application of the ac excitation current at frequency $f = 290 \text{ MHz}$ and current density $j = 3.5 \times 10^{11} \text{ A/m}^2$ through the disk with a duration of about 10 s. The dark spot at the center of the disk in (a) changed to a bright spot, indicating the switching of the core magnetization from up to down. The MFM scan area was limited by the experimental time, and the parts of the sample that are necessary to determine the core direction have been omitted from the images. The low MFM contrast for the core is due to the height difference between the disk and the electrodes. The white dotted circle is the perimeter of the Permalloy disk.

Magnetization reversal control using a current pulse in Permalloy nanowires.

Magnetic memory device records information by magnetic configuration in ferromagnetic elements implemented in the device. Thus, the magnetization switching in the magnetic domain is an important technology in the device operation. While the magnetization reversal using magnetic field is widely utilized to change the magnetic bits of domains in the device, the current-driven magnetization reversal due to the spin transfer torque[1,2] and spin-wave excitation[3] is one of the promising and useful methods to realize the magnetic device of smaller bit size with larger integrated density.

In the present study, we microscopically investigate the magnetization dynamics including the magnetization reversal induced by a current pulse in Permalloy nanowires with in-plane anisotropy by means of Lorentz microscopy and electron holography. We found that the magnetic domain is controllably induced and erased in the uniformly-magnetized wire using a current pulse in small magnetic fields, which enables the magnetization reversal control.

Permalloy wires with a chemical composition of $\text{Ni}_{80}\text{Fe}_{20}$ are prepared on a Si_3N_4 membrane 30 nm in thickness supported by a Si substrate by electron lithography and lift-off method. Zigzag shaped wire 500 nm in width and 30 nm in thickness is uniformly magnetized along the wire due to strong shape anisotropy when the wire is as-deposited. The magnetization is completely reversed all over the wire in an in-plane magnetic field above 60 Oe applied against the averaged direction of the magnetization. The magnetization is alternately reversed and the magnetic domains are induced in the straight segments of the wire between corners when the in-plane magnetic field as large as 260 Oe is applied perpendicular to the averaged direction of the wire. A variety of the magnetic domain movements occur as a function of applied current density below the Curie temperature T_C [4,5]. In the following, we focus on the magnetization reversal induced by the current pulse in the uniformly-magnetized wire[6].

The probability that the magnetic domain is nucleated by the current pulse changes drastically between 0 % and 100 % depending on whether or not the in-plane magnetic field is applied parallel to the averaged direction of the wire. The magnetization direction in the nucleated magnetic domain is parallel to the applied in-plane magnetic field. These features enable stable and selective manipulation of the magnetic domain state, which will be applicable to the magnetization switching of the magnetic bit. We interpret that observed current-driven magnetization reversal is associated with the spin-wave and thermal excitation in zero magnetic field and its stochastic nature turns into deterministic under small magnetic fields because of Zeeman energy stabilization.

Stochastic magnetic field driven domain wall motion in a spin-valve nanowire.

X. Jiang, L. Thomas, R. Moriya, M. Hayashi, B. Bergman, C. Rettner, S. Parkin
 IBM Almaden Research Center, San Jose, CA

Field and current driven domain wall (DW) motion in magnetic nanowires has attracted much attention due to its scientific importance and technological potential for logic and storage device applications[1-3]. Here we report single-shot, real-time measurements of the stochastic field-driven motion of domain walls in NiFeCo free layers of spin-valve nanowire devices.

The spin-valve film stacks were deposited onto thermally oxidized silicon wafers by magnetron sputtering. The layer sequence, from bottom to top, is as follows: 3 MgO/ 17.5 Ir₂₄Mn₇₆/ 3.5 Co₇₀Fe₃₀/ 2.4 Cu/ 1 Co₇₀Fe₃₀/ 20 Ni₆₅Fe₂₀Co₁₅/ 1 Co₇₀Fe₃₀/ 1.5 Ru, where the numbers represent film thicknesses in nanometers. A combination of electron beam lithography, argon ion milling, and optical lithography was used to pattern the films into nanowires with a width of 200 nm and a length of 22 μ m.

To measure the field driven DW motion, we inject a DW into the free layer of the spin-valve in the presence of a driving field. The DW propagation along the nanowire leads to a resistance change of the spin-valve due to the giant magnetoresistance effect, which, under a dc bias current, gives rise to a voltage signal that can be sensed by a real time oscilloscope. From single-shot measurements of the signal traces with sub-nanosecond time resolution, we extract the DW's maximum displacement and velocity in real time.

Fig. 1 (a – b) show the histograms of the DW velocity and displacement at fields of 6 Oe, 11 Oe, and 80 Oe. Each histogram of the DW velocity is fit by a Gaussian distribution, as shown by the solid lines in Fig. 1(a). The most probable velocity obtained from the fit is plotted as a function of the driving field in Figs. 1 (c). The DW velocity shows a maximum at ~ 10 Oe, which is the Walker breakdown field H_w [4, 5].

Interestingly, we find that the stochasticity of the DW motion depends strongly on the magnetic field. For fields below (6 Oe) and well above (80 Oe) the Walker breakdown, the DW moves to the end of the nanowire with a well defined velocity. However, for fields just above the Walker breakdown (11 Oe), the DW velocity distribution is very broad. Moreover, the DW tends to stop before reaching the end of the nanowire. This field dependent stochasticity can be understood using a 1-D model of DW dynamics. When the applied magnetic field is below the Walker breakdown, the DW motion is translational, i.e., the DW moves at a constant speed without changing its structure. Such a steady motion of the DW makes it less susceptible to the weak pinning sites in the nanowire since its momentum helps it to overcome these local pinning potentials. When the field exceeds the Walker breakdown, however, such a dynamic equilibrium can no longer be sustained. Instead, the DW motion becomes turbulent and its velocity oscillates with time. In this case, the DW is more likely to be pinned by imperfections in the nanowire whenever its momentum is close to the minimum of the oscillation. Depending on the details of the velocity oscillation and the time when the DW pinning occurs, the average DW velocity may vary considerably. For fields much larger than the Walker breakdown field, the DW still undergoes continuous velocity oscillations as it moves. However, the wall is less likely to be pinned due to the much larger driving force provided by the field. In addition, the oscillation period of the velocity is much shorter compared to the traveling time of the DW in larger fields. As a result, the average velocity shows less variation. Our study suggests that the pinning of a moving DW is a dynamic process, which depends not only on the pinning strength of the imperfections in the wire, but also on the mode of the DW's motion.

The recently proposed “storage track memories” concept consist in storing information on domain wall (DW) sequences moving in patterned magnetic tracks. Based on recent advances in spin electronics for reading (magnetic tunnel junctions) or writing (spin transfer torque) magnetic information, performances are predicted to be very competitive with potential for high capacity 3D architectures. However in such nanodevices, DWs have to be driven on large distances in narrow wires in presence of lithography induced defects and imperfections from the virgin films. It is then crucial to determine how such defects will affect DW dynamics in presence of a polarized current. Recently, current induced domain wall depinning on a nanometer scale were reported in nanostructures with high perpendicular magnetic anisotropy (PMA) [1,2]. Such perpendicularly magnetized wires that exhibit very narrow DWs and high pinning fields are model systems to study interaction of DWs with pinning sites. In addition they open new perspectives for more integrated memory devices or logic circuits.

Here, we study current induced steady DW motion on micrometric distances. We use Giant Magnetoresistance (GMR) effect in perpendicularly magnetized spin valves to track DW motion in nanowires. We evidence stochastic behaviour of DWs motion under a polarized current due to the presence of random pinning defects.

We used 40 microns long wires based on [(Co/Pt)/(Co/Ni)]Cu/[(Co/Ni)] spin valves with PMA [2]. A large reservoir allows injecting a single 10nm wide Bloch domain wall into the wires of the free Co/Ni layer. The high GMR ratio of about 1.5% allowed us to detect DW motion in the free layer with high spatial resolution down to 500nm. All experiments are done at room temperature. As seen in Fig. 1(a) for a magnetic field of $H=350$ Oe, the measurement of GMR as a function of time allows tracking spatially DW motion in the free layer along a 40 microns long and 500nm wide wire and determining its velocity.

We first evidenced that the threshold current value to move DWs at zero field is strongly dependent on the DW position in the wire. Also, it is found that it is not possible to move DWs at zero field on large distances (> 1 micron) by injecting a current through the stripe. These features are consistent with the presence of random pinning sites that interact with the single DW during its propagation in the wire. This is clearly seen in Fig. 1(b) where at $H=280$ Oe, a DW undergoes many pinning events (plateaus) followed by steady DW motion (abrupt transitions).

The different duration of pinning events indicates a distribution of pinning fields in the wire. These pinning centres are probably due to intrinsic pinning defects from the virgin films since we have managed to reduce the edge roughness arising from patterning down to a few nanometers. In a previous study [2], we have shown that the threshold current is determined by the pinning force. This explains why the threshold current value depends on the DW position in the wire, i.e., a distribution of pinning fields induces a distribution of threshold currents.

As shown in fig. 2, such a distribution of pinning sites in a 1 micron wide wire is responsible for a very stochastic behaviour under either magnetic field solely or the combination of magnetic field and current. Only current above 7mA (5×10^7 A/cm²) under a magnetic field of $H=300$ Oe are

sufficient to get reproducible DW propagation without any pinning in the 40 microns long wire, but then thermal effects may also contribute.

In conclusion, this demonstrates that in films with PMA the control of the random pinning potential is a key factor to get reproducible steady DW motion and increase the DW velocity. We will also show that irradiation with light He⁺ ions could be an elegant approach to homogenize and control the pinning potential.

Effect of anisotropy distribution on domain wall motion in nanowires with perpendicular anisotropy.

Y. Nakatani¹, T. Ono²

1. Department of Computer Science, University of Electro-Communications, Tokyo, Japan; 2. Kyoto University, Uji, Japan

Spin current-induced domain wall (DW) motion in nano-strips is one of the active subjects, and many works have been reported [1-6]. All of the experimental results with no anisotropy show very large threshold current density for the DW motion (10^{12} A/m²), but the simulation results show the low threshold current density in the wire with perpendicular anisotropy [7]. Because the distribution of the anisotropy can be considered in the real wire, we investigate the effect of anisotropy distribution on domain wall motion in nanowires with perpendicular anisotropy by micromagnetic simulation.

The cross section size of the wire is 280x6nm, and the cell size used in the simulation is 4x4x6nm. The same calculation method is used in [6] except for the anisotropy distribution. The pinning effect of the anisotropy distribution depends on the magnitude distribution and the space size of the fluctuation [8]. The normal distribution is assumed for the distribution of the magnitude. The $m \times m$ (m : block size hereafter) simulation cells are combined and set the same magnitude of the anisotropy to the cells to change the space size.

Figure 1 shows the averaged domain wall velocity $\langle v \rangle$ as the function of the current velocity u in no anisotropy distribution wire. The threshold current velocity is about 45 m/s with $\beta=0$ case, but it can be reduced with 140x6nm wire, because the demagnetizing field acting on the domain wall is small. There are not threshold current with $\beta>0$ case same as the no anisotropy wire case [6].

Figure 2 shows the averaged domain wall velocity as the function of the field and the block size of the anisotropy distribution (standard deviation of the anisotropy is 30%). The pinning field becomes maximum with $m=10$, and very large pinning field (500 Oe), which is the same value obtain by the experiment [9] is realized.

Figure 3 shows the averaged domain wall velocity as the function of the current and the β term. The threshold current is less than half with that of the perfect wire, and the results does not depend on the β term. The domain wall in the strip bends by anisotropy distribution, and the breakdown is occurred from the bend area. The domain wall motion velocity with breakdown only depends on the current velocity [6]. This is the reason why the β term effect is disappeared.

Current-driven domain wall motion, nucleation, and propagation in a Co/Pt multi-layer strip with a stepped structure.

T. Suzuki, S. Fukami, K. Nagahara, N. Oshima, N. Ishiwata
Device Platforms Res. Labs., NEC, Sagami-hara, Japan

Current-driven domain wall (DW) motion in nano-strips with perpendicular magnetic anisotropy is very suitable for spintronics devices such as MARMs because it has the potential to significantly decrease the operation current [1-3]. We have studied current-driven DW motion, nucleation, and propagation in a $[\text{Co}(0.7 \text{ nm})/\text{Pt}(2 \text{ nm})]_8$ multi-layer strip with a stepped structure by measuring the Hall effect with unique placement of via contacts. The strip is $1.68 \mu\text{m}$ long and $0.32 \mu\text{m}$ wide with a 10-nm deep step (Fig. 1), which acts as a pinning site for the DW, and was fabricated by KrF lithography and ion milling. Two via contacts, C_1 and C_2 , for a driving current pulse and a via contact C_3 for a sensing current, which is offset in the y-direction, are attached to the strip. Because the sense current has a y-component, which is vertical to the contacts for the voltage, the magnetization direction in a thin region can be detected by measuring the extraordinary Hall effect (EHE) voltage between C_1 and C_2 with a small sense current from C_3 to C_1 or to C_2 .

The EHE minor hysteresis loop of the strip after the initialization with -3kOe perpendicular field is shown in Fig. 2. Low and high resistances correspond to negative and positive magnetization in the thin region, respectively. The minor hysteresis loop shows asymmetry of field, and this suggests that the mechanisms for the resistance change are different in the positive and the negative one. The resistance increases at a positive threshold field because of a reverse domain nucleation and propagation in the thin region, but the resistance decreases at the negative threshold field because of a DW depinning from the boundary between the thin and thick regions.

The Hall resistance as a function of current pulse amplitude is shown in Fig. 3 for both of the low and high initial resistance states. Here the positive (negative) current was applied from $C_2(C_1)$ to $C_1(C_2)$ with a pulse width of 500 ns, and then we measured the Hall resistance. When the positive current is applied for the high resistance state, the resistance decreases to the low state at +5.5 mA, which seems to correspond to the DW motion driven by spin-transfer torque. However, the resistance increase is observed at -5.5 mA for the low resistance state, which should not have the DW. We applied negative current for the low resistance state and then measured the EHE hysteresis loops, which are shown in Fig. 4. The loop for the -4.8 mA one indicates that the threshold field is smaller than that for the zero current although the resistance change at the current is not so large. This suggests the reverse domain nucleates by the smaller current pulse and propagates by field. Moreover, the similar decrease of threshold field is observed after the positive current is applied for the low resistance state although the resistance does not increase to the high state even at +6 mA. Therefore, we deduce that the nucleation by the current occurs regardless of the polarity of the current, while the propagation of the reverse domain depends on the polarity of the current, and this propagation is related to the spin-transfer torque.

Current-Driven Domain Wall Motion in CoCrPt Wires with Perpendicular Magnetic Anisotropy.

H. Tanigawa¹, K. Kondou¹, T. Koyama¹, K. Nakano¹, S. Kasai¹, N. Ohshima², S. Fukami², N. Ishiwata², T. Ono¹

1. Institute for Chemical Research, Kyoto University, Uji, Japan; 2. Device Platforms Research Laboratories, NEC Corporation, Sagamihara, Japan

Domain wall (DW) motion in magnetic wires by current injection, first predicted by Berger [1], is now investigated extensively [2–7], since in addition to exciting fundamental physics, novel applications based on the current-driven DW motion have been proposed [8–10]. However, we need a high current density of around 1.0×10^{12} A/m² even in the case of very small DW pinning field of several Oe in the absence of a magnetic field [6]. Thus, it is required to explore a new material system from the viewpoint of practical applications. One of the candidates is the wire with perpendicular anisotropy in which the simulation results show the low threshold current density [11]. In this contribution, we report the current-driven DW motion in a CoCrPt wire with perpendicular magnetic anisotropy by means of the magnetic force microscopy (MFM) [12].

Magnetic nanowires were patterned by electron beam lithography from Pt(2nm)/Co63Cr11Pt26(8nm)/Ru(2nm)/Ta(5nm) films deposited on silicon substrates by dc magnetron sputtering. After the formation of a 280 nm wide current channel, a 2 nm surface layer was etched away from a part of the channel. The etched region has the smaller coercive field than the non-etched region, which allows us to initialize the DW position at the boundary of the two regions by an external magnetic field. A magnetic field of 2 kOe perpendicular to the substrate plane was first applied in order to align the magnetization in one direction (Fig. 1(a)). Then, a DW was introduced by applying a magnetic field of -580 Oe to the counter direction (Fig. 1(b)). After that, the MFM observations were carried out in the absence of a magnetic field.

Figure 1(d) shows an MFM image after the DW introduction. The boundary between the etched and the non-etched regions is shown by the vertical white dashed line. The dark contrast in the left part of the boundary corresponds to a downward magnetization, while the bright contrast in the right part corresponds to the upward magnetization, as shown in Fig. 1(b). Thus, Fig. 1(d) shows that a DW is trapped at the boundary. After the DW introduction, a pulsed-current with the current density of 1.3×10^{12} A/m² and the pulse duration of 8.2 μ s was applied through the wire in the absence of a magnetic field, and then the domain structure was observed after each pulsed-current injection. The actual current density in the Co63Cr11Pt26 wire is 1.0×10^{12} A/m² if we take the shunting effect by the Ru/Ta buffer and the Pt capping layers into account.

Figs. 1(e)–1(m) show successive MFM images with one pulse applied between each consecutive image. Current directions are indicated by the horizontal white arrows. DW positions are indicated by the white triangles. The DW always moved opposite to the current direction which is consistent to the DW motion by the spin transfer torque.

We would like to thank Y. Nakatani for valuable discussions. The present work was partly supported by NEDO Spintronics nonvolatile devices project.

Intrinsic threshold current density of domain wall motion in nano-strips with perpendicular magnetic anisotropy for use in low-write-current MRAMs.

S. Fukami, T. Suzuki, N. Ohshima, K. Nagahara, N. Ishiwata

Device Platforms Research Laboratories, NEC Corporation, Sagami-hara, Japan

It has been reported that the threshold current density required to induce domain wall (DW) motion is much smaller for nano-strips with perpendicular magnetic anisotropy (PMA) than for those with in-plane magnetic anisotropy (IMA) [1]. This suggests that current-induced DW motion in PMA strips may have potential for use in low-write-current MRAMs. In this study, we have used micro-magnetic simulation to calculate the threshold current density of DW motion in PMA strips as a function of a number of different parameters, and we have considered the results on the basis of a one-dimensional (1D) analysis. Further, on the basis of the obtained results, we have also estimated the writing properties of MRAMs with DW motion.

We first used a Landau-Lifshitz-Gilbert equation containing spin-transfer torque terms [2] to calculate the intrinsic threshold current density, u_w , which here represents the current density required to keep a DW in continuous motion under the assumption of adiabaticity. Figure 1 shows the threshold current density as a function of strip thickness, width, and magnetization. Threshold current density decreases with decreases in the value of each of the parameters. The decrease that accompanies width reduction below 100 nm is particularly significant. We may also note here that the dependence on width and thickness indicates an excellent potential for write-current scaling. Further, we have confirmed our results using a 1D analytical model. In our 1D model, intrinsic threshold current density, u_w , may be expressed as $u_w = \gamma H_k \Delta / 2$, where γ is the gyro-magnetic ratio, H_k is the hard-axis anisotropy field of the DW, and Δ is the DW width. Obtained analytical values are plotted in Fig. 1, where H_k has been derived by calculating the Walker field, H_w . The results presented in Fig. 1 show good agreement between 2D simulation values and 1D analytical values. This agreement may be attributed to simple magnetic structural changes that occur in DWs in PMA strips during motion, and it is not seen in IMA strips.

We have found that u_w is a good measure for critical current density even in nano-strips with pinning sites. Figure 2 shows the threshold current density, u_{th} , in nano-strips having various individual notch shapes. This variation results in different threshold field, H_{th} , values. Interestingly, u_{th} values in nano-strips having finite H_{th} values are smaller than u_w values and not strongly dependent on H_{th} . We have found that u_{th} is always smaller than u_w except for excessively large H_{th} values, and this is related to a characteristic depinning mechanism in PMA strips in which pinning potential enhances DW break-down. The fact that u_{th} is relatively independent of H_{th} is an advantage in MRAM devices, for which high energy stability is required.

We also estimated critical current density and corresponding critical current values as a function of strip width for various thicknesses and magnetizations, as shown in Fig. 3. We assumed here that polarization, P , is proportional to magnetization, M_s , and that $P=0.7$ when $M_s=800$ emu/cc. We also assumed that u_w approximates DW velocity, v_{th} . The results shown in Fig. 3 suggest the potential for MRAMs with DW motion in PMA strips to replace existing memories [3]. For a width of less than roughly 100 nm, for example, we get $I_{th} < 0.2$ mA and $v_{th} > 20$ m/s.

 1. IEF, Université Paris-Sud, Orsay, France; 2. LPN, CNRS, Marcoussis, France; 3. LPS, Université Paris-sud, Orsay, France

The Diluted Magnetic Semiconductor (DMS) GaMnAs is a promising material. Growing of high quality films is now well controlled, its ferromagnetic nature is quite well understood, and Curie temperature up to 170 K have been reported. As compared to usual ferromagnetic materials, GaMnAs exhibits several interesting features for current domain wall dragging : its magnetization is much lower than usual. What's more, it is possible to work very near the Curie temperature, where domain wall mobility is very high. This is probably why it has been possible to drag domain walls with a much smaller current density than in metals (3 orders of magnitude lower), and GaMnAs appears as a very interesting model system for this kind experiments(1).

Current induced propagation is very different from field induced propagation, one important feature is the fact that the dragging direction doesn't depend on the downstream and upstream magnetization of the domain wall. This has led to propose a new way to store data, called "racetrack"(2) : the tracks don't move, it is the whole domain structure which moves coherently through current domain wall dragging. We report here on experiments carried on perpendicularly magnetized GaMnAs tracks. They show there might be some difficulties to apply the racetracks concept to systems with perpendicular anisotropy.

We have studied propagation of not one single domain wall, but of a whole domain, bounded by a wall upstream and a wall downstream, on a wire of GaMnAs. The wires were made out of a 50 nm thick $\text{Ga}_{0.93}\text{Mn}_{0.07}\text{As}$ film, with $T_C = 130\text{K}$ before patterning(3). To get a perpendicular magnetic anisotropy, a buffer layer of GaInAs was inserted between the GaAs substrate and the GaMnAs layer. The patterning was carried out using e-beam lithography to create a protection mask, and Ion Beam Etching to remove GaMnAs everywhere except on the wires. A bigger pad was also kept at the end of the track to enable easy initial nucleation under magnetic field. The track width was 4 μm and its length was 90 μm . The domain structure was checked using polar Kerr imaging. The magnetic state was always checked in zero applied field and current, current was applied during very short pulses.

The result is presented on figure 1 : one can see that the size of the domain fluctuates and tends to increase during propagation. This increase phenomenon is reproducible. After some pulses, a slight decrease of domain length could sometimes be seen (for example figure 1.2 and 1.3) : we have been able to correlate such a decrease to the presence of a defect in the track. Due to it, the front domain wall is slowed down, and the back wall can catch up with him. But once the wall depinned from the defect, the domain size grows again.

This result can be explained by dipolar interactions between domain walls(3,4). Indeed, these interactions are very strong for films with perpendicular anisotropy. For a single domain, each wall is submitted to two forces (figure 2) : the current-induced one, which is the same for both walls, and the repulsive force due to the other wall. When summing these two contributions, the total force applied on the front wall is bigger than the one applied on the back wall (figure 2). So, the front wall moves faster and consequently the domain size increases.

As a conclusion, we have demonstrated that, due to dipolar interaction between domain walls in tracks with perpendicular anisotropy, the domain structure is modified during current-induced propagation.

Aerodynamic damping on vibration of rotating disks and effects of shroud and top cover.

T. Eguchi

Central Research Laboratory, Hitachi, Ltd., Fujisawa, Japan

This paper experimentally investigated aerodynamic damping for vibration of rotating disks surrounded by a shroud, a top cover, and a base plate.

It was shown that a narrow disk-shroud gap and disk-cover gap causes a large damping effect, and is remarkably effective for suppressing disk flutter vibration of a hard disk drive.

Comparing with squeeze film bearing plate reported by Deeyinyang and Ono, the damping effect caused by the narrow disk-shroud gap is smaller, but it can keep a distance between a disk and an adjacent plate wider and shock tolerance of a HDD better.

This is a great advantage of the narrow disk-shroud gap over the squeeze film bearing plate in terms of applying to commercial hard disk drives.

Experimental setups are shown in Fig. 1.

Frequency response functions (FRFs) measured under vacuum and atmosphere pressures are compared in Fig. 2.

The rotating speed was 9000 rpm (150 Hz), the disk-shroud gap was 0.4 mm, and the top cover was removed in order to place the capacitance probe close to the top disk.

All resonance peaks in the figure are related to normal modes of the rotating disks that appear as disk flutter of a hard disk drive.

These peaks of the disk modes under the atmosphere pressure have more rounded shapes and smaller amplitudes than the vacuum pressure.

Therefore, this figure shows that the air around the disks caused substantial aerodynamic damping effect on the disk vibration.

Hammer tests were performed for various disk-shroud gaps and disk-cover gaps and damping ratios of each the disk modes were computed by using a curve-fit technique.

The results are plotted double logarithmic in Fig. 3-5 by each the disk modes, and can be categorized into four groups.

The first group is the cases that disk-shroud gap was narrower than 0.3 mm, the second group is the cases that disk-shroud gap was wider than 1.0 mm, the third group is an intermediate group between the first and second.

The last group is the cases that disk-cover gap was 0.4 mm.

The results in the last group had very large damping ratios even if the disk-shroud gap was wide.

So, it is likely that the squeeze film damping was working in this group.

In the first and second groups, the results for a certain disk-cover gap were almost on a line respectively.

Solid and dashed lines in the figures represent regression lines for the case that the disk-cover gap was 2.7 mm, and p_1 and p_2 are exponents of the regression expressions.

According to these results, aerodynamic damping was inversely proportional to disk-shroud gap powered by 1.3 to 3 when the disk-shroud gap was narrow, and inversely proportional to disk-shroud gap powered by 0.2 and 0.4 when the disk-shroud gap was wide.

Moreover, another experiments confirmed that the aerodynamic damping effect was independent of the vibration amplitude of the disks.

Therefore, it is thought that the aerodynamic damping effect in the first group came from shear viscosity of the axial flow through the narrow disk-shroud gap rather than dynamic pressure loss.

And, the narrow disk-cover gap improved the effect of the disk-shroud gap.

Adaptive frequency identification method for multiple unknown disturbances in HDDs.

Q. Jia¹, Z. Wang²

1. Storage Mechanics Lab, Hitachi Asia Ltd, Singapore, Singapore; 2. School of Electrical Engineering and Computer Science, Oregon State University, Corvallis, OR

In hard disk drive (HDD) systems, non-repeatable runout (NRRO) disturbances often contains components with time-varying phases and magnitudes at unknown frequencies. To reject the disturbances, the dominant frequencies of the disturbances usually need to be identified first. As the dominant frequencies of NRRO disturbances often vary with read/write head position (from track to track) and operation environment, for example, temperature, on-line identification is required. On-line adaptation is not easy to be implemented in HDD products due to stability and transient convergence issues. One well-used method to estimate unknown disturbance frequencies is adaptive notch filter [1]. For cases with multiple unknown disturbances, when the dominant frequencies are distinct and roughly known, band-pass filters can be applied to each dominant frequency and thus for each frequency, an adaptive notch filter can be designed independently. However, if the dominant frequencies are totally unknown or very close to each other, it is hard to design the adaptive notch filters independently. In [1], adaptive identification method has been introduced for identification of multiple unknown frequencies. However, the method is very sophisticated and hard to be applied practically. In this paper, a new online adaptive identification method has been proposed. The algorithms of the proposed method are much simplified and thus can be easily implemented in practice.

Suppose the disturbance $d(t)$ with 2 unknown dominant frequencies can be expressed as addition of 2 sinusoidal signals:

$$d(t) = A_1 \sin(\omega_1 t + \phi_1) + A_2 \sin(\omega_2 t + \phi_2),$$

where A_i , ω_i and ϕ_i , $i=1,2$, are unknown.

Let the adaptive identifier output $\hat{d}_0(k)$ and identifier error $e(k)$ be

$$\hat{d}_0(k) = 4\hat{d}(k-1) - 6\hat{d}(k-2) + 4\hat{d}(k-3) - \hat{d}(k-4) - T^4 \lambda'_1(k) \hat{d}(k-4) - T^2 \lambda'_2(k) [\hat{d}(k-2) - 2\hat{d}(k-3) + \hat{d}(k-4)];$$

$$e(k) = \hat{d}_0(k) - d(k) = -(\lambda'_1(k) - \lambda_1) T^4 \hat{d}(k-4) - (\lambda'_2(k) - \lambda_2) T^2 [\hat{d}(k-2) - 2\hat{d}(k-3) + \hat{d}(k-4)].$$

T is the sampling time; $\lambda'_i(k)$, $i=1,2$, are the estimates of constant values $\lambda_i(k)$. It can be shown that the adaptive laws based on the gradient algorithm can be designed as:

$$\lambda'_1(k+1) = \lambda'_1(k) + \gamma_1 e(k) \hat{d}(k-4);$$

$$\lambda'_2(k+1) = \lambda'_2(k) + \gamma_2 e(k) [\hat{d}(k-2) - 2\hat{d}(k-3) + \hat{d}(k-4)].$$

γ_1 and γ_2 are adaptation gains. The unknown frequencies ω_1 and ω_2 can be calculated from the estimation values λ'_1 and λ'_2 easily. Although the discussion has been focused on cases with 2 unknown frequencies, the above adaptive method can be extended to identify n unknown frequencies online. The order of the adaptive identifier will be $2n$. The effectiveness of the proposed online adaptive method has been verified by both simulation and experimental studies. Fig.1-2 show the experiment results for applying the proposed method to a 2.5-inch form factor HDD product with 2 dominant unknown disturbances.

From the measured disturbance spectrum shown in Fig. 1, it can be observed that there exist two close dominant frequencies in the HDD system. The adaptive notch filter method can be hardly applied to such kind of HDD systems. The estimated unknown frequencies using proposed online adaptive identification method are shown in Fig. 2. It clearly shows that the adaptive identification process is stable and the transient convergence is fast. The average estimated frequencies are $\omega_1 = 370\text{Hz}$ and $\omega_2 = 529\text{Hz}$, which are exactly the two dominant frequencies shown in Fig.1. Several methods can be applied to attenuate the dominant disturbances based on the identified frequen-

cies. In this paper, adaptive peak filters have been adopted. The position error signals (PES) before and after adaptive attenuation are shown in Fig.3. It is obvious that the dominant disturbances have been significantly attenuated.

Scanning probe microscopy-based data storage (SDS) system is one of the next generation storage devices. Nano scale precision control of SDS stage must be considered to realize the small form factor[1]. SDS stage is fabricated by Micro-Electro-Mechanical System (MEMS), and is the spring-mass-damper system as shown in Fig. 1. The nonlinear effects such as coupling dynamics and parameter uncertainties are the main issues of precision control of SDS stage. In [1], the coupling dynamics are treated as output disturbance and are reduced by the system feedback controller. However, only the feedback controller, it may not be sufficient to reject the output disturbance. Also the parameter uncertainties can arise during the operating time. These problems can be reduced by the enhanced system's sensitivity function.

Disturbance observer (DOB) is known as an effective method to improve the system's sensitivity function. In DOB, the performance and robustness depend on DOB Q-filter. Various methods have been developed to design Q-filter. However, despite all these methods, we still have to determine design parameters of Q-filter for the robustness and performance. Recently, we have proposed robust DOB which is based on robust stabilization and H_∞ loop shaping method[2]. The advantage of this method is that the parameters of Q-filter for the robustness and performance can be determined systematically. In this paper, we apply this proposed DOB to SDS system to reduce the stage coupling and parameter uncertainties. The coprime uncertainty DOB model is shown in Fig. 2. In this figure, Fig. 2(a) can be represented to the equivalent model of a single loop controller of Fig. 2(b). Using this equivalent model, we can design DOB with the desired target loop transfer function by H_∞ loop shaping method[2].

Fig. 3 shows the singular values of the system feedback controller K_x , and its DOB controller, K_{DOB} . These controllers are designed by H_∞ loop shaping method. Fig. 4 shows the experimental results of the sensitivity functions of the closed loop system. The improved sensitivity function is obtained by the proposed DOB. This result indicates that the nonlinear effects of SDS stage can be reduced and the tracking performance can be improved by DOB. Finally the maximum value of the sensitivity function is less than 6dB, the proposed DOB guarantees the robust stability.

A discrete-time modified sliding mode proximate time optimal servomechanism for SPM-based data storage systems.

J. Jeong¹, C. Lee¹, C. Chung¹, Y. Kim²

1. Electrical Engineering, Hanyang University, Seoul, South Korea; 2. Devices & Materials Lab., LG Elite, Seoul, South Korea

The growth rate of data storage density of scanning probe microscope (SPM)-based data Storage (SDS) system has been increased. Thus, access time is one of the key parameters characterizing SDS systems. It is always desirable to minimize the seek time. In Hard Disk Drive, the Proximate Time Optimal Servomechanism (PTOS) was proposed by Workman to reduce chattering problem [1]. The PTOS is robust to model uncertainties, but has slower settling time than time optimal control. To eliminate the common chattering and overshoot problem, variable structure control with sliding mode control, such as Sliding Mode PTOS (SMPTOS) for double integrator system [2] and discrete-time sliding mode control [3], was proposed.

In SDS systems, recently, the Proximate Time Optimal Servomechanism (PTOS) for damped harmonic oscillator model was proposed by IBM [4]. However, this method is difficult to obtain some design parameters satisfying an acceptable overshoot margin both short and long strokes. In this paper, we propose a discrete-time Modified Sliding Mode Proximate Time-Optimal Servomechanism (MSMPTOS). In the proposed method, the convergence rate factor, θ , affects settling time. Fast settling time causes large overshoot, so there is a trade-off between settling time and overshoot in sliding mode control. We applied SMPTOS in SDS systems, but the variable convergence rate factor which is a nonlinear function of position error is used. The convergence rate factor, depending on position error determines the width of unsaturation region. As we use the convergence rate factor varying to position error, the system has the fast settling time with much less overshoot than the previous methods.

Fig. 1 and Fig. 2 illustrate the simulation results of PTOS, SMPTOS and MSMPTOS for the seek operation, where the step input for the X-direction has an amplitude of 35[μ m]. The seek time of the proposed algorithm obtained from Fig.1 is 3.7[ms] which is smaller than 4.4[ms] in PTOS and 4.1[ms] in SMPTOS. Fig. 2 also shows the input voltage signal of PTOS, SMPTOS and MSMPTOS, which is constrained to ± 10 V. The control command of MSMPTOS is similar to time optimal control due to use varying θ rather than PTOS and SMPTOS. Phase portrait of PTOS, SMPTOS and MSMPTOS is shown in Fig. 3. This shows velocity profile of MSMPTOS is faster than PTOS and SMPTOS and it results in fast settling time in MSMPTOS.

Magnetic recording performance of 'Bit Printing method' on PMR media and its extendability to the higher areal density.

A. Morooka¹, M. Nagao¹, T. Yasunaga¹, K. Nishimaki²

1. Recording Media Research Laboratories, FUJI FILM co.,LTD., Odawara, Japan; 2. Production Engineering & Development Center, FUJI FILM co.,LTD., Odawara, Japan

The increase of servo track writing time according to the HDD density and capacity increase is a growing concern of the HDD industry. Servo pattern printing which supports bulk printing of the servo pattern is expected to be the ultimate solution for it(1). There are two printing methods, 'Edge Printing (EP)' and 'Bit printing (BP)' for PMR media. EP method applies horizontal external magnetic field, and its reproduced waveform is not compatible with head writing. On the other hand, BP method applies vertical external magnetic fields, is able to give the waveform like head write. But the experimental result was reported only for micron order bit length pattern(2). This paper describes the BP performance and the extendability to the future high areal density application.

The master with unevenness corresponding to the expected servo pattern is fabricated with lithography, EB-draw and electro plating technique. The magnetic layer of master is made of FeCo sputtered layer. The hard disk is initialized with 10KOe, then master disk is put on the hard disk with uniform contact and the external field is applied toward the opposite direction to the initialization. The reproduced signal was collected using spin stand. The magnetic spacing loss factor was calculated from the experiments with two master disks. One is with 10nm carbon overcoat and the other is without carbon overcoat. It is assumed that the magnitude of the reproduced signal is proportional to bit length and it is inverse proportional to the magnetic spacing. SNR was calculated from S as magnitude of 40MHz and N as integral of magnitude ranging from 0.5MHz to 80MHz. Fig.1 shows the comparison of head writing signal and BP signal at the bit length of 70nm ($\lambda=140\text{nm}$). Even with 70nm bit length, no significant difference between them on the amplitude and the signal shape is observed. This proves the printed pattern has a good magnetic contrast corresponding to the mater pattern.

Fig.2 shows the spacing loss factors of BP. The spacing loss factor of BP is about 8dB at 80nm bit, it is smaller than that of head write recording (3). This is the merit of BP method. We thought this comes from that magnetic printing is static recording method and is not affected by dynamic recording demagnetization. In addition, the mirror effect of media SUL (Soft Under Layer) works not only for head write recording, but also for BP method.

Fig.3 shows the SNR dependency of 100nm bit length pattern on the applied magnetic field normalized with H_c . In the case of BP, SNR has its peak at the point where H_a is close to H_c . Too large H_a over H_c leads to the initialized magnetization flip of the master depression and too small H_a can't print the pattern which corresponds to the master projections. A simulation result leads that ΔH , which is the magnetic field delta between the vicinity of the master projection and depression, is proportional to the applied external magnetic field H_a (4). From these two facts, the media H_c increase to achieve higher areal density allows BP to apply higher H_a , which leads higher ΔH , and it gives better signal quality. The write element of the head has to control the magnetic flux distribution and amount at the same time and it's difficult to provide enough flux at short bite length, while BP controls the flux amount by hard magnet and controls flux distribution by master pattern separately and it is easy for BP to apply large H_a .

BP performance was demonstrated with 70nm bit length. The head writing compatible waveform signal was obtained with enough signal amplitude. The magnetic spacing loss is enough small and

the optimum performance is obtained with the H_a close to media H_c . No significant concern to increase H_a on BP is observed, and BP is suitable for the future short bit length pattern. The authors would like to thank members of Sugita Lab. of Ibaragi University for their productive discussion.

Using steady solutions of Reynolds-Averaged Navier Stokes (RANS) equations to estimate flow induced vibrations (FIV) of hard disk drive carriage arms.

T. Yip, E. Ong, A. Yudhanto, Z. He, Q. Zhang
Data Storage Institute, Singapore, Singapore

Flow induced vibrations (FIV) caused significant positioning errors to hard disk drives (HDD) particularly the higher rpm types. As a consequence, FIV constitutes a significant portion of NRRO budget during the design stage of higher rpm drives. To compute for FIV, the first step of the most common approach begins from a quantitative description of the HDD flow field. From the velocity and pressure fields, the various forms of time dependent forces from the fluid are quantified and apply on the solid surfaces of the HDD carriage arms. By assuming a unidirectional coupling from the fluid forces to the solid carriage arms, the dynamic response of the HDD carriage subjected to complexly distributed three dimensional forces from the high speed fluid could be obtained subsequently. The above method was first reported by Kubotera et al (2002) and subsequently extend to the study of FIV on head gimbals assembly by Shimizu et al (2003). The HDD flow fields were obtained from time dependent solutions obtained from Large Eddy Simulation (LES) as described by Shimizu et al (2001). Abrahamson et al (2006) reported a similar LES/FEA approach towards FIV on disk vibrations. Although there is a good agreement between computed and measured results, one of the conclusion from the investigation was the time required to model and compute LES solutions being overly excessive. As a consequence, such LES approach is of limited practical use as a HDD design tool because computational design of experiments are not permitted. It was suggested that the steady solutions of the Reynolds-Averaged Navier Stokes (RANS) equations may be more appropriate for the purpose because of the economy RANS could offer in time. However, it has to be pointed out that RANS equations yield only ensemble averaged descriptions of flow properties. Instantaneous informations of velocities and pressures had been lost during the time-averaging process. Therefore, the major challenge of employing RANS equations is to reconstruct time dependent instantaneous fluid forces from the time averaged ones obtained from ensemble averaged HDD flow field. In this investigation, time independent ensemble-averaged turbulent fluid forces to act on hard disk drive carriage arms were first estimated from a statistically averaged Reynolds Averaged Navier Stokes (RANS) description of the flow field inside a 3.5 inch format simplified HDD model. Subsequently, by incorporating dominating convective time scales with the turbulent velocity-vorticity interaction terms from the RANS flow field, instantaneous turbulent fluid forces were reconstructed. The corresponding dynamic displacement of hard disk drive carriage arms caused by the estimated instantaneous turbulent fluid forces was computed numerically and validated using a laser Doppler Vibrometer (LDV) experimentally. The proposed FIV code offers tremendous saving in computing time and resources because steady RANS solutions of HDD flow field can be employed instead of time dependent solutions from Large Eddy simulation (LES). Other than computing for weeks and months, estimation of FIV can be expected in just hours or atmost a few days. The new FIV code may potentially be a tool for computational design of experiments of HDD designs. In the present investigation, the RANS description was obtained experimentally with non-intrusive optical measurement using a laser Doppler anemometer (LDA) because experimentally validated RANS solutions from computational fluid dynamics (CFD) of the simplified HDD model were not available during the investigation period. Steady solutions of RANS equation obtained by CFD or via LDA measurements are indifferent to the present RANS/FEA approach. However, experimentally validated CFD

solutions from RANS equations for the present HDD model were not available yet during the investigation.

A Novel Settling Controller for Dual-stage Servo Systems.

J. Zhang¹, C. Du¹, S. Ge²

1. Data Storage Institute, Singapore, Singapore; 2. Department of Electrical & Computer Engineering, National University of Singapore, Singapore, Singapore

The dual-stage servo system is necessary in the future to support 1 Tb/in² and beyond. In this paper, we discuss the unique characteristics of settling controller for dual-stage servo system [1, 2]. An initial error shaping (IES) settling controller is designed to shape the position error signal profile before it is fed into the nominal controller. The proposed method is convenient and suitable for real implementation.

Fig. 1 shows a typical master/slave dual stage servo structure for on-track mode. The seeking can very fast respond to the command due to the boosted high servo bandwidth. The whole system has no obvious slow modes, since PZT is used to compensate the slow modes in VCM loop, but it has relatively large overshoot. Therefore, it is important to achieve a smooth and fast settling to deal with the non-zero VCM states when switching from VCM seeking to dual stage on-track mode. The major initial values of VCM states that need to be considered are initial position y_0 and velocity v_0 . Denote VCM plant as P_v : (A_v, B_v, C_v), and PZT plant as P_m : (A_m, B_m, C_m) with $D_v = 0$, and $D_m = 0$. Then the dual-stage plant is described as (1).

IES for initial position y_0

For initial position value of VCM, it is equivalent to apply a disturbance at the output as shown in Fig. 2. Our objective is to design a feedforward controller $F(z)$ such that the transient due to y_0 is cancelled out. From Fig. 2 we have (2). Obviously, if there is no IES and $F(z)=1$, the transient of PES while settling is the same as the transient of step response of the closed-loop system. To improve the transient of settling, the mode added inside $F(z)$ should be the inverse of the transient of closed-loop system. In other words, the mode added by $F(z)$ should cancel the undesired on-track modes. $F(z)$ can be designed using ZPETC method [3]. Let $B_a(z)$ and $B_u(z)$ respectively include acceptable and unacceptable zeros of $B(z)$, where acceptable zero means that it is within acceptable circle in the pole/zero maps. Ultimately we can have (3).

Note that $B_u^*(z^{-1})$ is the complex conjugate of $B_u(z)$. Therefore, after $(n-m+q)$ step delay, the second part of the above equation is a moving average of a constant y_0 , which means PES is zero after $(n-m+q)$ step delay.

IES for initial velocity v_0

Let $T_v(z)$ be the transfer function from initial velocity v_0 to pes. From Fig.2, we have (4). When $x(t)$ is designed as $x(z) = z^{-(n-m+q)}T_v(z)v_0$, we have (5). Note that $B_u^*(z^{-1})$ is the complex conjugate of $B_u(z)$, therefore, the first part of the above equation is the moving average of $(-T_v(z)v_0)$, which is very close to $-T_v(z)v_0$ due to the fact that it is transient response to slow energy loss stored in VCM. Thus it compensates for the second part.

The simulation results in Fig. 3 and 4 with $y_0 = 0.5$ track show that output settles to on-track very fast (less than 0.2 ms) and with no acoustic problem in control effort. Fig. 5 shows the transient due to $v_0 = 2000$ track/sec. The curve A is without IES compensation, the curve B is with IES compensation. Fig. 6 and 7 shows the settling performance with IES to compensate y_0 and v_0 . Fig. 8 and 9 are experimental results. With IES, the transient due to the initial position is significantly improved. Although the feedforward controller is of higher order, actually the implementation of this controller is much simple. We only need to create a look up table (LUT) to store the compensator output corresponding to unit initial position and velocity. While online compensating, we only

need to multiply the value in LUT with the corresponding initial values and inject into the nominal controller. As we know, the transients for both initial velocity and position are only significant for the first 2 ms. If we use 20 kHz sampling frequency, only 40 points are needed for this compensation. In the future, the simplification and optimal switching condition for this method will be studied.

PES Generation and Evaluation for Bit Patterned Servo.

S. Zhang, W. Wong
Data Storage Institute, Singapore, Singapore

1. INTRODUCTION

With the proposal of bit-patterned-media (BPM) [1] in next generation magnetic recording system, readback signal profile and media noise profile are expected to be much different from that of previous HDD systems. Evaluating the performance of servo pattern with BPM is therefore necessary to help advanced servo controller design as well as head/media design for future HDD systems. In this work, we developed a simulation platform based on 3D analytical read head modeling and BPM media modeling to generate readback signal from bit-patterned-servo. With this platform, media noise due to manufacturing defects [4] and other head/media parameters can be effectively modeled and their impacts on the performance of the PES generation/demodulation are analyzed.

2. PES GENERATION AND PERFORMANCE EVALUATION

The simulation model is based on the widely used reciprocity principle where the details of the modeling process are addressed in [2]. In this work, we target ultra-high density of 1 Tera-bits per square inch (Tbpsi) and above, with a small bit-aspect-ratio (BAR) of 2-4 due to the smallest lithography imprinting feature size.

Amplitude based servo pattern is considered here (full paper will include other servo pattern but omitted here due to size limit of web-submission). Demodulation of PES can be done through either area demodulation or DFT based demodulation [3].

In Fig. 1, we illustrate the simulated readback signal from a bit-patterned-servo (BPS) pattern. The readback signal at the track center resembles a waveform commonly seen in amplitude servo pattern. From the 3D readback signal plot it is clear that the signal amplitude drops nonlinearly when the read head moves from the center of the island outwards. This suggests the need of a mapping function that translates the raw PES to the offtrack position of the read head in such system.

In Fig. 2, it shows that the larger the BAR the better the resolution of PES, as well as steeper the curve transitions. Lower density has similar advantage over higher density as shown in Fig. 3. In other words, wider track pitch for the same read head means sharper transition at the servo bursts edge.

In Fig. 4, we compare the PES demodulation noise at different additive white Gaussian noise (AWGN) level. By comparing Fig. 5 with Fig. 4, we can see that 5% island position jitter has roughly the same destructive effect of AWGN in 15dB SNR. This is roughly equivalent with 5% size fluctuation as shown in Fig. 6. These observations and further results maybe used as guidance for manufacturer on the maximum media noise a system can tolerate. But unlike transition jitter noise in conventional continuous media, these media noise are fixed once the media is manufactured and can be dealt as repeatable run out (RRO) instead of non-repeatable run out (NRRO).

3. CONCLUSION

With the help of the 3D analytical signal model for BPM, we can generate readback signal for arbitrary sets of head/media parameters. Servo signal is generated based on this model for bit-patterned-servo. Effects of media noise on PES demodulation noise is analyzed using this platform and useful information on servo design can be obtained from this analysis.

Mean-Adjusted PDNP Detector for Perpendicular Recording Channels With NLTS.

Z. Wu¹, P. H. Siegel¹, J. K. Wolf¹, N. Bertram^{1,2}

1. Center for Magnetic Recording Research, University of California, San Diego, La Jolla, CA;

2. Hitachi Global Storage Technologies, San Jose, CA

In high density perpendicular magnetic recording channels, nonlinear transition shift (NLTS) is one of the distortions that can degrade the system performance. Write precompensation is a standard method used to offset the negative effect of NLTS. In this paper, we propose a modified pattern-dependent noise predictive (PDNP) detection algorithm for use on channels with electronics noise, transition jitter noise, and NLTS. We show that this detector can offer significant improvement in bit error rate (BER) compared to conventional Viterbi and PDNP detectors. Moreover, the system performance can be further improved by combining the new detector with a simple write precompensation scheme.

PDNP detectors have been shown to reduce the BER in recording channels with data-dependent media noise and correlated additive Gaussian noise by incorporating pattern-dependent noise prediction into the branch metric computation of the Viterbi algorithm [1][2]. We introduce a “mean-adjusted” PDNP (MA-PDNP) detector that also takes into account the effect of NLTS on the mean and covariance of the channel noise. Equation (1) of Fig. 1 gives the modified branch metric of the proposed detector for a trellis branch e_k at time k . In the equation, r_j denotes the equalized readback sample at time j , while $y_j(e_k)$, $j=k-L_y, \dots, k$ denote the noiseless channel output samples. The noise variance $\sigma^2(e_k)$, noise prediction coefficients $p_i(e_k)$ and noise means $m_i(e_k)$ corresponding to branch e_k are all data-dependent and may differ from branch to branch.

In our performance simulations, we use the channel model described in equation (2) of Fig. 1. The channel output signal, $z(t)$, incorporates a second-order approximation of the error-function transition response, $s(t)$, whose first and second derivatives are denoted by $s'(t)$ and $s''(t)$, respectively. For the i th transition, d_p , the net transition shift, δ_p , incorporates both NLTS as well as write precompensation (if any), and the random transition jitter, denoted a_p , is assumed to be a Gaussian random variable, independent from transition to transition, with variance σ_f^2 . The contribution of AWGN is represented by $n_w(t)$.

As with PDNP detection [2], there are several ways to derive from the MA-PDNP detector a variety of simpler, yet still effective detectors. Strategies for reducing detector complexity include lowering the prediction filter length L_y , limiting the required number of predictors by shortening the data-dependence length L_x , and eliminating trellis states by using feedback of tentative decisions. Our error-rate simulations used PDNP and MA-PDNP detector trellises with the same number of states as the conventional Viterbi detector. The data-dependence range of the noise predictors was set to $L_x=6$.

Performance results for the MA-PDNP detector are shown in Fig. 2. The simulated system uses a 3-tap equalizer target and an MMSE monic-constraint equalizer design. The channel density and normalized jitter-noise standard deviation are $T_{50}/B = 1$ and $\sigma_f/B = 0.1$, respectively, where B is the channel bit spacing. The signal to noise ratio is defined as $SNR_w = 20 \log(V_{max}/\sigma_w)$, where σ_w is the standard deviation of the sampled white Gaussian noise. Fig. 2(a) shows that the MA-PDNP detectors with prediction filter lengths $L_y=0, \dots, 3$ are all superior to both the Viterbi detector and the PDNP detector with $L_y=3$. We note that for SNR_w equal to 23dB and 26dB, the BER of the MA-PDNP detector does not depend upon L_y over the range of values considered.

The MA-PDNP detector can be used together with any write precompensation scheme. Fig. 2(b) shows that the system performance can be improved by combining the new detector with simple

dibit precompensation. We see that, with large enough L_y , the combined scheme achieves the same performance as a PDNP detector applied to a channel with no NLTS. This is true over a wide range of precompensation values.

Ordered statistics soft decoding of Reed-Solomon codes over intersymbol interference channels.

F. Y. Lim, A. Kavčić, M. Fossorier
University of Hawaii, Manoa, Honolulu, HI

Ordered Statistics Decoding (OSD): The aim of this paper is to implement and test OSD techniques [1,2] over intersymbol interference (ISI) channels. For any $[n,k]$ block code, the principle of OSD is to process low-weight (sparse) error patterns in the k most reliable basis (MRB) positions. However, in ISI channels, the errors in the MRB are observed to consist of sparse error-events (not bit errors). Consequently, an efficient technique needs to process error-events that may occur in the MRB.

Improvements for ISI channels: We define the most-likely path as the (uncoded) signal sequence with the largest likelihood, out of all possible 2^n binary sequences. For any two sequences, the positive difference between their Euclidean distances to the received sequence will be termed the metric difference. The problem of implementing OSD for ISI channels can now be restated as processing error-events with different supports in the MRB in order of increasing metric differences. To reduce the implementation complexity, we do not use the Generalized Viterbi Algorithm [3], which sorts all 2^k possible paths in terms of increasing metric difference, but rather, our proposed solution is a modification of Battail's algorithm [4] which solves a related problem in memoryless AWGN channels.

Battail's Algorithm: We briefly review Battail's algorithm [4], which constructs k lists of low weight error patterns over the k MRB positions. Conceptually, the algorithm orders the error patterns in k FIFO lists. Every error pattern is associated with a unique parent error pattern, and the parent has a lower discrepancy [1,2] than any of its children. New error patterns are added for future processing only after the parent has been processed. Using this approach, the lists have been observed to grow quite fast, but Valembos, et al. [4] proposed a solution that involves introducing an additional list to overcome this problem.

Modification for ISI Channels: We create $n \times S$ lists, where S is the state size of the ISI channel trellis. Using the Soft-Output Viterbi Algorithm [5], we compute and store, for every time instant and every state, the corresponding path difference and error event. We now use Battail's algorithm to process and combine error events (rather than single bit errors). If an error event includes MRB positions, we process it by computing the corresponding codeword and its likelihood. The algorithm is stopped when a pre-determined number of codewords has been processed. Out of all the processed codewords, the most likely is chosen and returned as the decision.

To make the search more efficient, we combine error events only if the errors occur in the MRB positions. We call an error event complete if it diverges from the same state as the most-likely path, and incomplete otherwise. The structure of Battail's algorithm guarantees that all error events of interest are processed if the following rules are followed:

1. Incomplete error events that do not contain MRB positions are discarded.
2. A complete and incomplete error event are combined only if they are not disjoint (e.g. Type I, II).
3. Two complete error events are combined only if both occur in the MRB.

Simulations: We experimented on the perpendicular recording $(1 + D)^2$ ISI channel, for the standard (255,239) Reed-Solomon code binary image. We processed 2 million error patterns, which is approximately $O(n^2)$, thus a similar list size as OSD(2) processing [1]. The performance is compared to that of a "bit" Chase decoder, and the message passing (iterative) decoder proposed by

Bellarado-Kavcic [6] for RS codes (which performs similarly to the Jiang-Narayanan iterative decoder [7], but at much lower complexity). We also show the performance of a similar complexity OSD-based decoder (BMA(2, 22) [2]), that was demonstrated to give a 1.5 dB gain on the AWGN channel over HDD. On the ISI channel, our decoder achieves approximately 1 dB gain over HDD, and the BMA only achieves a 0.5 dB gain. The iterative decoder [6,7] performs similarly as the BMA, giving a 0.45 dB gain. The gains of both the new decoder and the BMA come with the cost of $O((1 - R)n^3)$ complexity over GF(2) due to the required Gaussian elimination.

Enhanced Message Passing in Turbo Product Code.

N. Yeh¹, P. Steiner¹, Y. Li^{1,2}

1. Seagate Technology, Fremont, CA; 2. Presently with AMD, Yardley, PA

Introduction:

Iterative code has been shown to provide significant performance advantage but may be slow to converge and even exhibit a residual error floor. It is proposed in this paper to improve the performance of turbo product code with single-bit parity check (TPC/SPC) [1] by adding cyclic redundancy check (CRC) to the sub-blocks. A sub-block can be ensured error free after it passes both the parity check and CRC. At the completion of each iteration, the message from the error free sub-blocks can be modified to greatly increase its confidence level. The artificially high confidence level from those error free sub-block bits results in much more efficient iterations subsequently and greatly lowers the error floor.

Enhanced Message Passing:

Passing the parity check in TPC/SPC does not guarantee the sub-block to be error free since four error bits sitting on a rectangular grid does not cause any parity violation. Additional CRC is required to ensure a sub-block to be free of errors. When all the bits in a sub-block are correctly decoded, the log-likelihood ratio of these bits can be increased to $+\infty$ and $-\infty$, respectively, as shown in Fig. 1. These sub-blocks will have all the bits assigned to the correctly decoded values without going through further local iterations. The artificially high log-likelihood ratios from these bits after interleaving would have good influence on the adjacent bits in soft Viterbi algorithm (SOVA) decoder. It is equivalent to pruning the trellis when there is a definite "0" or a definite "1" as illustrated in Fig. 2. This enhanced message passing enables much more efficient iteration and faster convergence.

Results:

Bathtub curves were measured from high-density head/media on spindles with on-track first-pass SOVA BER about 10^{-2} . Waveforms were captured and processed through software TPC/SPC channel. A data sector of 512 bytes including CRC is divided into four sub-blocks each with 32×32 bits. The sub-block is encoded to 33×33 bits after adding parity bits. The bits from all the four sub-blocks are interleaved, serialized and recorded onto the disk. It was found that CRC combined with the noise prediction maximum-likelihood (NPML) detection in SOVA [2] gives the best performance. With simultaneous application of NPML and CRC, the burst error profile is greatly improved (Fig. 3) and the residual error floor is brought down well below $\text{BER}=10^{-9}$ (Fig. 4). Incremental enhancement of message passing and NPML is plotted in these figures to demonstrate the algorithm capabilities.

Summary:

Enhanced message passing opens opportunities for additional performance gain from traditional TPC/SPC. Application to magnetic recording would allow continuing advancement of areal density in the future.

A New Burst Detection Method Using Parity Check Matrix of LDPC Code for Bit Flipping Burst-like Signal Degradation.

Y. Nakamura¹, M. Nishimura¹, Y. Okamoto¹, H. Osawa¹, H. Muraoka²

1. Graduate School of Science and Engineering, Ehime University, Matsuyama, Japan; 2. RIEC, Tohoku University, Sendai, Japan

I. Introduction

Low-density parity-check (LDPC) coding [1] and iterative decoding system with a burst detector has the resistance to the burst-like signal degradation due to detectable media defects. There is a possibility that the undetectable signal burst called bit flipping gives the fatal influence on the LDPC coding and iterative decoding system with the conventional burst detector using a reproducing waveform, an equalizer output, an a posteriori probability (APP) decoder output and so on [2]. We propose and evaluate a new burst detection method using a check matrix of LDPC code for the bit flipping media defects under the long sector format of 4096 Byte/sector.

II. R/W channel

Fig. 1 shows the block diagram of an R/W system. In this study, we assume that a sector of user data sequence consists of 4096 Bytes. The 128/130(0, 16/8) RLL code and the regular(22, 3) LDPC code are employed. We assume the bit flipping of the length L_{flip} , normalized by user bit interval as the undetectable burst-like signal degradation, which is functionally equivalent to flipping the recording sequence as shown in the figure. We also assume a perpendicular magnetic recording (PMR) channel with a hyperbolic tangent isolated waveform [3] at a linear density of $K = 1.5$ defined as the transition width T_{50} normalized by user bit interval. The noise at the reading point is composed of a jitter-like medium noise and a system noise with power ratio of 8:2. The equalizer is adjusted so as to convert the bit response of R/W channel into a PR1 characteristic [4]. The APP decoder has an autoregressive (AR) channel model as a channel estimator [5]. The iterative decoder consists of an APP decoder and a sum-product (SP) decoder. In this study, we set the iteration limits in the SP and iterative decoders to 5. The burst detector detects the position and length of the bursts by using parity check matrix of the LDPC code. Our proposed burst detector obtains the burst information for iterative decoding from the parity check results of LDPC code. The detector checks whether an error has occurred in each row by parity check, and makes the error flag sequence by the sum of the check results. The error flag sequence consists of "0", "1", "2" and "3" if the column weight is three. The burst information is made by the threshold decision after the moving average of the error flag sequence. The SP decoder decodes the recorded sequence using the constraint of LDPC code from LLR with the burst information by controlling the amplitude of LLR not to cause error propagation due to the burst-like signal degradation. After the given iterations, the output data sequence is recovered by the hard decision and the RLL decoding.

III. Performance comparison

Fig.2 shows the relationship between L_{flip} and the required SNR to achieve the error free detection for about 10M bit sequence. The symbols circle, triangle and square show the performance of LDPC coding and iterative decoding system with the proposed burst detector (LDPC-PCBD), the LDPC coding and iterative decoding system with the conventional burst detector (LDPC-BD) and the erasure correcting system using Reed-Solomon (RS) code (RLL-RS-EC), respectively. As can be seen from the figure, the LDPC-PCBD system shows the better performance and has the resistance to a bit flipping signal burst of about 1500 bits.

IV. Conclusion

We have proposed and evaluated a new burst detection method using a check matrix of LDPC code for the bit flipping signal bursts under a long sector format of 4096 Byte/sector. The results show that the LDPC coding and iterative decoding system with the proposed burst detector shows the better performance and has the resistance to a bit flipping signal burst of about 1500 bits.

Low-Complexity LDPC Decoder Architecture for High-Speed Magnetic Recording.

C. Zhang^{1,2}, Z. Wang³, L. Li^{1,2}, J. Lin^{1,2}, M. Gao^{1,2}

1. Institute of VLSI Design, Physics Department, Nanjing University, Nanjing, China; 2. Key Laboratory of Advanced Photonic and Electronic Materials, Nanjing University, Nanjing, China; 3. School of Electrical Engineering and Computer Science, Oregon State University, Corvallis, OR

Low Density Parity-Check (LDPC) code has been considered in magnetic recording for its outstanding error correcting capability. Recently *shift*-LDPC code structure [1] was proposed for low-complexity high-speed implementation. It was shown in [2] that a 8192-bit LDPC decoder chip in 0.18 μm CMOS technology can achieve over 5Gb/s throughput at 15 iterations with only 11.3 mm^2 . In this digest, algorithmic transformations are employed to further reduce the complexity of LDPC decoder

The parity check matrix of a regular (N, M) (c, t) *shift*-LDPC code consists of $c \times t$ submatrices, where P is a $L \times L$ permutation matrix. In each clock cycle, the column process and the row process are interleaved. One iteration can be finished in t clock cycles. Using Min-Sum algorithm for *shift*-LDPC code has led to significant memory reduction compared with using Sum-Product algorithm as demonstrated in [1]. In this work, we will introduce 2 algorithmic transformations to further reduce overall hardware. The first one is single minimum scheme, which only requires the single minimum value of all inputs in the check node process [1]. This modified algorithm is provided in Fig. 1. The second one is a non-uniform quantization scheme. Specifically 5-bits are considered per soft message to achieve comparable decoding performance to that using 6-bit per message in the prior design. Table 1 shows how to convert between 6-bit uniformly quantized messages and 5-bit non-uniformly quantized messages. The non-uniformly quantized messages are directly used in Check node Processing Units (CPUs), which find only the minimum values. While in Variable node Processing Units (VPUs), both the expansion and compression blocks are required. Simulation results for a regular $(8192, 7168)$ $(4, 32)$ *shift*-LDPC code is shown in Fig. 2. It can be observed that the proposed Min-Sum algorithm achieves slightly better performances than that with (6:3) uniform quantization scheme.

Based on the non-uniform quantization scheme, the expansion block and the compression block can be easily derived. The overhead of the part of logic is small. Due to the reduced wordlength, the routing complexity and memory usage will be significantly decreased. Fig. 3 shows the structures of CPU and VPU. The proposed *shift*-LDPC decoder has been synthesized in SMIC 0.18 μm CMOS technology, using Synopsys Design Compiler. The implementation results in Table 2 show that compared with [2] the proposed design saves 14.2% area with the same throughput. And the new design has big advantages in both throughput, and hardware cost over the one presented in [3] targeting for magnetic recording.

Abstract

For higher density perpendicular magnetic recording systems, it is hard to expect improving the performance any more by using only NPML. We exploit serial concatenated system with channel detector and recursive systematic convolutional (RSC) code decoder using message-passing algorithm and evaluate the performance on the perpendicular magnetic recording channel.

1. Introduction

As the density of perpendicular magnetic recording system is getting higher the storage capacity of hard disk drives is increased. However, the higher bit density causes the degradation in signal-to-noise ratio (SNR). Kurkoski and et al. proposed the joint message-passing detector with LDPC code[1]. In this paper, we apply the joint message-passing algorithms between channel detector and recursive systematic convolutional (RSC) code instead of the LDPC code for the simplicity. Furthermore, we even use the max-log method[2] for reducing the complexity. The proposed algorithm is applied to perpendicular magnetic recording (PMR) channel with jitter noise, and we investigate the performance.

2. Perpendicular magnetic recording channel

In PMR channel, the signal-transition step response can be approximated as follows[3].

$$g(t) = \text{Atanh}(2t/(0.597\pi T_{50}))$$

where A is the maximum amplitude of $g(t)$ and T_{50} is the required time to go from $-A/2$ to $+A/2$. The normalized recording density is $K=T_{50}/T_b$, and T_b is the recording bit interval. Then, the read-back signal response can be modeled as follows.

$$r(t) = \sum_{k=-\infty}^{\infty} a_k [g(t-kT) - g(t-(k+1)T)] + n_w(t) + n_j(t)$$

where $n_w(t)$ and $n_j(t)$ are AWGN and jitter noise, respectively.

3. Joint Message-Passing Detector with RSC Decoder

The message-passing algorithm is a state-based parallel algorithm. We propose the joint message-passing detector/decoder for reducing the calculation delay and apply the max-log approximation for low calculation complexity. Fig.1 shows the block diagram of the proposed system using the message-passing detector/decoder and a random interleaver(Π). The channel detector uses the PR(12321) target and $1/(1+D^2+D^3+D^5)$ precoder. The RSC code has the generator polynomial of $(31,23)_8$.

4. Simulation Result

The user bit density (UBD) for simulation is $D=1.7$. The normalized recording density is $K=UBD/R$, where R is the code rate of $0.945(=4096/4336)$. Fig. 2 shows the performance with 80% jitter noise and 20% AWGN on the PMR channel when we do the precoding or not. The precoding channel performs 1dB better than non-precoding channel at 10^{-5} BER. Fig. 3 shows the performance that there is 100% AWGN on the PMR channel. We can see that the precoded channel performs 1dB better than non-precoding channel at 10^{-5} BER. As usual, we can notice that the channel iteration improves the decoding performance in both of the precoding and non-precoding cases.

5. Conclusion

We have presented the joint message-passing detector/decoder reducing calculation delay and complexity. The precoding case performs 1dB better than the non-precoding case when there is jitter

noise or not. The joint message-passing detector/decoder scheme with one channel iteration performs 1.8dB better than the NPML in PMR channel.

A. Overview

Quasi-cyclic LDPC (QC-LDPC) codes can achieve very low sector failure rate with very high code rate [1-3] in magnetic recording channel. Conventionally, the switching network of a QC-LDPC decoder is implemented with barrel shifters [3], which generally consume a significant portion of silicon area for high-speed QC-LDPC decoder. Shift matrix structure is much simpler as it can be implemented with one-stage of multiplexer array. However, it is not applicable to general QC-LDPC codes.

In this work, matrix permutation and column grouping schemes are employed to convert the H matrix of a (generic) QC-LDPC code into a shift matrix hence to reduce the implementation complexity for high-speed QC-LDPC decoder. Based on shift matrix structure, we developed an optimized QC-LDPC decoder architecture which employs shuffled message scheduling (proposed by Zhang and Fossorier) to increase decoding converge speed. In this way, only one copy of compressed check-to-variable (C2V) messages is needed and variable-to-check message (V2C) are used on-the-fly. Thus, the VLSI implementation cost of this design is significantly lower over the prior art [3], which used two copies of C2V messages.

B. Matrix Transform

It can be proved that for any no cycle-4 quasi-cyclic LDPC code whose H matrix contains only cyclic shifted identity submatrices and zero submatrices, its H matrix can be converted into a form such that, 1) each submatrix in one block row (denoted as block-row-0) contains only one non-zero row; 2) the block column $i+1$ is a one-step cyclic shift of the block column i ; and 3) each submatrix in any block column (except for the submatrices in the block-row-0) has a row weight of at most one. Fig. 1a shows the permuted H matrix of a QC-LDPC code example. To enable high parallelism, the matrix can be arranged as shown in Fig. 1b.

C. Decoder Architecture

We will illustrate the design with the matrix shown in Fig. 1b. The decoder architecture is shown in Fig. 2. Only one copy of compressed C2V messages (i.e., the smallest magnitude, Min1, the second smallest magnitude, Min2, the index of Min1 and all signs) is stored. The R-mem and R-regs are storage components for C2V messages corresponding to the first block row and other block rows of the matrix, respectively. De-comp/pDe-comp units are used to completely/partially recover original C2V messages. The left and right connection networks are hardware mapping of the edges in tanner graph corresponding to the first block column of the matrix shown in Fig. 1b. A parallel check node unit (CNU), P-CNU, get all input messages in parallel. A recursive CNU, R-CNU, get one or two input messages per clock cycle. Because the proposed matrix transform method minimize the (maximum) row weight (except block-row-0) of a block column, the number of input messages to R-CNUs per cycle is minimized. This helps maximize clock speed and minimize implementation complexity of R-CNUs. P-CNUs are pipelined to match its critical path with that of R-CNUs.

In summary, the shift characteristic in H matrix of generic QC-LDPC has been maximally exploited and the switching network is implemented with very simple one-stage multiplexer array. The matrix permutation method also enables high clock speed and minimizes implementation complexity of CNUs. Shuffled message scheduling is embedded to increase converge speed. Compared

to the prior art [3], more than 30% of storage components can be saved and much higher throughput is expected.

Perpendicular Magnetic Recording Channel Model : Perpendicular magnetic recording (PMR) scheme is a technology for achieving high magnetic recording density beyond the super-paramagnetic limitation. The PMR system with a single-pole-type (SPT) head provides a practical approach for high-density hard disk drives [1]–[3]. Signal processing techniques play an important role in achieving high-density PMR systems. This paper focuses on equalization techniques of the PMR channels. The mathematical models of the PMR channels in [4], [5] are considered in simulation experiments of this paper.

Equalizer Based on Gaussian Sum Approximations : In this paper, we apply and formulate the Gaussian sum approximation (GSA) in [6], [7] into the PMR channel equalization problem and propose a GSA-ML P equalizer. The proposed GSA-ML P equalizer is a bank of conventional linear filters based on the state and measurement equations for the Kalman filter. In addition, we extend the GSA-ML P equalizer by modifying the state equation for the GSA-ML P equalizer, which is called the GSA-DS-ML equalizer. The GSA-ML P and GSA-DS-ML P have a filter bank with 2^P conventional linear equalizers where P is an integer and combine each output based on the GSA in [6], [7]. The GSA-DS-ML P equalizer uses the information on the previous detected symbol.

Simulation Results : Fig. 1 shows the bit-error-rate (BER) curves for the minimum mean square error (MMSE), Kalman, GSA-ML P and GSA-DS-ML P equalizers and the maximum likelihood sequence estimator (MLSE) bound when the normalized channel density is $K=1.6$ and the additive white Gaussian noise (AWGN) is considered. The simulation results are omitted when there is the transition jitter noise in the PMR channel model in addition to the AWGN. The proposed equalizers show the better BER performances than the other linear equalizers. The GSA-ML and GSA-DS-ML approaches a BER performance of the MLSE as P increases. Fig. 2 shows the required signal-to-noise ratio (SNR) to obtain the BER of $1.0E-3$ for each equalizer when $K = 1.6$ to 1.9 .

Conclusion : In this paper, GSA-ML and GSA-DS-ML equalizers in order to enhance the performance of the conventional linear equalizers are proposed. Through simulation experiments it was found that the proposed equalizers are capable of augmenting the BER performances of the other linear equalizers and approach the BER performances of the MLSE as the number of the filter in the bank increases.

Introduction

The generalized partial response (GPR) channel represented by the transfer polynomial with the noninteger coefficients consists of the PR channel followed by a noise whitening filter which subtracts the noise predicted by the previous noise samples from the output noise of PR channel. In this work, a new constitution method of the simplified neural network equalizer (NNE) with the noise whitening function for the GPR channel is proposed. The long-term bit error rate (BER) performance of GPR class-I maximum likelihood (GPR1ML) system based on the NNE in perpendicular magnetic recording (PMR) with thermal decay is also obtained by computer simulation using our thermal decay model [1].

R/W channel

Fig.1 shows the block diagram of GPR1ML system with NNE. The rate 128/130(0,16/8) code is employed as a run-length-limited (RLL) code. The isolated transition response is assumed to be $h(t) = A \tanh(\ln 3 / T_{50}) t$ where A is the saturation level and T_{50} is the $-A/2$ to $A/2$ rise time. Here, a normalized linear density is defined as $K = T_{50} / T_b$ where T_b is a user bit interval. The reproducing waveform is generated by using the thermal decay model for a CoPtCr-SiO₂ PMR medium with $K_u V / kT = 60$ [1]. It is also assumed that the noise at the reading point consists of an AWGN and a jitter-like medium noise whose power ratio in a bandwidth of $0.6f_b$ is $\sigma_w^2 : \sigma_j^2$ where f_b is a user bit rate. The SNR at the reading point is defined as $20 \log_{10} A / \sigma$ [dB] where $\sigma^2 = \sigma_w^2 + \sigma_j^2$ is the total noise power and the percentage of the jitter-like medium noise power to the total noise power as $R_f = \sigma_j^2 / \sigma^2 \times 100$ [%]. The high-pass filter (HPF) represents the low cut-off characteristic due to AC coupling in a head amplifier which has a normalized low cut-off frequency x_l by f_b . The PR channel response is equalized to a required PR1 target by NNE which consists of a low-pass filter with a normalized high cut-off frequency x_h by f_b and a three-layered neural network [2]. The GPR1 channel output is obtained by subtracting the output of M th-order noise predictor from PR1 channel output.

Neural Network Equalizer

The neural network having 13-7-1 neurons for the input layer, hidden layer and output layer, respectively, and 98 connections between neurons is assumed. Then, the simplification by thinning out the connections and the noise-whitening are performed by finding the optimal weights of connections based on a hybrid genetic algorithm (HGA) which is the combination algorithm of GA [3] and back-propagation algorithm (BPA) [2]. In HGA, a chromosome of individual is given as a sequence of 98 weights of connections in the neural network. Forty individuals are arranged according to the value of the fitness which is defined as the weighted sum of the negative logarithm of BER of GPR1ML system and the ratio of the initial number of connections to the current number of connections. Here, the prediction coefficients of the noise predictor in GPR1ML system are obtained by using the Levinson-Durbin Algorithm [4] from the autocorrelation function of output noise in the previous-generation NNE. In the current generation, the genetic operations [3] based on the fitness for the GPR1ML system which consists of the previous-generation NNE and noise-whitening filter are performed on the individuals, and then BPA is done where the ideal PR1 response sequence is employed as the desired signal in supervised learning. The next-generation NNE is obtained by rearranging the individuals in descending order of the fitness. These operations are

repeated until the fitness of the best individual saturates. The chromosome of this best individual gives the desired weights of the neural network where the connections with a weight of 0 which is brought by the mutation are thinned out.

Results and Discussion

Fig.2 shows the relationship between the BER performance of GPR1ML system and the elapsed time t_E where $K=1.5$, $x_h=0.4$, $x_l=0.001$, SNR=24.5dB, $R_f=90\%$ and $M=3$. The symbols \circ , \triangle and ∇ indicate the performance of GPR1ML system having a simplified NNE with the 11-3-1 neurons and 25 connections, GPR1ML system having a conventional transversal filter (TF) with the number of tap $N_t=15$ and PR1ML-NNE, respectively. The PR1ML-NNE does not need a noise whitening filter because the NNE based on the proposed method can equip the noise whitening function. The performance of GPR1ML-NNE system is superior to that of GPR1ML-TF system. The PR1ML-NNE system having a two-state Viterbi detector provides the almost equivalent performance to that of GPR1ML-NNE having a 16-state detector.

Digital Storage Channel Equalization Using A Bilinear Recursive Polynomial System.

S. Choi¹, H. Cho¹, G. Kong¹, J. Lee³, J. Lee²

1. School of Electrical and Electronic Engineering, Yonsei University, Seoul, South Korea; 2.

School of Electronic Engineering, Soongsil University, Seoul, South Korea; 3. Storage System

Division, Samsung Electronics, Suwon, South Korea

Motivations : As recording density increases in digital storage systems, distortions are severer. Therefore, more powerful signal processing techniques are essentially demanded. A new nonlinear equalizer based on a bilinear recursive polynomial (BRP) system is introduced and investigated for magnetic channel equalization in this paper.

System Model : To achieve high magnetic recording density beyond the super-paramagnetic limitation the perpendicular magnetic recording (PMR) technique is a promising scheme. For high-density hard disk drives (HDD), the PMR system with a single-pole-type head is considered as a practical approach [1]–[3]. In this paper, we consider the mathematical models of the PMR channels in [4],[5] to conduct simulations for performance comparisons.

Equalizer based on a Bilinear Recursive Polynomial System (BRP) : Fig.1 shows the simplified digital transmission system with the BRP equalizer. The BRP equalizer uses the noisy channel output as well as the 2nd order informations from the noisy channel symbols and the detected symbols as shown Fig. 1. Therefore the proposed BRP equalizer has a form of a recursive structure.

Simulation Results : The bit error rate(BER, bit error probability) performance of the proposed BRP equalizer is compared with the minimum mean square error (MMSE) and Kalman equalizers and the maximum likelihood sequence estimator (MLSE) bound. The Kalman equalizer also has a recursive structure. Fig. 2 shows the bit-error-rate (BER) curves for the minimum mean square error (MMSE), Kalman, and proposed equalizers and the MLSE bound when the normalized channel density is $K=1.6$ and the additive white Gaussian noise (AWGN) is considered. The simulation results are omitted when there is the transition jitter noise in the PMR channel model in addition to AWGN. The proposed equalizers show the better BER performances than the other linear equalizers. Fig. 3 shows the required signal-to-noise ratio (SNR) to obtain the BER of $1.0E-3$ for each equalizer when $K = 1.6$ to 1.9 . The proposed BRP equalizer provides about 20dB and 10dB of gain over the MMSE and Kalman equalizers at the BER of $1.0E-3$ when $K = 1.9$, respectively.

Conclusion : In this paper, the BRP equalizer in order to enhance the performance of the conventional linear equalizers is proposed. Through simulation experiments it was found that the proposed BRP equalizer with a moderate complexity is capable of augmenting the BER performances of the other linear equalizers.

Interleaved Modified Array Codes (IMAC) Hardware Design and Performance for High-Rate Perpendicular Magnetic Recording Systems.

P. Leekul^{1,3}, W. Singhaudom¹, P. Supnithi^{1,2}

1. Faculty of Engineering, King Mongkut's Institute of Technology Ladkrabang, Bangkok, Thailand; 2. Data Storage Technology and Applications Research Center (D*STAR), King Mongkut's Institute of Technology Ladkrabang, Bangkok, Thailand; 3. Research Center for Communications and Information Technology (ReCCIT), King Mongkut's Institute of Technology Ladkrabang, Bangkok, Thailand

Modified Array Codes (MAC) is a structured low-density parity-check (LDPC) code with parity-check matrix described in terms of the parameter (p, j, k) , where p is prime and $j \leq k \leq p-1$, $\mathbf{0}$ is the $p \times p$ null matrix and \mathbf{I} is the $p \times p$ identity matrix. The matrix \mathbf{P} is a $p \times p$ circulant permutation matrix which shifts the identity matrix \mathbf{I} to the right once. An advantage of modified array code over array code [1] is efficient encoding due to the upper triangular structure of \mathbf{H} . Thus, unlike an array code, matrix inversion is unnecessary.

In ISI channel, iterative processing of channel APP decoder and LDPC decoder can cause pseudo-cycles even if there is no length-4 cycles in the Tanner graph. A solution is to modify the matrix \mathbf{H} of an array code. In [2], an additional permutation matrix α and a quasi-cyclic matrix ω is used to design an array code. This causes additional interleaving every p columns of the matrix \mathbf{H} .

By combining the concepts in [2] and advantages of modified array code, in this paper, we propose an Interleaved Modified Array Codes (IMAC), with a new parity-check matrix \mathbf{H}_{IMAC} as shown in Fig. 1.

where ω is a quasi-cyclic matrix. The code rate is $R = 1 - j/k$. An IMAC still has efficient encoding when compared with array codes; there is no need for matrix inversion, and the decoding process is not affected. We design high-rate MAC and IMAC suitable for high-density perpendicular magnetic recording system. The sector size is in the range of 1000 and 4000 bits/sector. We simulate the performance of IMAC and MAC using message-passing algorithm with 30 iterations. For AWGN channel, the results show that the performance of IMAC is superior to MAC for about 0.1-0.2 dB at bit error rate of 10^{-5} as shown in Fig. 2. In addition, the burst error pattern of IMAC is shorter than MAC at both low and high bit error rates. When included in a high-density perpendicular magnetic recording channels with iterative processing and turbo equalization, the SNR gain over MAC is more significant.

We also propose a subblock-based encoder design of QC-LDPC and IMAC for high-rate applications. The parity-check subblock computation is explicitly derived in a recursive manner as shown in Fig. 3, where where \mathbf{p}_i , $i = 1, 2, \dots, j$ is a subblock of parity bits of size $L \times L$. Thus, each subsection of parity-check bits can be computed from two parts: the higher-indexed parity-check subsection and all the message subsections. There is a total of j parity subblock equations. We start from the computation of \mathbf{p}_j all the way to \mathbf{p}_1 . Notice that subblock-type encoding does not require any real multiplication due to the fact that the result of a vector multiplying with permutation matrix is nothing but cyclic-shift the vector to the right by the power of the matrix \mathbf{P} . The design is implemented on a Xilinx FPGA platform then the comparison of hardware usage is then done for serial network, semi-parallel network and fully-parallel network as illustrated in Fig. 4.

Nonbinary LDPC codes for 4K-byte sectors.

W. Chang, J. CRUZ

The University of Oklahoma, Norman, OK

I. INTRODUCTION

Soft iterative decoding of binary low-density parity-check (LDPC) codes provides a considerable coding gain over the Reed-Solomon (RS) codes currently used on perpendicular magnetic recording channels (PMRCs) with the 30-year old sector length standard of 512 bytes. The use of nonbinary LDPC codes further improves performance, especially at high recording densities. With the recent approval of a new and longer sector length standard, it is expected that most hard-disk drives will be formatted using 4K-byte sectors, and is therefore timely to investigate the performance of nonbinary LDPC codes on PMRCs with long sectors. Nonbinary LDPC codes have high complexity on both encoding and decoding. For long sectors, the complexity problem becomes more severe. A way of reducing the encoding complexity is to consider nonbinary quasi-cyclic (QC) LDPC codes. To lower the decoding complexity, we can divide each long sector into short sectors, then encode and decode these short sectors separately.

In this work, we investigate the performance of two encoding schemes for long sectors on PMRCs. In the first scheme, each 4K-byte sector is encoded by a long QC or non-QC nonbinary LDPC code. In the second scheme, each 4K-byte sector is broken into eight 512-byte sectors and then encoded.

II. CODE DESIGN

By shortening and dispersing some RS codes [1], we design a (4, 41)-regular (5207, 4702) long QC-LDPC code over GF (27) and a (3, 30)-regular (930, 839) short QC-LDPC code over GF (25). The long and short non-QC LDPC codes are designed by the progressive edge-growth (PEG) algorithm. We construct a (5202, 4682) PEG-LDPC code over GF (27) and a (911, 820) PEG-LDPC code over GF (25). In addition, we design and simulate long RS and binary LDPC codes to be used as baselines.

III. PERFORMANCE OF NONBINARY LDPC CODES FOR LONG SECTORS

We assume a mix of 90% jitter noise power and 10% electronics noise power in all simulations and consider user densities as low as 0.8741 and as high as 1.2238. Firstly, it is not surprising that nonbinary LDPC codes provide a fairly large coding gain over both binary LDPC and RS codes, and that long nonbinary LDPC codes outperform the short ones, as shown in Fig. 1. Secondly, the coding gains obtained with three turbo iterations are negligible for short nonbinary LDPC codes and barely observable for long nonbinary LDPC codes. Thirdly, as shown in Fig. 2, a maximum of three readings achieves a considerable coding gain for both long and short nonbinary LDPC codes. Although the re-reading scheme makes the short LDPC codes outperform the long ones at low signal-to-noise ratios (SNRs), these coding gains will vanish as the SNR increases.

IV. ERASURE CORRECTION CAPABILITY

We compute the largest correctable erasure length for each code, under iterative decoding and maximum-likelihood (ML) decoding, according to the algorithms proposed in [2] and [3], respectively. The results are listed in Table I. Under ML decoding, PEG-LDPC codes are capable of correcting more erasures than QC-LDPC codes. However, they have similar erasure correction power under iterative decoding. Furthermore, it is intuitive that longer codes can correct longer erasures, which is an advantage of using long LDPC codes. Note that QC-LDPC codes have exactly the same erasure correction capability under ML and iterative decoding, which is an interesting property.

Colloidal dispersed nanoparticles (NP) self assemble into complex structures when segregated from the solvent either by evaporation or precipitation. Thus, different micro and macroscopic structures like opals, fractals, anisotropic structures and others formed by nanoparticles are observed as a result of the balance between electrostatic forces, surface tension, entropy, topography, substrate affinity, among others, and evidently, the size, shape and concentration of the particles. In addition, in ferromagnetic materials, the dipolar magnetic interactions, add a new term in the interactions balance.

The micro and macro self-assembled structures resulting from the evaporation of a solution of cobalt nanoparticles onto a high oriented pyrolytic graphite (HOPG) substrate give a conceptual framework to study the magnetic properties of both the material at the nanometric level and at the macroscopic level on the obtained structures. This is relevant, not only to built up super-structures for specific applications, like compact monolayers for magnetic recording media, but also to elucidate the behavior of nanoparticles in liquid media, often out of equilibrium, aiming to disperse them in biological media.

In this work we report on the static and dynamic magnetic properties of these colloidal and self-assembled structures integrated by Co nanoparticles of about 10 nm in diameter (see Fig. 1). Microstructural characterization of the Co nanoparticles has been performed by using transmission electron microscopy (TEM) (see Fig. 2 left). Self-assembled structures on graphite have been characterized by optical microscopy (see Fig. 2 right) and atomic force microscopy (AFM) (see Fig. 3 left). The magnetic force microscopy (MFM) shows the magnetic character of these self-assembled structures (see Fig. 3 right).

One-Dimensional Hierarchical Nanostructure Generated by Coating SiOX Nanowires with L10 CoPt Nanoparticles.

J. Kim, J. Kim, J. Park, K. Baek, H. Woo, S. Kim, C. Kim, C. Yoon
Materials Science and Engineering, Hanyang University, Seoul, South Korea

Nanosized structures such as nanowires and nanoparticles have recently received considerable interest due to their potential applications in high density storage media [1] and sensors [2]. Especially, L10 CoPt nanoparticle array with the high magnetocrystalline anisotropy and the resulting large coercivity is a candidate for ultra high density magnetic recording media. In the present study, we demonstrate that it is possible to uniformly coat the SiOX nanowires (SiOXNWs) with L10 CoPt nanoparticles by physical deposition to produce one-dimensional hierarchical nanostructure.

In order to grow the SiOXNWs, a monolayer of Au nanoparticles dispersed on a polyimide film was produced by thermally imidizing the polyimide (PI) precursor with thin layer of Au deposited on its top surface. The PI precursor solution was spin coated onto a Si substrate. After depositing 4-nm-thick Au layer on the PI-precursor-coated substrate, the Au/PI/Si sample was cured at 400°C for 1 h in vacuum ($\sim 10^{-3}$ Pa). The imidized film stack was further treated by thermal annealing at 800°C for 1 hour under vacuum ($< 10^{-3}$ Pa), followed by another heat-treatment step at 1000°C for 1 hour under Ar atmosphere to grow the SiOXNWs. Co-Pt alloy film was produced using dc magnetron sputtering by placing Pt chips on top of a Co target in a mosaic pattern. Initial and post-annealed compositions were verified using energy-dispersive x-ray spectroscopy (EDS).

Figure 1(a) is a scanning electron microscopy image of the dense network of SiOXNWs grown on the Si substrate, based on the vapor-liquid-solid mechanism. The wire diameter ranged from 50 nm to 80 nm. Figure 2 (b) shows a transmission electron microscopy image of the SiOXNWs onto which 6-nm-thick Co-Pt layer was deposited without any pretreatment of the wire surface. Annealing at 650 °C resulted in formation of CoPt nanoparticles on the SiOXNWs surface which acted as a one-dimensional substrate. CoPt particles were uniformly distributed over the nanowire surface. The magnified TEM image in Fig.1 (c) shows that the particle size tended to decrease towards the nanowire edge. In fact, no metal particles were found near the very edge of the nanowire. The average particle size was 2.4 ± 0.9 nm. EDS analysis of the nanoparticles confirms that atomic ratio of Co to Pt was 1:1.5, slightly enriched in Pt due to the preferential loss of Co during annealing [3]. We attempted to control the particle size by multiple depositions of the Co-Pt film on the preexisting particles formed during the initial deposition. When a layer of 1.5-nm-thick Co-Pt was deposited on the preexisting particles, Co-Pt tended to heterogeneously nucleate on the preexisting CoPt particles. The average size of the CoPt particles rose to 5.3 ± 2.1 nm after the third deposition and annealing with somewhat broadened size distribution as a result of impingement of the particles. Figure 2 shows the magnetic hysteresis loop measured at room temperature from the sample which underwent three cycles of Co-Pt deposition and annealing. Although the as-deposited CoPt particles were magnetically soft, the coercivity of the particles annealed at 650°C drastically increased to 550Oe.

We demonstrated that one-dimensional hierarchical nanostructure can be fabricated by simple physical deposition of metal layer on the oxide nanowire surface. The proposed method can be extended to other metal particles for potential use in nano catalyst arrays.

Effects of oxidation and particle size on saturation magnetization of iron nanoparticles.

H. Matsuura¹, K. Seto², K. Kawano¹, M. Takahashi³, T. Ogawa⁴

1. TAIYO YUDEN Co.,Ltd., Takasaki-shi, Japan; 2. Dept. of Elec. Eng., Tohoku Univ., Sendai, Japan; 3. NICHe, Tohoku Univ., Sendai, Japan; 4. CRESS, Tohoku Univ., Sendai, Japan

Superparamagnetic nanoparticles with high saturation magnetization (M_s) have been proposed as a hopeful material for possible application to new nanoparticle/dielectric hybrid material for high frequency devices¹⁾. In order to obtain high permeability in the high frequency range, large M_s of nanoparticle is required, and the pure iron is one of attractive candidates. However, the smaller values of M_s than bulk (220 emu/g) were reported in the chemically synthesized iron nanoparticles, and thus, effects of oxidation, particle size and crystalline structure on the M_s of the iron nanoparticle should be clarified. In this study, the effects of oxidation during the synthesis have been precisely investigated by controlling O, O₂ and H₂O impurities in the solvents and the particle size dependence of M_s has been discussed in connection with the oxidation.

Fe nanoparticles has been synthesized by our uniquely developed thermal decomposition method using an iron carbonyl in a glove box under Ar gas atmosphere with 0.1-1ppm of O₂ and H₂O impurities. At first, these impurities dissolved in kerosene and octylether as a solvent, and oleylamine as a surfactant have been removed by a freeze-pump-flaw technique. And then, in order to control the concentration of O, O₂ and H₂O impurities in the reaction solution, addition of H₂O, gas bubbling of O₂ or mixing of DOE were performed into the solvent. After injection the Fe(CO)₅, the reaction solution was kept at 180 C for 1h. The Fe nanoparticle size was controlled by changing a reaction time from 1 min to 120 min. Particle size and crystalline structure were evaluated by the transmission electron microscopy (TEM). The magnetization curves of the synthesized Fe nanoparticles encapsulated in a quartz tube was measured by a superconducting quantum interference device (SQUID) magnetometer and the M_s was evaluated from the average magnetic moment in the higher field range and the mass of iron obtained from a X-ray Fluorescence Analysis (XRF).

Figure1 shows the dependence of O impurity ratio to iron, O/Fe, in the solvent on M_s of iron nanoparticles at 300K. The average particle size (8.9nm ~9.6nm) and size distribution rarely change by controlling the O impurity ratio in the present range, and rarely change by H₂O/Fe ratio in the range ratio from 0.001 to 0.3. M_s shows independent of the O/Fe ratio in the lower range of O/Fe<10. Assuming that all dissolved O impurity contributes to oxidize the nanoparticle during the synthesis, the decreament in M_s between nanoparticle and bulk should be less than 1%. However, M_s of 152emu/g is obtained at 300K, which is much smaller than the bulk value even at the minimum O/Fe ratio. On the other hand, M_s decreases in the higher range of O/Fe>10, suggesting that the DOE decomposed during the reaction and produced iron-based oxide material because in which the O atom was contained in the DOE molecular structure. Furthermore, the H₂O/Fe ratio rarely contributes the decrease in M_s in the present experimental condition from 10⁻² to 10⁻⁵. These results suggest that the solvent with small amount of O impurities brings about minimal oxidation of iron nanoparticle during the synthesis. Therefore, we concluded that the decrement of M_s could not be explained in terms only of the oxidation in the iron nanoparticles. One possibility to explain the decrement of M_s might be the particle size, namely the increment of the relative surface area might be very crucial for the decrement of M_s . Fig.2 shows the size dependence of M_s of iron nanoparticles at 5K. This result strongly suggests that M_s of the iron nanoparticles depends on the particle size. Nanoparticles with very small size, in addition, has the larger coercivity than that for the bigger size, indicating the change of the crystalline structure and/or the increment of the surface

anisotropy. These features might be due to the increment of the number of surface atoms in each particle, and as a result M_s of the nanoparticles might be decreased.

Phase transition of the escape rate for ferromagnetic nanoparticles: A magnetic quantum tunneling study.

J. Florez, P. Vargas

Phys. Dept. USM, Valparaiso, Chile

A study of the phase transition in macroscopic quantum tunneling of a magnetic moment is presented. We show results for different terms in the magneto crystalline anisotropy, these terms can change the behavior of the period of the thermom solution and the quantum to classic transition for the escape rate. Moreover, the transition controlled by the external magnetic field can disappear when higher terms in the anisotropy term are considered.

The phenomena of the macroscopic quantum tunneling and coherent quantum tunneling have been relevant since the intensive studies of Chudnovsky, Caldeira and Leggett and others. Experimental studies have showed the relevance of these phenomena and are now very import in the study of the quantum effects in mesoscopic and nanoscopic magnetic systems. In this work we consider tunneling in a spin model with an applied magnetic field and different contributions to magneto crystalline anisotropy along an easy axes. With the instanton formulation we calculate the period of the thermom solution to escape trajectory, as well as the escape exponent and crossover temperature. In this model, a contribution of the type $H_A(p) = k_p (\mathbf{m} \cdot \mathbf{n})^p$ is considered as anisotropy energy ($p=2,4,\dots$), \mathbf{m} is the magnetic moment and \mathbf{n} a unitary vector. We also considered an external magnetic field and the total Hamiltonian is $H = -H_x S_x + H_A(p)$. Chudnovsky already showed that in this form with $p=2$, the external field controls the order of the transition in these spin systems when the field flips the sign of the anharmonic term in the expansion of the equivalent particle potential.

Our results shows the period of the thermom solutions and the escape temperature, which is related to the escape exponent by inverse proportionality, for the configurations with $p=2, k_2=0.8$, and two magnetic fields $H_x=6.1$ and $H_x=11.1$ where the change in the transition has been showed, see Fig.1. Also we calculated the same case adding a new anisotropy term with $p=4, k_4=0.9$, with the same magnetic fields. The results are shown in Figure 2. Other contributions can be also easily considered.

The phase transition between the classic to quantum region is showed in a magnetic system controlled by and external field. The behavior of the period and the escape temperature reproduces previous known calculations. Also, the inclusion of several term in the crystalline anisotropy shows the change from the second to first transition when the magnetic field is below a critical value.

Magnetic characterization of nanowire arrays using first order reversal curves.

R. Lavín¹, J. C. Denardin¹, J. Escrig¹, D. Altbir¹, A. Cortés², H. Gómez²

1. Física, USACH, Santiago, Chile; 2. Química, UCV, Valparaíso, Chile

The study of highly ordered arrays of magnetic wires is a topic of growing interest. The high ordering, together with the magnetic nature of the wires, may give rise to outstanding cooperative properties of fundamental and technological interest. In these arrays, inter-element interactions play an important role and have been subject to strong investigation.

In this work, first order reversal curves (FORC) and their respective diagrams have been used to investigate in detail the magnetization reversal process as a function of the interwire interactions in the array. Three hexagonal arrays of Ni nanowires of diameters $d=50$ nm and different lengths $L=1$ μm , $L=4$ μm and $L=12$ μm have been prepared by electrodeposition into nanopores of alumina membranes with interpore distance $D=100$ nm [1]. The magnetization measurements were performed with a home-made alternating gradient force magnetometer (AGFM).

In order to understand the role of the length of the nanowires on the interwire interactions, parameters obtained from experimental magnetization measurements and FORC diagrams were compared with micromagnetic simulation [2,3].

The FORC diagrams for the three arrays are shown in Fig1. a to c. A FORC diagram is a contour plot of the probability density function. The FORC diagrams are presented in terms of the coordinates of the switching fields (H_c) and interaction fields (H_i), respectively [4]. In the FORC diagrams of the samples (Fig1. a-c) a very large distribution of the interaction fields (in the direction H_i) is observed, which is expected for highly interacting systems. Another important feature which appears in the diagrams and which is not possible to observe from a simple hysteresis loop is the reversible component of the magnetization. This reversible component vanishes as L increases, as expected, since a system with a significant reversible component of the magnetization has a low coercivity [5].

The coercivity of arrays calculated by means micromagnetic simulations and the normalized magnetostatic interaction energy per wire (E_{int}) as function of L are shown in Fig1. d. As can be observed in this figure, the interaction per wire, E_{int} , decreases and the coercivity increases with increasing values of the length L . The experimental data points in the Fig1. d represent the coercivities obtained from hysteresis curves, and are in good agreement with our micromagnetic simulation.

One can also observe from the FORC diagrams (Fig1. a-c) that as L increases the distribution of coercivities increases, as well as the maximum of the distribution of coercivities. This behavior is in agreement with the dependence of measured values of the coercivities (black dots in Fig1. d) and micromagnetic simulations (solid line in Fig1. d). In the FORC diagram of the sample with $L=12$ μm , a significant increase appears in the distribution of coercivities (which appears as a “tail” in the direction of H_c). It is worth noting that from the FORC diagrams we can also observe a decrease in the distribution of interaction fields as L increases, as expected from the simulations. In conclusion, FORC diagrams provide a more complete characterization of the system because they provide information of the reversible component of the magnetization and information about the importance of interactions. These factors can not be easily extracted from hysteresis curves.

AC susceptibility study of spin dynamics in Fe-doped $\text{La}_{0.7}\text{Pb}_{0.3}\text{Mn}_{0.8}\text{Fe}_{0.2}\text{O}_3$

L. Fernandez Barquin¹, J. Gutiérrez², J. Barandiarán², J. Bermejo², S. Kaul³

1. CITIMAC, Facultad de Ciencias, Universidad de Cantabria, Santander, Spain; 2. Electricidad y Electrónica, UPV / EHU, Fac. Ciencia y Tecnología, Bilbao, Spain; 3. School of Physics, University of Hyderabad, Hyderabad, India

Manganites or mixed manganese oxides of the formula $\text{La}_{1-x}\text{M}_x\text{MnO}_3$ where M is a divalent cation (Pb in our case), are Double Exchange (DE) ferromagnets (FM) that attract great interest in view of their colossal magnetoresistance around the magnetic order temperature. They have a strong tendency to grow in small coherent regions due to the coupling of the magnetic and charge carriers and local distortions like Jahn-Teller or charge ordering. Those ensembles of magnetic atoms at the nanometric scale are known as clusters or grains. Such a tendency is enhanced by doping the Mn with other 3d-metals, like Fe [1], that break up the FM chains by suppressing the DE between Mn ions, and can eventually give rise to spin glass-like structures. The latter magnetic arrangement is consequently maximized with the increase of Fe-content in the compound. Due to the similarities of the relaxation behavior in manganites with the dynamic behavior observed in nanomagnets of strong technological applications, the manganites can be seen as an excellent playground to ascertain the interactions between ensembles of randomly disposed magnetic clusters. In this case, results from dynamic techniques can give insight both into the magnetic coupling and the spatial correlation ranges.

In this work we present recent results obtained by AC magnetic susceptibility experiments in the $\text{La}_{0.7}\text{Pb}_{0.3}\text{Mn}_{1-x}\text{Fe}_x\text{O}_3$ ($x = 0.2$) manganite, where the frustration is enhanced respect to the $x = 0$ compound. All measurements were recorded at several frequencies ($100 \text{ Hz} \leq f \leq 10 \text{ kHz}$) between 10 K and 220 K in a Quantum Design-PPMS magnetometer, allowing the instantaneous recording of the in-phase (χ') and quadrature (χ'') components. The samples were warmed up from helium temperatures at steady heating rates, ranging from 0.1 K/min (where peaks were detected) to 2 K/min, in featureless regions. The amplitudes of the oscillating AC-field were $h = 1$ and 0.1 Oe. Among the macroscopic techniques, the AC-susceptibility (ACS) is one of the best suited for a spin dynamic study. This is due to its intrinsic sensitivity to detect very subtle magnetic transitions and/or different magnetic phases and because when there is a need to define a magnetic relaxation process, it is recommendable to cover several decades of measuring time, ideally using a single technique.

In figure 1 (left) we show the measured in-phase and out-of phase responses. Thus, the sample with $x=0.2$ shows a component with a single broad peak centered around 70 K. This peak looks like as if a single transition should be taking place. By contrast, in it seems that up to three contributions can be present. It is likely that the highest-temperature one (around 100 K) is related to the paramagnetic to ferromagnetic transition which evolves into a blocked or spin-glass peak at around 70 K. Finally the susceptibility displays another shoulder at 50 K more difficult to interpret. Increasing the frequency, the commented features in the curves (marked by arrows) shift to higher temperatures. The detailed analysis of the observed frequency-shift as well as the possible critical behavior of those transitions are the object of the analysis to be presented in this work.

The non-linear susceptibility behavior which can give hints to clarify the critical dynamics, specially for inhomogeneous magnetic systems [2,3]. This kind of analysis has been widely used in other CMR oxides doped with 3-d elements at the Mn^{3+} site [4,5] as well as in quite different families of perovskites [6,7] without such a doping. In our case, the third harmonic component χ'_3 (see figure 1, right) confirms the previously observed two transitions: a sharp one at $\approx 65 \text{ K}$ and a well

separated broad hump at $\approx 100 \text{ K}$. These results are discussed in terms of the presence of short-range magnetic correlations which can give rise to a ferromagnetic percolated state of a spin-glass-like structure depending on the coupling among those regions.

Exchange coupling in core(ferromagnet)-shell(antiferromagnet) structured nano-particles.

N. N. Phuoc¹, T. Suzuki¹, R. W. Chantrell², U. Nowak²

1. Information Storage Materials Laboratory, Toyota Technological Institute, Nagoya, Japan; 2. Department of Physics, University of York, York, United Kingdom

Exchange coupling in ferromagnetic(FM) and antiferromagnetic(AF) nano-composite particles is an appealing subject among many studies on nano-particles [1] but there is still very little work on this theme. This work hence focuses on the study of the exchange coupling in FePt(core)/FeMn(shell) nano-composite particles by two approaches: atomistic simulation [2] and micromagnetic simulation [3].

The micromagnetic simulation is based on the Landau-Lifshitz-Gilbert equation, where the equilibrium state of the spin configuration is obtained by minimization of the total energy from the random state. The equilibrium state, on the other hand, from the atomistic model is obtained by heating the nano-particles beyond the Curie temperature and cooling down to $T = 0\text{K}$. Another major difference between micromagnetic and atomistic models is that the atomistic approach is based on the calculation at the atomistic level, using a reasonable physical model for the exchange, rather than using the long-wavelength (micromagnetic) approximation [2]. In particular, the Heisenberg form of exchange is used in the atomistic model. In other words, although the cell sizes of both micromagnetic and atomistic models look to be the same, the calculation method is totally different. For micromagnetic cells, a constant value of magnetization is taken while in the atomistic model, the magnetization is averaged over all atoms [2].

Shown in Fig. 1 are some representative spin structures of the core/shell particles obtained from micromagnetic and atomistic simulations with different interlayer exchange coupling constants. It is interesting to see that for the case of weak interlayer coupling, the magnetization arrangement of the core break up into domains even the particle size is very small (4.8 nm) if using micromagnetic simulation. The formation of multiple-domain in this case is unreasonable as it costs a lot of exchange energy in FM system. For stronger interlayer coupling, the core becomes single-domain. Such a behavior cannot be observed if using atomistic simulation. It was reported previously similar failure of the micromagnetic simulation in describing the domain structure and the switching behavior of the hard/soft layers when the interlayer exchange coupling is small [2]. The reason for this failure is possibly due to the under-estimation of the exchange energy for rapid spatial fluctuations of the magnetization by the (continuum) exchange formalism [2]. Another reason for this might be due to the cooling procedure, where the micromagnetic model does not really cool the system and might get trapped in unphysical states while the spin model does really a cooling, i.e. a slow lowering of temperature.

Figure 2 shows the variation of the spin directions of the core and the shell as a function of the anisotropy of the AF shell in the case of strong interlayer coupling. It can be seen that the spins of the core are influenced by the spin of the shell as the K_{AF} increases. In particular, when the K_{AF} is large enough, the FM core spins are canted from the easy axis. As a result, the coercivity of the system is reduced with the increasing of K_{AF} . This behavior and also the discrepancy between atomistic and micromagnetic simulations will be discussed in details in the presentation.

When decreasing the size of the magnet down to the nanometric range, the thermal fluctuation of the magnetization (*superparamagnetic* state) will be seen as an advantage[1] or a poison[2] depending on the expected application. Nevertheless, in both cases, technological improvements require the understanding of dynamical magnetization reversal processes at the nanosecond time scales. Generally, high fields are needed to reverse the magnetization of nanoparticles, which are difficult to achieve in current devices. One way to overcome this limitation is to apply a constant magnetic field, well below the switching field, combined with a radio-frequency (RF) field pulse. The efficiency of this method has been previously demonstrated on a 20 nm cobalt particle by using the micro-SQUID technique[3]. Our aim is to extend this magnetization reversal technique on a cobalt nanoparticle with only 3 nm in diameter, in order to study the dynamics behaviour of only a thousand of spins.

In this paper, we report recent experimental results on the magnetic properties of cobalt clusters prepared by Low Energy Clusters Beam Deposition[2], embedded in insulating matrices. This technique allows us to synthesize highly diluted samples, where clusters are considered as isolated. First of all, from macroscopic measurements on these cluster assemblies we deduce the average structural and magnetic properties (see figure 1).

The final step of this research work consists to use an improved micro-SQUID device coupled with a gold stripe line. With this system, we succeed in the magnetization reversal of a single cobalt cluster at low temperature ($T = 35$ mK) using a RF pulse (see figure 2).

A qualitative understanding of the magnetization reversal by non-linear resonance can be obtained with the Landau-Lifschitz-Gilbert (LLG) equation.

For each field point inside the Stoner-Wohlfarth astroid, the LLG equation was integrated to calculate the switching times. Assuming that in such Co-nanoparticle, bi-axial surface anisotropy terms dominates all the others terms[4], the anisotropy energy can be written as the sum of second order terms: $E_a = -K_1 m_z^2 + K_2 m_y^2$. The best simulations of the field dependence of the switching field (dynamic Stoner-Wohlfarth astroid) for frequencies of 5-6 GHz and a few nanosecond pulse duration, are obtained for $K_2 = 0.5 K_1$ and α , the damping term lower than 0.01. Larger studies by varying matrix and clusters size are in progress.

Experimental magnetic susceptibility curve and hysteresis loop of Co nanoparticles embedded in Ge matrix. The fits lead to the clusters magnetic size distribution and the efficient anisotropy constant (K_{eff}).

Experimental field dependence of the switching field for a 3 nm single Co particle by applying a RF pulse frequency of 5.91 GHz. For each field point, the shortest pulse length leading to magnetization switching is indicated with a colour. In the black region the magnetization did not reverse whereas the white region is outside the Stoner-Wohlfarth astroid.

Thermal relaxation phenomena probed by transverse susceptibility measurements performed at different frequencies.

Thermal relaxation phenomena in particulate media have been extensively studied by several techniques, among them Mössbauer spectroscopy, SQUID magnetometry [1] and Transverse Susceptibility (χ_t) [2]. Superparamagnetic behaviour is observed by using an instrument with a characteristic measuring time τ and at temperatures above the blocking temperature T_B , which depends on the value of the energy barrier KV , K being the magnetic anisotropy constant and V the average volume of a particle. In most experiments, the transition from the superparamagnetic to the ferromagnetic states is investigated using two techniques with very different characteristic measuring times [1]. In this work we present measurements of one physical quantity, χ_t , performed at two different characteristic times below the blocking temperature. As χ_t depends strongly on the value of the observed effective anisotropy energy, $(KV)_{\text{eff}}$, it is our aim to show how this value depends on the characteristic time used. Two magnetic media have been chosen, one in which thermal relaxation phenomena are expected to play an important role (Co nanoparticles) and another one in which they are expected to be negligible (continuous polycrystalline CoFe thin films). Co nanoparticles were grown on amorphous Si_3N_4 substrates by triode sputtering at 550°C to favour the formation of nanoparticles. Ex-situ XRD showed that Co crystallizes in the hcp phase without texture. Atomic Force Microscopy results revealed a well-defined nanostructured pattern without coalescence [3]. Polycrystalline CoFe thin films 20 nm thick were deposited on glass substrates. Ex-situ XRD confirmed the bcc structure of the samples with a preferred (110) out-of-plane orientation. TEM measurements showed that the samples were polycrystalline. χ_t measurements were performed by two methods. One based on the transverse magnetooptical Kerr effect (MOKE), working at a frequency of 127 Hz [3] and the other one based on a tunnel diode oscillator (TDO) working at 22 MHz [2]. All the samples studied exhibited a magnetic isotropic behaviour. Figure 1a shows the χ_t for a particulate Co thin films with nominal thickness of 3 nm and a mean particle diameter of 15 nm. Although the value of the magnetic field at the peak in the χ_t curves is to be close to the anisotropy field H_k of the particles [4] in this case it is remarkable that: 1) it is too low to be identified as H_k for hcp Co, and 2) it is lower for TS measured at 127 Hz than at 22 MHz. In Figure 1b the χ_t for a CoFe polycrystalline sample is shown. In this case, the measurements performed at 127 Hz and at 22 MHz coincide perfectly. Furthermore, the value of H_k obtained from the χ_t peak is consistent with the magnetocrystalline anisotropy of CoFe: taking $H_k \sim 125$ Oe, and the saturation magnetization $M_s = 1700 \text{ emu/cm}^3$ we obtain a magnetic anisotropy constant $K \sim 1.1 \times 10^5 \text{ erg/cm}^3$, a bit lower than the magnetocrystalline value of K for CoFe ($1.5 \times 10^5 \text{ erg/cm}^3$). The slight difference can be attributed to interparticle interaction and anisotropy dispersion [4].

We conclude that in the case of Co nanoparticles the thermal relaxation affects very strongly the value of the effective anisotropy observed. Taking the characteristic measurement time as the inverse of the frequency of the alternating field used, we have $\tau(\text{MOKE}) = 8 \times 10^{-3} \text{ s}$ and $\tau(\text{TDO}) = 5 \times 10^{-8} \text{ s}$. The larger the observation time used, the larger the probability for a particle to overcome the energy barrier during the observation. The key parameter governing the transition from one energy minimum to the other is $\alpha = KV / k_B T$. At room temperature, and taking the anisotropy constant of bulk hcp Co ($K = 4.1 \times 10^6 \text{ erg/cm}^3$) we estimated $\alpha \sim 20$ -50. The medium thermal stability criterion is given by $\alpha \geq 60$ [3]. So the magnetization equilibrium position is not only

determined by the value of the applied magnetic field and its orientation with respect to the easy axis but also by the thermal relaxation which favours the switching of the magnetization, yielding an observed effective magnetic anisotropy which is lower than the magnetocrystalline one. These results show that when investigating particulate media thermal relaxation has to be taken into account even when working below the blocking temperature.

The constant search of increasing the memory density justifies the interest on the production of self-assembled magnetic nano-objects. In studying their magnetic features the first approach consisted, historically, on working with magnetic transition metals (Ni, Fe, Co; see for instance [1]). Recently, nanocolumns of cobalt ferrite, a magnetic oxide, have been grown embedded on a ferroelectric matrix, by a co-deposition process, obtaining composite multiferroic materials of new generation [2]. Magnetoelectric coupling in these nanocomposites is expected to be determined by interface strain, thus detailed control of shape and distribution of the ferromagnetic columns is essential. Deposition temperature is traditionally considered the key parameter [3], however details of the growth, role of the substrate and magnetic structure of the films are not yet fully elucidated. In particular, substrate symmetry and composition can affect the epitaxial character of the nano-objects, determining their magnetic properties.

Aim of this work is to explore and compare the initial growth mechanisms of CoFe_2O_4 (CFO) on substrates with different atomic arrangements and thus crystallographic structures. We selected an isostructural spinel (MgAl_2O_4 , MAO) and a perovskite (SrTiO_3 , STO) single crystalline substrates, both (001) oriented: we will show that, under the appropriate growth conditions, the formation of pyramidal objects with magnetic behavior is favored on both substrates. Lateral size and surface density of the pyramids can be tailored changing the substrate. We emphasize that this, rather than temperature changes, is a preferable way to control the size distribution of the magnetic nanoobjects: in fact, the growth modes generated at different temperatures cannot be easily separated. Moreover, in growing nanocomposites by co-deposition, immiscibility is essential, although limited to a narrow temperature range; otherwise intermixing can occur. For comparison purposes, series of CFO films have also been grown on (111) STO monocrystals: instead of the pyramidal structures observed on (001) substrates, relatively flat CFO surfaces (typically ~ 10 nm of RMS roughness) constituted by 3D islands are observed.

Samples presented on this work were grown by RF magnetron sputtering, in a mixed atmosphere of argon and oxygen, for a total pressure of 250 mTorr. Deposition duration was 100 minutes and the grow rate was determined by x-ray reflectometry from a thin sample, in which the formation of nano-objects was still in an embryonic phase, and it resulted of the order of $1 \text{ \AA}/\text{min}$. Morphology was studied by atomic force microscopy (AFM); magnetic characterization was performed by magneto-optical Kerr effect (MOKE). Depositions with substrate temperature of 650°C , was realized simultaneously on MAO (001) and STO (001): AFM scans of these samples are presented in Fig. 1a and 1b respectively. 3D structures with pyramidal shape are found on the surface: bases are oriented along the substrate crystallographic directions and the lateral size is strongly dependent from the substrate material, resulting double, in average, for the case of STO respect to MAO (~ 220 nm and ~ 110 nm respectively). Both images present in an inset graph an analogous deposition, realized with substrate at 700°C . The higher temperature generates a larger surface density of pyramids, so lateral size is smaller, ~ 60 nm for both substrates.

When depositing over STO (111), at 650°C , 3D islands were found, with planar top and triangular bases oriented along the crystal axes of the substrate, reflecting its three-fold symmetry. This growth is promoted by the lower surface energy of CFO (111) face respect to the (001): in fact, for

any substrate, the film tends to maximize the (111) surfaces, i.e. the pyramids' faces or the planar tops of the island in the case of STO (111).

Samples deposited over both STO orientations were magnetically characterized by room-temperature MOKE, under an external field up to 1.15 T. MOKE loops with the field applied either perpendicular (polar) or parallel (longitudinal) to the sample surface were collected; longitudinal measurements were collected with the field at two different in-plane angles (0 and 90°). It is found that in both cases the out-of-plane direction is the hard one, whereas the film-plane is an easy plane. For the films grown on (001) substrates, no significant in-plane anisotropy is observed, as expected from the substrates symmetry. However, a similar behavior is observed on (111) substrates. We will discuss on the origin of this unexpected result.

Concluding, we have shown that appropriate substrate selection allows a more efficient growth control of self-assembled ferrimagnetic CoFe_2O_4 nanostructures. This approach should permit a better understanding of magnetoelectric properties of biferroic nanocomposites.

Magnetic nanoparticles were synthesized by normal micelle micro-emulsion method at room temperature. The ratio between Mn/Zn and Fe cations is adjusted to 1:2 for every sample, the value of x varied in the $0 \leq x \leq 0.75$ range. We estimated nanoparticle size through a chemometric approach introduced by A. Rodinone *et al* [1] as $d \sim 33$ nm. The ferrite structure was identified by XRD, where peaks can be indexed to planes (220), (311), (400), (422), (511), and (440) of single-phase MnZn ferrite. From the Scherer equation we obtained experimental nanocrystallite size values as $d \sim 27$ -55 nm. These values correspond to the magnitude expected by Rondonone's approach. At 180 K, the ESR spectra were recorded on the nanoparticles with different stoichiometries. A set of dilution samples were prepared by diluting 0.5 mL, 1.0 mL and 1.5 mL in 10 mL water, to obtain variable interparticle distances. ESR shows that the ΔH_{pp} linewidth increases as inter-particle distance L decreases, indicating the existence of magnetic inhomogeneities as the effect of inter-particle interaction on the L scale. This interaction can also be responsible for the resonant field, H_r , shift to higher values. This behavior can be discussed in terms of particle size distribution and inter particle dipole-dipole interaction [2]. If the distance between particles increases, the inter particle dipole-dipole interaction decreases. A set of $\text{Mn}_x\text{Zn}_{1-x}\text{Fe}_2\text{O}_4$ samples were prepared in the $0 < x < 0.75$ range at the same dilution, e.g., with same inter-particle distance. For $x < 0.5$, the EPR spectra consist of a single resonance signal, strongly symmetrical, with $g=2.01$. The resonant field is approximately constant for $x \leq 0.5$ $H_r = 3350$ G. While the x concentration increases, the Lorentzian character of the signal reduces. The same behavior is observed by feeble dilution of the magnetic particles. These results indicate that x increases the ferrimagnetic character of $\text{Mn}_x\text{Zn}_{1-x}\text{Fe}_2\text{O}_4$ nanoparticles. For low concentrations, the ΔH_{pp} value remains approximately constant. This was expected, given that at this concentration the single line in the EPR signal at $g = 2.01$ indicates the presence of Fe³⁺ of the octahedral sites. For $x \geq 0.5$ close to 1399 G, a second line appears (see Fig. 1) in the EPR signal, corresponding to $g = 4.10$. This is attributed to a random distribution of the anisotropy in the system, with perpendicular and parallel modes, giving information about the effective anisotropy of the system [3]. As the inset in Fig. 1 shows, the contribution of the second line decreases when x decreases. The latter reinforces the suggestion of a local field created by the Mn in the cell. For high concentrations, the resonant field shifts drastically to 2875 G. This phase was verified through hysteresis curves, measured between 10 K to 300 K, by using a Vibrating Spectro-Magnetometer. From the field-cooled (FC) magnetization curves, the behavior of dM/dT (see Fig 2a) as a function of the magnetic field were obtained. This behavior shows a minimum about $T_{\min} = 145$ K, and a soft shift to low temperature as the applied field reduces. Below T_{\min} a reduction in the rate of ordering moments indicates the existence of strong interactions among particles. A maximum is observed above $T_{\max} \approx 25$ K (Fig. 2b) for $H > 20$ Oe. T_{\max} was interpreted as the beginning of a glassy spin-like behavior. The slope of dM/dT can be interpreted as the moments ordering rate. A dependence of this slope as a function of the magnetic field is discussed in the framework of nanoparticle interaction theory. This work was partially supported by COLCIEN-CIAS under Research Project 1106-05-17612 and CENM, under contract 043-2005.

Magnetostatic interactions between magnetic nanotubes.

J. Escrig¹, S. Allende¹, D. Altbir¹, P. Landeros², M. Bahiana³

1. Departamento de Física, Universidad de Santiago de Chile, Santiago, Chile; 2. Departamento de Física, Universidad Técnica Federico Santa María, Valparaíso, Chile; 3. Instituto de Física, Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil

Since the discovery of carbon nanotubes by Iijima in 1991, [1] intense attention has been paid to tubular nanostructures because of their importance for future applications in spintronic devices. [2] In particular, the study of highly ordered arrays of magnetic nanotubes is a topic of growing interest. This is a consequence of the development of experimental techniques that lead to fabricate in a controllable and ordered way such arrays. [3] Magnetic nanotubes may be suitable for applications in biotechnology, where magnetic nanostructures with low density, which can float in solutions, become more useful for in vivo applications. [4] In this way tiny magnetic tubes could provide an unconventional solution for several research problems, and a useful vehicle for imaging and drug delivery applications. In such systems, effects of interparticle interactions are complicated by the fact that the dipolar field depends on the magnetic state of each element, which in turn depends on the field due to adjacent elements. Although the magnetostatic interaction between nanowires has been intensely investigated, [5] tubes have received less attention, in spite of the additional degree of freedom they present; not only can the length and radius be varied, but also the wall thickness.

The purpose of this work is to develop an analytical model for the full long-range magnetostatic interaction between nanotubes that lead us to understand variations of the squareness of the hysteresis of these arrays as a function of the interaction between the elements. Our model goes beyond the dipole-dipole approximation, giving an analytical expression for the interaction in which the shape of the tubes have been taken into account. Using those expressions we developed Monte Carlo simulations to investigate the hysteretic behavior of the array.

Geometrically, tubes are characterized by their external and internal radii, R and a , respectively, and length L . It is convenient to define the ratio $\beta=a/R$, so that $\beta=0$ represents a solid cylinder (wire) and β close to 1 corresponds to a very narrow tube. We adopt a simplified description of the system, in which the discrete distribution of magnetic moments is replaced by a continuous one characterized by a slowly varying magnetization density $\mathbf{M}(\mathbf{r})$. The full dipolar interaction of an array can be calculated by evaluating the interaction energy between two magnetic bodies and summing up over the array. [5] Thus, the total magnetization can be written as $\mathbf{M}(\mathbf{r})=\mathbf{M}_1(\mathbf{r})+\mathbf{M}_2(\mathbf{r})$, where $\mathbf{M}_1(\mathbf{r})$ and $\mathbf{M}_2(\mathbf{r})$ denote the magnetization of each tube. In this case, the magnetostatic potential $U(\mathbf{r})$ splits up into two components, $U_1(\mathbf{r})$ and $U_2(\mathbf{r})$, associated with the magnetization of each individual tube. Then, the dipolar interaction between both tubes can be written as $E_{\text{int}}=\mu_0\int\mathbf{M}_1(\mathbf{r})\nabla U_2(\mathbf{r})d\mathbf{v}$.

In order to evaluate the magnetostatic interaction, it is necessary to specify the magnetization of each tube. We consider tubes with an axial magnetization defined by $\mathbf{M}_i(\mathbf{r})=M_0\sigma_i\mathbf{z}$, where \mathbf{z} is the unit vector parallel to the axis of the tube and σ_i takes the values ± 1 , allowing the tube i to point up ($\sigma_i=+1$) or down ($\sigma_i=-1$) along \mathbf{z} . Results are given in units of $\mu_0 M_0^2 V$, where $V=\pi R^2 L(1-\beta^2)$ is the volume and M_0 is the saturation magnetization of each tube.

The interaction between two nanotubes is obtained using the magnetostatic field experienced by one of the tubes due to the other so that the final result reads $E_{\text{int}}=(2\sigma_1\sigma_2/(1-\beta^2))\int_0^L(dq/q^2)J_0(qd/L)(J_1(qR/L)-\beta J_1(q\beta R/L))^2(1-e^{-qL})$ (1), where J_p is a Bessel function of the first kind and p order and d is the center-to-center distance between the tubes.

Equation (1) has to be solved numerically. However, tubes that motivate this work satisfy $L/R\gg 1$, leading us to expand J_1 as $J_1(x)=(x/2)+\sum((-1)^k(x/2)^{1+2k}/k!\Gamma(k+2))$. (2) Then we can approximate equation (1) by $E_{\text{int}}^\lambda=\sigma_1\sigma_2(R^2(1-\beta^2)/2Ld)\sum g_\lambda$, where λ indicates the order of the expansion. An example, the first term in the sum is $g_1=1-(1/\sqrt{1+(L/d)^2})$.

Figure 1 illustrates the interaction energy between two identical nanotubes ($L/R=100$) with parallel axial magnetization as a function of $2R/d$. When the two tubes are in contact, $2R/d=1$; when they are infinitely separated, $2R/d=0$. From this figure we can conclude that by increasing the internal radii of the tubes, the magnetostatic interaction between them decreases, changing their magnetic behavior, as evidenced in Monte Carlo simulations. These results lead us to related changes in squareness with β .

The key advantage of nanowires is their very large shape anisotropy that can provide a high intrinsic coercivity to the material. A hard magnetic behaviour is expected when the diameter of the wires is small enough to ensure a single domain state. The liquid phase chemical processes are very efficient for the synthesis of monodisperse magnetic particles with a very good control of size and shape. They afford the opportunity to get new insights on the properties of such nano-objects.

By reduction of cobalt and nickel acetate salts in liquid polyols we obtained homogeneous cobalt-nickel metal nanowires with a mean diameter less than 10 nm and a mean length of 200 nm [1,2]. This process was recently extended to the synthesis of pure cobalt wires with the same length by reduction of cobalt carboxylates (*Inset* Fig. 1). The mean diameter is controlled in the range 10-20 nm by varying the cobalt precursor. These wires crystallize in a hcp structure with the crystallographic c-axis laying along the wire axis. HRTEM showed that they are nearly single crystal. The control of the morphology of cobalt and cobalt-nickel particles by reduction in liquid polyol is achieved through a kinetic control of growth of the metal in solution. No template was necessary. We showed that a high growth rate favours the wires whereas platelets and spheres are obtained with lower growth rates. The control the growth step was realized by acting upon three parameters: the basicity of the medium, the metal salts and the polyol that acts both as solvent and as reducing agent.

Magnetic measurements showed a ferromagnetic behaviour at room temperature. Coercivity and remanence strongly depend on the orientation of the wires with respect to the applied field. Square magnetization curves were measured on samples obtained by freezing the wires in toluene under an external field (Fig. 1). For such samples remanence to saturation ratio, M_r/M_s , are close to 1 (Tab. 1). In case of $\text{Co}_{80}\text{Ni}_{20}$ wires aligned parallel to an external field the magnetization curve was well fitted considering the Stoner Wolfarth model with a dispersion of the nanowires orientation $\sigma = 10^\circ$ (HWHM). The coercivity $H_c = 6.5$ kOe was found to be a sum of two equivalent contributions: a magnetocrystalline anisotropy $H_{MC} = 3$ kOe (which is very close to the value for bulk hexagonal cobalt) and a shape anisotropy which contributes to $H_{\text{shape}} = 3.5$ kOe [3]. With pure cobalt wires coercivity values up to 9 kOe at 140K (10 kOe at 5K) were obtained. These higher values are well explained by a higher saturation magnetization of cobalt than alloys. These magnetic properties are very interesting because the coercivity reaches much higher values than magnetic wires obtained by other methods. Arrays of nanowires grown by electrochemical routes are perfectly aligned but never exhibit coercivities higher than 3 kOe even for Fe where the theoretical value could be as high as 10 kOe [4]. These good results are related to the growth process that affords both smaller wire diameter and better crystallinity.

These nanowires may present interesting applications for “high-temperature magnets”. The use of 3d transition metals provides high remanence and high Curie temperature (T_C). We showed that the saturation magnetization of cobalt wires is very stable since it is only reduced by 2% at 240°C. In the regime where $T \ll T_C$ the shape anisotropy is temperature-independent. Thus, we think that these wires could fill a gap between rare earth (RE) magnets like SmCo and AlNiCo magnets. RE magnets have higher coercivities but they show stronger softening upon warming while AlNiCo magnets exhibit much lower coercivities in the whole temperature range of interest.

Introduction

Several authors investigated the effect of magnetic clusters on recording properties [1, 2]. They used models in which the grain sizes and the positions were fixed, a cluster size was formed from several grains and the cluster size did not change through recording processes. On the other hand, we used a perpendicular medium model in which the grain size and its position can be changed. In our previous study, the effects of grain size dispersion and exchange interaction between adjacent grains on magnetic cluster sizes in perpendicular thin films under uniform field were reported [3]. In the present study, the same effects on magnetic cluster size in the transition regions in recorded patterns were estimated. A new method for estimation of magnetic cluster size for magnetic recording was used. Furthermore, the transition shift was investigated in this study.

Calculation conditions

A thin film perpendicular recording medium was represented by a two-dimensional array of hexagonal pillars (grains) for our simulation [4]. The magnetization in each grain was assumed to be uniform and to precess according to the Landau – Lifshits – Gilbert equation. Total number of grains is 4096 (64×64), average grain size $\langle D_{\text{grain}} \rangle$ is 6.35 nm, film thickness is 20 nm, packing fraction is 90% and a grain size dispersion, $\sigma/\langle D_{\text{grain}} \rangle$, is changed to 0-30%. In the case of $\sigma/\langle D_{\text{grain}} \rangle = 0\%$, the grains were located in honeycomb structure. In the other cases, the grain sizes were distributed and the center of a grain was moved so that the adjacent grains were not overlapped.

The magnetic properties of the medium are $M_s = 800 \text{ emu/cm}^3$, $H_k = 12 \text{ kOe}$, exchange stiffness constant $A = (0-0.15) \times 10^{-6} \text{ erg/cm}$.

Ten different type media were prepared for each $\sigma/\langle D_{\text{grain}} \rangle$ and A . The effect of thermal switching was calculated according to the Monte – Carlo calculation [5]. Ten different patterns were recorded for a medium model with different temperature random numbers; the temperature is 350 K and it is given by a random number for a recording step. On the DC erased state, NLTS 1111 pattern was written. The length of bit was ten times as long as grain size (63.5 nm).

Results and discussion

Two reversed patterns were written on DC erased state. There are four transition regions, T1, T2, T3 and T4. Figure 1(a) shows a typical write pattern. In order to investigate cluster size in the transition regions, we defined that the widths of the transition regions are two grain length.

A scheme of estimation method of magnetic cluster in a transition region is shown in figure 1(b). A rectangular window with width of one-tenth the average grain size and height of the track width was placed on the medium and it was scanned to the down track direction. In the rectangular window, a reversed area which was not separated by a non-reversed area was defined as one cluster (such as cluster 1, cluster 2 in fig. 1(b)). Length of a cluster i^{th} in the cross track direction was defined as CSaxi, and the average of the cluster lengths was named CSax.

Figure 2(a) shows average cluster size as a function of exchange stiffness constant A . The solid lines show average cluster sizes of CSax. The broken line shows cluster sizes which were estimated from M-H loops by using our previous method. These cluster sizes are named CSaa in order to distinguish them from CSax. In the region of the large A , CSaa increases with increasing A and CSax is almost constant. Therefore, CSaa is larger than CSax in the large A region. The CSaa is decreased with increasing $\sigma/\langle D_{\text{grain}} \rangle$, but CSax slightly increases with increasing $\sigma/\langle D_{\text{grain}} \rangle$.

Therefore, in magnetic recording, it is inappropriate to use the cluster size estimated from M-H loop for the discussion of medium noise.

Figure 2(b) shows distance between adjacent peaks with various A and $\sigma/\langle D_{\text{grain}} \rangle = 0\%$. The distances between adjacent peaks increase with progressing the recording. In the region of large A ($\geq 0.03 \times 10^{-6} \text{ erg/cm}$), the distance between peaks became larger than ideal value. In the other grain size dispersion, the same tendency were obtained through $A = (0-0.15) \times 10^{-6} \text{ erg/cm}$.

Ligand exchange in gold-coated FePt nanoparticles.

P. de la Presa¹, T. Rueda¹, M. Morales², A. Hernando¹

1. Instituto de Magnetismo Aplicado, UCM, Las Rozas, Spain; 2. ICMN-CSIC, Madrid, Spain

The useful magnetic properties of FePt nanoparticles (NPs) arouse the interest of this material for biological applications.[1] However, the synthetic procedure to obtain high quality NPs involves organic phase processes. The NPs resulting from these procedures are stable in nonpolar solvents (such as hexane) and capped with nonpolar endgroups on their surface. The capping molecules (also called ligands) are typically long-chain alkanes with polar groups that bind to the nanoparticles' surface. To obtain a biocompatible and water dispersible compound the ligands must be exchanged by polar endgroups. Some efforts have been done to find a proper ligand that can bind both Fe and Pt simultaneously. Furthermore, functionalization of the NPs has been recently improved by coating the FePt NPs with gold [2]. The coating procedure requires also an organic phase process resulting in FePt@Au NPs capped by oleic acid and oleylamine and dispersed in hexane.

In this work we present the magnetic properties of gold coated FePt NPs and the study of stable aqueous dispersions of FePt@Au and FePt synthesized after ligand exchange with mercaptoundecanoic acid (MUA). The synthesis of the FePt and FePt@Au NPs is described elsewhere [1,2]. The particle size determined from TEM micrographs goes from 4 nm for the uncoated NPs to a maximum of 10 nm for the gold coated ones indicating that the thickness of the shell ranges from 1 to 3 nm. The magnetic characterization consists in hysteresis cycles at 5 K and 300 K (see Fig. 1) and zero-field-cooled (ZFC) and field cooled (FC) curves at 100 Oe. The results show that the blocking temperature and coercive field decrease for the gold coating NPs, and it is related to the reduction of the magnetic anisotropy due to the presence of gold atoms at the surface.

The ligand exchange is performed by dispersing the NPs in chloroform containing MUA and stirring during one day; Then NPs are collected by precipitation with ethanol and centrifugation. As can be seen from Fig. 2, the ligand-exchanged NPs are successfully dispersed in water and stable at pH 7. We observe by TEM that, whereas the NPs dispersed in hexane tend to self assembling keeping a certain distance between NPs, in the MUA ligand exchanged NPs there is no sign of pattern, tending to agglomerate instead of self assembling. The hydrodynamic radius of the uncoated, gold coated and the ligand-exchanged NPs is determined by means of dynamic light scattering (DLS). The oleic acid and oleylamine FePt have hydrodynamic diameter (Dh) of about 5 nm, whereas Dh ranges from 7 to 12 nm for gold coated NPs. These values are in agreement with well dispersed NPs which have an organic layer about 1 nm in size surrounding the surface. On the other hand, the ligand-exchanged NPs have a much greater Dh (ranging from 150 to 240 nm) indicating that FePt and the FePt@Au slightly agglomerate during the ligand-exchange process, in agreement with TEM results. The measurement of the isoelectric point shows that the MUA ligand-exchanged NPs have negative charges at the surfaces and are stable in water for pH > 3.

These results make the MUA ligand-exchanges FePt@Au NPs an interesting material for biological applications since the magnetic properties do not vary significantly from the FePt, the size of the agglomerates are around 200 nm and are negatively charged, which can facilitate the cellular uptake of the NPs. Studies of toxicity are underway.

Magnetic behavior of oleate-capped monodisperse iron oxide nanoparticles prepared in polyol solutions.

G. Caruntu^{1,2}, D. Caruntu^{1,2}, C. J. O'Connor^{1,2}

1. Advanced Materials Research Institute, New Orleans, LA; 2. Chemistry Department, University of New Orleans, New Orleans, LA

The magnetic characteristics of well-separated monodisperse iron oxide nanoparticles with sizes varying between 6.6 and 17.8 nm prepared in non-aqueous solutions have been investigated. Both morphology and mutual interactions between the nanoparticles have been identified in influencing the magnetic response of the nanopowders. While the smaller nanocrystals exhibit superparamagnetism with blocking temperatures increasing gradually with the particle size, above a critical size the particles are ferromagnetic at room temperature (Fig.1).

Assuming that the particles are non-interacting and possess a uniaxial anisotropy, the corresponding blocking (TB) can be used to estimate the values of the anisotropy energy constant (K) of the oleate-capped

Fe₃O₄ nanocrystals. The calculated values of the constant are $K = 4.74 \times 10^5 \text{ Jm}^{-3}$ for the particles with an average diameter of 6.6 nm and $K = 1.11 \times 10^5 \text{ Jm}^{-3}$ for those with a mean size of 11.6 nm, respectively. These values are about one order of magnitude higher than that of the bulk material ($K_{\text{bulk}} = 0.135 \times 10^5 \text{ Jm}^{-3}$) [1] and were found to increase with decreasing size of the nanoparticles. Additionally, they are slightly larger, but yet in good agreement with the K values estimated by Mossbauer spectroscopy for 6 nm ($K = 1.4 \times 10^5 \text{ Jm}^{-3}$) and 12 nm ($K = 0.9 \times 10^5 \text{ Jm}^{-3}$) [2,3] particles or by using the equation $KV = 25 k_B T$ for 7 nm Fe₃O₄ particles ($K = 2.8 \times 10^5 \text{ Jm}^{-3}$) [4], but much lower than that for 3–7 nm sized particles obtained by the microemulsion technique ($K = 10^6 \text{ Jm}^{-3}$) [5]. The anisotropy constant (K) of the nanocrystalline materials can incorporate different contributions from magnetocrystalline shape and surface anisotropy [4, 6]. Thus, assuming that the magnetocrystalline anisotropy of the Fe₃O₄ nanoparticles prepared in the polyol media is invariant to the reaction conditions (the nature of the solvent, the heating time) and the shape of the nanoparticles does not change significantly with their size, the variation trend in K can be ascribed to the concurrent effect of the interparticle interactions [7] and the surface anisotropy [6]. The saturation magnetization values are slightly smaller than that of the bulk material, suggesting the existence of a disordered spin configuration on their surface. The thickness of the magnetically inert shell estimated from the size variation of the magnetization is 1.9 Å. The dipole–dipole interactions between the particles were tuned by changing the interparticle distances, e.g. by diluting the nanopowders in a non-magnetic matrix at concentrations ranging from 0.25 to 100 wt% (Fig. 2). As the strength of the interactions is decreased with dilution, the energy barrier is substantially lowered; this will induce a drastic decrease of both the blocking temperatures and the coercivity with decreasing concentration of the nanoparticles [8].

Navarro et al. (1) have reported the magnetic behavior of Fe (100) nanoparticles induced by different capping layers. In that work, they showed that the interplay between the nanoisland sizes and the capping materials is crucial to govern the magnetic coupling among Fe nanoparticles. In this work we are going to address magnetic/superconducting proximity effect between the Fe nanoislands and superconducting films mediated by a capping material. The samples are grown by sputtering technique and following several in-situ steps. First of all, the Fe (100) nanoparticles are grown on sapphire substrates, see Navarro et al (1) for details, after the appropriate capping layer is deposited and finally Nb thin film is grown on top. In situ MOKE hysteresis loops allow us obtaining the magnetic properties of the samples. AFM scans and hysteresis loops are used to extract the nanoparticles morphology, see (1). In this work we will show that the magnetic/superconducting proximity effect is a powerful tool to explore the tuning of magnetic coupling between magnetic nanoparticles mediated by different capping materials. In figures 1,2 we show a typical example. These figures shown an enhancement of the proximity effect due to the strong coupling of the Fe nanoparticles induced by Pt capping, this coupling vanishes in the case of Al capping layer and the Nb film critical temperature increases in comparison with the critical temperature of the Nb/Pt/Fe sample.

Lube depletion caused by thermal-desorption in heat assisted magnetic recording.

Y. Ma, B. Liu

Data Storage Insitute, Singapore, Singapore

Heat assisted magnetic recording (HAMR) is a promising technique to overcome the superpara-magnetic limit. However, it brings about serious problems to the slider-disk interface. One is the lube depletion on disk surface caused by the laser heating. At elevated temperature, lube depletion can be caused by either the desorption of the lube from the disk surface or the decomposition of the lube on the disk surface depending on the relative rate constants for each process [1]. In this article, lube depletion caused by lube desorption from disk surface during laser heating is studied based on adsorption/desorption theory and previous lube transfer studies [2, 3].

A physical model is developed aiming at studying the lube depletion quantitatively. The lube depletion process under laser heating in slider-disk interface and underlying physics are explained. The effects of slider air-bearing pressure and temperature on the saturated vapor pressure of lube, the effect of temperature on lube viscosity, and the difference between the desorption of bonded and unbonded lube molecules on disk surface, etc are also addressed. Then, equations governing the lube depletion are proposed based on the Langmuir and the Brunauer-Emmett-Teller theories.

Lube thinning rate over laser heating area as a function of lube molecular weight is calculated and shown in figure 1. The temperature at laser spot is 450C. The thinning rate decreases dramatically with the increase in the lube molecular weight. To unveil the meaning of the thinning rates, the time for lube in the area from 20 mm to 40 mm in radius on a 3.5" disk surface to thin 1 angstrom is calculated by assuming a 100 nm laser spot size. The results are also shown in figure 1. The time for 6 kDalton Zdol is about 0.42 year, for 7 kDalton Zdol about 19.6 years and for 8 kDalton Zdol about 893 years. It is acceptable if 7 kDalton Zdol is used to deal with the lube depletion problem caused by the lube desorption from disk surface during laser heating.

Lube thinning rate over laser heating area under 180 atm slider air-bearing pressure and the ratio of lube thinning rate under 180 atm over that under 18 atm as a function of lube molecular weight is summarized in figure 2. The temperature at laser spot is 450C. The slider air-bearing pressure shows significant effect on increasing the lube thinning rate and the higher the lube molecular weight the more significant the effect. Therefore, it is very important to avoid designing a slider that produces high air-bearing pressure on the laser heating area in HAMR.

It is also found that lube thinning rate can be reduced significantly by lowering laser heating temperature and lowering lube saturated vapor pressure.

Study of slider's flying behavior under by various temperature and humidity conditions.

T. Watanabe, K. Kusakawa

Fuji Electric Device Technology Co.,Ltd, Matsumoto, Japan

[Abstract]

Due to decrease of slider-disk space and usage of Hard Disk Drive under extensive environmental conditions, slider-disk interaction has become more pronounced. Therefore, it is necessary to understand the slider's flying dynamics under extensive environmental conditions.

In this study, we have investigated flyability performances of slider under various temperature and humidity conditions. As the results of touch-down/take-off (TD/TO) tests, it is revealed that water's meniscus formation between slider and disk surface increases slider-disk interaction and degraded slider's flying ability.

[Experiment]

For understanding the temperature and humidity effects on flying slider's behavior, TD/TO tests were performed under various atmosphere conditions. The disk used in this study was coated with a DLC layer and lubricated Fomblin Z-tetraol.

Figure 1 shows the dependence of TD/TO velocities on various temperature and humidity conditions. Under low temperature (22 degree) region, a slight increase in TO velocity is observed as increase of relative humidity. On the other side, remarkable increase was observed under higher temperature region (70 degree) as increase of relative humidity. This result indicates that degradation of slider's flying ability is originated in the water in atmosphere.

[Consideration]

We assumed that high humid air flows between flying slider and disk surface caused the formation of water's meniscus such as Fig.3. According to Kelvin's equation, water's meniscus between two plains is described as follows.

$\ln(P/P_0) = -2\gamma M \cos(\theta) / (RT\rho r)$, where P is vapor pressure at temperature T , P_0 is saturated vapor pressure at T , γ is surface energy, M is molecular weight of water, ρ is density of water, θ is contact angle, R is gas constant, T is absolute temperature and r is radius of water's meniscus.

Figure 4 is the correlation between "Diameter of water's meniscus" and "Relative humidity at three temperature conditions (22,55,70 degree)" derived from equation (1).

This figure indicates that the growth of meniscus diameter strongly depends on humidity at high temperature. Moreover, this correlation is similar to that of Fig.1.

Fig5 shows correlation between Diameter of water's meniscus and TD/TO velocity. From this figure, TD/TO velocity strongly depends on the water's meniscus diameter. Therefore, we conclude that the water's meniscus formation degrade slider's flying ability.

[Summary]

We studied the flying slider's behavior under various temperature and humidity atmosphere, and concluded the water's meniscus formation between slider and disk surface increased slider-disk interaction and degraded slider's flying ability under high temperature and high humidity condition. It is expected realizing of hydrophobic surface will be suitable for improving slider's fly-ability.

We will present the method of hydrophobic treatment on the disk surface at meeting.

A novel simulation of air/liquid bearing based on lattice Boltzmann method.

D. Kim, M. S. Jhon, H. Kim

Depart of Chemical Engineering and Data Storage Systems Center, Carnegie Mellon University, Pittsburgh, PA

With the continuous demanding of increasing the areal recording density, head media spacing is expected to be less than 6.5 nm for 1Tbit/in² hard disk drive (HDD) implying that the budget for the thickness of lubricant film is 1 nm and with a few nanometer air spacing [1].

Therefore, to accurately model nano-mechanics of head disk interface (HDI), a hybrid approach of air and liquid bearing simultaneously in a non-isothermal environment is required. To achieve this goal we will adopt lattice Boltzmann method (LBM) [2]. LBM has emerged as a promising numerical tool for simulating fluid flows and thermal management with complex physics [2]. The numerous advantages, including clear physical pictures, an inherently transient nature, multi-scale simulation capabilities, and fully parallel algorithms, make LBM to be a strong candidate to model HDI nano-mechanics. Since the application of LBM to air bearing has been reported in other place [3], we will focus on liquid bearing modeling in this paper. Viscoelastic liquid bearing (VLB) [4] can be used as a benchmark problem in studying lubricant rheology in a non-isothermal environment. Due to the high spinning speed of disks and ultra-thin film thickness, the shear rate of this liquid may reach values on the order of 10^{10} sec^{-1} . In this ultra-high shear rate regime, shear thinning effect becomes very subtle. Although the standard modeling for VLB in conjunction with VISqUS technology [5] has been reported in the past [4], we developed a novel three-dimensional mathematical tool based on LBM.

By adopting the Taylor series expansion and least squares based LBM and non-Newtonian fluid models [6], our LBM scheme can predict the flow behavior and stress distribution under an arbitrary shaped slider in three dimensions, which is useful for simulation of VLB. To illustrate the capabilities of our novel LBM methodology, we first simulated the Poiseuille flow in a 3D square duct, which is driven by the pressure difference. Figure 1 shows the nondimensional velocity profiles for Newtonian, truncated power-law, and Bird-Carreau fluids. The power-law exponent was set as 0.9 and the velocity of non-Newtonian fluids (Figs. 1 (b) & (c)) increased in comparison with Newtonian fluid due to shear thinning. LBM described the shear thinning behavior accurately for non-Newtonian fluid models.

After the benchmark study of 3D Poiseuille flow, VLB of a model slider was simulated to illustrate essence of air/liquid bearing simulation. The dummy slider has the dimension of 4 mm \times 0.416 mm. The disk is operated at angular velocity of 3,600 rpm and the velocity at pivoting point is 15 m/s. We chose the pitch angle to be 80 μrad and slider flying height $h_m=25 \text{ nm}$. Figure 2(a) shows the normalized isothermal pressure profiles for the truncated power-law fluid with $n=0.9$. The pressure builds up under the slider and reaches maximum near the trailing edge, and then sharply decreases to ambient pressure. In addition to the advantage of transient dynamic calculation, one of the strength of LBM computational tool over the well-known modified Reynolds equation or Boltzmann equation [7] is the direct calculation of stress field, which is critical to determine the friction force or power consumption for HDD. Figure 2(b) shows the isothermal shear stress profiles at the slider bottom surface. As the spacing decreases from leading to trailing edge, the shear rate increases gradually. We are currently developing air/liquid bearing simulation in a non-isothermal environment using LBM to make integrated HDI simulation. This computational tool can be further applied to predict the flow field, temperature and pressure profiles, and shear stress for a slider with complex geometry.

Numerical Simulation of Touchdown/Takeoff of Sphere-Pad Slider.

H. Li¹, J. Li², J. Xu², Y. Shimizu², K. Ono², S. Yoshida¹

1. Storage Mechanics Laboratory, Hitachi Asia Ltd., Singapore, Singapore; 2. Central Research Laboratory, Hitachi Ltd., Kanagawa, Japan

This work numerically simulates the static TD/TO hysteresis of the sphere-pad slider[1][2] in the terms of meniscus bridge formation and breakage. It proposes a geometry model for the lubricant bridge between the sphere-pad slider and lubricant over the disk surface, and the corresponding meniscus force model. By applying them into the air-bearing simulator, the TD/TO hysteresis of the sphere-pad slider is analyzed. **(1) Mathematical Model of Sphere-pad and Meniscus Bridge** The geometry of the sphere-pad is expressed as a sphere model (Fig. 1). The meniscus bridge between the sphere-pad and disk is modeled as Fig. 2. With considering the liquid pressure balances at the meniscus boundary, it can obtain the average contact angle, then the side meniscus radius and ring meniscus radius at given separation [3]. **(2) Flying Model of Slider** A three-dimensional (3D) model of sphere-pad slider/disk interface is built (Fig. 3). A sphere-pad is designed at the top of slider's trailing pad. There is a smooth air pressure distribution and the achieved mesh size is about 1~2 μm . The air bearing pressure distributions on the slider's ABS with/without the sphere-pad are compared in Fig. 4. **(3) Parametric Study of Mobile Lubricant Thickness on Hysteresis and Meniscus Force** Fig. 5 shows the meniscus forces interaction on the sphere-pad slider under the different mobile lubricant thickness (T). It is found that thinner the mobile lubricant thickness, lower the meniscus force as well as the break height of the meniscus bridge. When T is 0.5, 0.7 and 1.0 nm, the lubricant bridge's break heights are about 1, 3 and 9 nm, respectively. For both two sliders with 5/10 nm height sphere-pads, the break height is kept almost same at the give lubricant thickness, although the meniscus force is reduced much by the increase of the height of sphere-pad. For example, the meniscus force on the slider with a 5 nm height sphere-pad is about 2 times of that with a 10 nm height sphere-pad. Fig. 6 shows that the FH and RPM hysteresis reduces much with the reduction of T due to the increase of the dispersion pressure. So the reduced mobile lubricant thickness can both reduce the FH and RPM hysteresis as well as the meniscus force. **(4) CONCLUSION** It is found that the reduced mobile lubricant thickness can both reduce the FH and RPM hysteresis as well as the meniscus force. The increase of the Hamaker constant (the absolute value) will reduce the TD/TO hysteresis of FH and RPM of the sphere-pad slider as well as the meniscus force. The increased surface energy will increase the TD/TO hysteresis of FH and RPM of the sphere-pad slider as well as the meniscus force. The large height and small horizontal radius of the sphere-pad can reduce the meniscus force, but do not affect the FH hysteresis much.

1. Introduction

To achieve ultra-low flying height, magnetic spacing variations due to manufacturing tolerances and temperature-induced thermal protrusion need to be reduced. We have developed a thermal flying-height control (TFC) slider that carries a micro-thermal actuator [1] [2]. Previous TFCs were mainly statically controlled by a constant power supply. Our purpose is to demonstrate dynamic control of a TFC slider to compensate for high-speed magnetic signal modulation using feed-forward control methods.

2. Experimental methods

We used a spin stand and applied the following two feed-forward control methods.

Method 1: Only time domain information was used. The average magnetic signal modulation data without TFC (Fig. 1) was used to adjust TFC power.

Method 2: In addition to time domain information, frequency domain information of a TFC actuator was considered. First, the transfer function of the actuator was calculated from its frequency response. The calculated transfer function P is

$$P = (0.0007072S + 347e6) / (-S-4.356E4) \quad (1)$$

Next, input data to adjust TFC power was calculated using P and magnetic signal modulation data. In this method, target motion was created by cutting frequency components above 5 kHz using a low-pass filter.

3. Experimental results

The experimental results of methods 1 and 2 are shown in Figs. 2 and 3, respectively. A comparison of modulation by 3-sigma showed that method 1 reduced modulation from 38 mV to 22 mV and method 2 reduced modulation from 38 mV to 18 mV. Method 2 has better compensation than method 1. FFT analysis results are shown in Figs. 4 and 5. Method 2 showed better reduction of modulation in frequencies of 2–5 kHz. A decrease in magnetic signal modulation was confirmed in frequencies up to 5 kHz. The FFT analysis results roughly corresponded to a 5 kHz target frequency.

4. Summary

To dynamically compensate for magnetic signal modulation using TFC, two methods were examined. Method 1 adjusted TFC power using only time domain information. Method 2 adjusted TFC power using frequency domain information in addition to time domain information. Method 2 showed better compensation for magnetic signal modulation due to better compensation at higher frequencies. These results showed that a dynamically controlled TFC is feasible in compensating for kHz order modulation.

A spacing of 2.5 nm is required in order to achieve a density of 1 Tbit/in² in hard disk drives. Static loss of flying height (FH) due to manufacturing tolerance, ambient pressure changes and the temperature variations can cause head disk contact at such a low FH. The dynamic instability should be minimized. All these challenges make a conventional air bearing surface slider an unlikely choice for density of 1 Tbit/in². Thermal flying height control (TFC) sliders have been recently introduced in commercial products for compensating the static FH loss and reducing the risk of head disk contacts.

Finite element method has been used to model and simulate the static analysis of the temperature distribution and thermal protrusion of the TFC sliders [1]. Experiments were also conducted to verify the nano-protrusion performance and reliability. It was found that the response time of the actuator is about 1ms [2]. Analysis has been conducted to formulate the heat transfer across the head disk interface using velocity slip and temperature jump boundary conditions when a slider flies over a spinning disk [3].

In this paper, a finite element model is created and the cooling effect of the air bearing is included in the model as thermal boundary conditions. Steady-state analysis is firstly performed, the effects of heater input power and distance from ABS to heater were investigated. The results fit well with the previous research results.

Transient simulations are conducted using coupled field finite element analyses to study the bandwidth of the thermal protrusion of the slider, which include the temperature and thermal deformation responses. Firstly we compare the results of two cases, one case we consider the heat transfer on ABS is constant, the other case we consider the heat transfer differs with the pressure differences on ABS. The simulation results show that both the temperature and thermal protrusion of the second case response faster than the constant heat transfer case. It takes about 0.3 ms for the temperature and 0.6 ms for the protrusion to reach static state values. This is because that high pressure or high thermal conduction at the read/write elements location can fasten the temperature and thermal protrusion responses.

In order to compare the responses of power turn on and off, the power is applied from 0 to 0.6 ms and was turned off at 0.6 ms. Time constant (defined as the time for the actuator to reach (1-1/e) times of its full stroke) is used to quantitatively compare the response time of temperature and deformation [1]. Figure 1 (a) and (b) show the time response of temperature and deformation at different locations from the heater. We compare the results of different nodes between actuator and ABS, and at reader position as well. In the figures, D is the distance from ABS. D=15μm means the node is inside the slider body, 15μm away and normal to ABS. D=0 means the node is on the ABS. From figure 1(a), the temperature rise at D=15 μm is about 18 degree, but at the reader location is only about 6 degree. And the response time at D=15 μm is much faster than at reader location. From Figure 1(b), the deformations only differ about 1 nm from node at ABS plane to node that is 15 μm from ABS, and all the response times are similar. Figure 2 listed the response times of the temperature and deformation at D=0 and reader location (T0T and TRT is the temperature response time at D=0 and at reader location respectively, T0D and TRD is the protrusion response time at D=0 and at reader location respectively). It is shown that the response times at these two locations show very small changes and the time constant of power off is slightly longer than power on. The reason for

the facts that temperature response strongly depends on distance from the heater is because that the temperature can only transfer from heater to nearby location, and then to further location. But for the deformation response, the expansion around the heater location will push the outer nodes to expand at the same time, thus the response times at different locations are quite similar. When the power is off, no expansion effect exist, the deformations vanish with time and the response time is longer than the expansion time.

The static and other transient results would be included in the full paper.

Origin of Heater Induced Voltage in Magnetic Recording Heads.

D. Song, M. T. Johnson
Seagate Technologies, Bloomington, MN

Heater induced pole tip protrusion is a popular means of controlling and reducing the head-media spacing (HMS) in a hard disc drive [1]. We found that the heater power can induce a thermoelectric voltage in the transducer. Recall that the thermoelectric effect describes a voltage/current in a circuit where dissimilar metal junctions are placed at different temperatures [2]. In our experiments, recording heads with longitudinal writers were flown on discs. A voltage V_0 was applied to the writer leads to obtain a zero net current in the circuit. Thus V_0 is the reverse of the thermally induced voltage. Data from three heads showed that the voltage V_0 has a parabolic dependence to the heater voltage and is linearly proportional to the heater power (Fig. 1). This suggests that the voltage V_0 is thermoelectric in nature and is not due to capacitive coupling.

After studying the writer coil structure, we identified that the dissimilar metal junctions are two Cu/NiFe contacts in the writer coil leads. One contact is positioned next to the heater while the other is substantially further away. Consequently, the two contacts are at different temperatures during heater operation. The measured writer voltage offset is up to 4 mV at 160 mW heater power. Assuming a Seebeck coefficient of 40 $\mu\text{V}/\text{C}$ [3], this suggests the two interfaces have ΔT of about 100 C. Our finite-element modeling results using ANSYS indicates that ΔT is about 64 C for 160 mW heater power. This is within a factor of two compared to the measurement.

The finding implies that one needs to be careful in accounting for voltage offsets during any accurate writer or reader resistance measurements. The effect may be further developed for monitoring temperatures in the transducers if necessary. The effect may also be eliminated by not using dissimilar metals at the contacts, or by placing these contacts such that they are kept at similar temperatures during heater actuation.

Signal modulation study of TuMR reader near head/disk contact.

N. Kim, Y. Tang, X. Che

Samsung Information Systems America, San Jose, CA

Control on head-disk spacing is one of the enabling technologies for continued the higher areal density recording. Flying Height has been significantly reduced over the years and the heating element on heads has been introduced to reduce the spacing even further [1]. The inclusion and proper use of this heater has played a pivotal role in increasing the capacity and the overall performance of magnetic recording.

As this technique allows us the flying height to be in sub nanometer range, proper touch down detection is a necessity for accurate flying height calculation and preventing head-disk interface contact. It is desired to have that detection to be picked up before its catastrophic contact. Such detection could be observed by an acoustic sensor or signal modulation as the head vibration occurs when clearance is minimal [2]. It is also shown that the modulation in an electric signal has the same mechanism vibration with that of acoustic sensor output [3].

Signal modulation has been an excellent indicator for head-disk contact. This resonance signal caused at near contact is generally known as a head vibration. At near contact however, the mechanism of this effect is not well identified. In this paper, we will discuss the origin of this low frequency signal.

The experiment was conducted using a spin stand and a scope to record the read signal from TuMR head. First we checked the head resistance and the signal polarity by injecting a test pulse into the head. We verified the increase of head resistance, resulting in a positive signal on our scope. Heater was used to control on head-disk spacing to create an oscillation when touchdown has occurred. Figure 1a shows the measured signal when head-disk is near contact. From this figure, we can observe clear amplitude change but it is more visible on the positive side. The frequency of the modulation is around 200~300 KHz.

The asymmetrical nature of amplitude modulation can not be explained by Wallace spacing loss. Our study showed that it is caused by a combination of two distinct mechanisms: the magnetic signal amplitude and reader thermal resistance change. To quantify these two effects, the readback signal was passed through a narrow band digital filter centered at recording frequency. The filtered signal was rectified and the envelope was extracted using a low pass digital filter. The Results are plotted in the upper graph of Fig 1b. This envelop represents the magnetic read signal amplitude modulation. To analyze the thermal resistance change effect, the same readback signal was passed through a low pass filter. The result was plotted in the lower part of Fig 1b. The two lines are well synchronized in phase. The well synchronized demodulated magnetic signal and low pass filtered thermal signal suggests that as head-disk spacing is reduced, TuMR resistance increase. This indicates that the temperature has been lowered due to the negative temperature coefficient of the TuMR readers.

This proposition was confirmed with a similar experiment using a GMR reader in which, the magnetic signal amplitude and reader thermal resistance change are synchronized but opposite in phase. Such phase change is expected from the positive temperature coefficient of the GMR readers.

These findings also indicate that the cooling effect increases as the reader approaches the disk surface. Thus, the mechanical vibration of the head results in head-disk spacing change which causes both magnetic signal amplitude modulation (due to Wallace spacing loss) and low frequency reader resistance change (due to thermal cooling effect).

Nano-mechanics of Perfluoropolyether Films: Compression vs. Tension.

Q. Guo^{1,2}, P. Chung¹, M. S. Jhon¹

1. *Department of Chemical Engineering and Data Storage Systems Center, Carnegie Mellon University, Pittsburgh, PA*; 2. *Seagate Technology, Fremont, CA*

Molecularly-thin perfluoropolyether (PFPE) lubricant films are commercially used in the magnetic recording media for their long-term reliability. During the hard disk drive operation, the intermittent contact between the slider and lubricant surface inevitably results in the lubricant pick-up, where lubricant molecules could partially transfer to the air bearing surface due to the shear stress and the vertical head-disk interaction and eventually affect the tribological performance of the head-disk-interface (HDI) integration, *i.e.*, lubricant depletion and head vertical displacement. Therefore, compression and tension, the basic vertical modes that PFPE films could undergo, are of technical significance in the HDI integration. Here, using molecular dynamics simulation [1], we examined the nano-mechanics of PFPE films, including compression and tension, along the normal coordinate.

In our “thought experiment,” 150 functional PFPE molecules described by the coarse-grained, bead-spring model were simulated onto two solid surfaces facing each other with the horizontal dimension of $15\sigma \times 15\sigma$ and a vertical separation of 25σ (σ is the diameter of the bead). The “compression” mode was achieved by moving the top surface downwards at a constant speed. As the separation becomes less than the Lennard-Jones (LJ) interaction range, interfacial molecules began to interact with each other (Fig. 1b) and eventually formed a nano-confined film (Fig. 1c). During the “tension” process, while the top surface was retracted with the same constant speed, a fluid bridge was formed in between (Fig. 1d), and became thinner and thinner as the wall separation increased (Fig. 1e), and eventually separated into two individual films. Similar nano-mechanics simulation was also performed for nonfunctional PFPE nanofilm, which showed significant difference than functional film. Especially during the “tension” process, with the same time interval, no apparent fluid bridge was observed. Also, its wall separation at the “break” point is much smaller than that of functional PFPEs.

We calculated the normal stress for both nonfunctional and functional PFPEs (Fig. 2). The film normal stress remains constant as the top surface moves downward, but quickly drops when the partial film contact occurs, and eventually reaches the minimum as two separated films completely merge into one confined film. The normal stress may significantly increase with even a minor compressive strain due to the strong intermolecular repulsion force, *i.e.*, the LJ potential. During the tension mechanics, an irreversible normal stress profile was observed, especially for the functional PFPE film, implying the hysteresis phenomenon which may be relevant to the viscoelasticity of PFPE nanofilms and also depend on the retraction rate of the top surface.

The N-mode Maxwell model is employed here to understand the viscoelastic properties of PFPE nanofilms. The simulated “tension” normal stress profile suggests that PFPE molecules may experience two steps of relaxation, especially for functional PFPEs, showing a sharp slope in the beginning of “tension” (backbone-contributed) while the slope gets compromised (endgroup-contributed) once the wall separation is larger than 20σ in Fig. 3.

To satisfy different aspect of disk lubrication requirements, we also explore a multi-component lubricant film system on its fundamentals of nano-mechanics and interfacial properties (*i.e.*, surface tension/disjoining pressure) that have been attempted via both experimental [2] and theoretical tools [3].

Ultraviolet Bonding of PFPE with Carbon Overcoat: Surface Energy and Spreading.

H. Chen², P. Chung¹, M. S. Jhon¹

1. *Department of Chemical Engineering and Data Storage Systems Center, Carnegie Mellon University, Pittsburgh, PA*; 2. *Hewlett-Packard Company, San Diego, CA*

In this paper, to clarify the bonding mechanism, UV irradiation effects on the molecularly thin PFPE films were investigated by analyzing the surface energy using Lifshitz-van der Waals and Lewis acid/base (LW/AB) theory [1]. In the LW/AB theory, the surface energy was decomposed into three components, *i.e.*, LW (γ^{LW}), Lewis acid (γ^+), and Lewis base (γ^-) surface energy. We have found that the bonding of functional PFPEs with a carbon overcoat is a Lewis acid-base interaction, where the overcoat is an electron donor and functional PFPEs are electron acceptors.

Ztetraol (molecular weight of 2,200 g/mol) were deposited on Seagate disks with ion beam deposited carbon overcoat (COC) via standard dip-coating procedure. These lubricated disks were treated by UV irradiation from a few seconds to 10 min with a low-pressure mercury lamp providing UV light at both 185 nm and 254 nm with the ratio of 1:5. UV irradiations were performed under nitrogen purge to avoid ozone production at room temperature. The contact angles of three test liquids, *i.e.*, DI water, diiodomethane (DIM), and ethylene glycol, were measured on these UV treated disks to determine γ^{LW} , γ^+ , and γ^- . Delubing test was performed to measure the bonded film thickness.

It is found that the total film thickness decreased after 5 mins of UV irradiation. The decrease of film thickness indicates the photochemical degradation of PFPE chain and evaporation of short broken chain under UV irradiation. We also found that UV irradiation can enhance the bonding of Ztetraol with ion beam deposited carbon overcoat (< 1 min). However, UV irradiation for longer period (> 1 min) may decrease the bonded film thickness due to the photochemical degradation of PFPE chain.

Figure 1 shows the LW, Lewis acid, and Lewis base surface energies of bare COC and 16Å & 38Å Ztetraol film as a function of UV exposure time. The LW surface energy of Ztetraol film depends weakly on UV exposure time (Fig. 1a). The Lewis acid parameter of Ztetraol film dramatically changed with UV irradiation, which was assigned to the physiochemical changes in the lubricant instead of COC. According to the Lewis acid parameter curve, several stages can be assigned during UV exposure as shown in Fig. 1b. In stage I, the Lewis acid parameter decreased, and the surface became less acidic. In stage II, the Lewis acid parameter increased, which may be due to the dominant photochemical degradation of Ztetraol under UV irradiation. The photochemically degraded PFPE pieces may contain functional groups capable of providing electrons. In stage III, the Lewis acid parameter decreased again then leveled off, which was believed to correlate with the evaporation of broken PFPE.

The Lewis base parameter of bare COC dramatically increased (Fig. 1c), *i.e.*, UV irradiation increased the basicity of the surfaces. It indicates that UV irradiation changes the chemical features of COC. For Ztetraol films, the Lewis base parameter slightly decreased first and reached minimum, then increased (Fig. 1c). The minimum point was related to the maximum bonded film thickness, *i.e.*, 1 min for 16Å Ztetraol and 2 mins for 38Å Ztetraol films.

Short-time UV irradiation can enhance the bonding of functional PFPE, *i.e.*, Ztetraol film with ion beam deposited carbon overcoat, although the energy of UV lights (185 nm and 254 nm) is smaller than the work function of ion beam deposited COC (> 30 eV). It is likely that UV direct photodissociation of PFPE molecules [2] is responsible for the short-time bonding. Long-time UV irradiation degrades the PFPE chain and cause the loss of lubricant by evaporation.

To study the UV effects on the dynamic properties of PFPE film, the spreading profiles of UV irradiated PFPE films were monitored on the partially dip-coated film using optical surface analyzer. Figure 2 shows the spreading profiles of Ztetraol film having the initial thickness of 15 Å without and with 1 min UV irradiation. In comparison to without UV irradiation case, the spreading rate was found to decrease for the films with UV irradiation. We found that the spreading profiles with UV irradiation were much sharper.

L-t plot was adopted to analyze the spreading behaviors. A simple relation $L \propto t^{1/2}$ was found for spreading profiles without UV irradiation indicating diffusion mechanism. With UV irradiation, the spreading of Ztetraol films was retarded, which can be attributed to the enhanced bonding of Ztetraol with overcoat and cross-linking between Ztetraol molecules. In addition, the slope of L-t plot was found to deviate from 0.5. It can be interpreted that UV irradiation produced smaller chain pieces thus led to non-uniform spreading of the film.

Binary Mixture Lubricant Film of PFPE Lubricants.

P. Chung¹, H. Chen², M. S. Jhon¹

1. *Depart of Chemical Engineering and Data Storage Systems Center, Carnegie Mellon University, Pittsburgh, PA*; 2. *Hewlett-Packard Company, San Diego, CA*

New types of disk lubricants, such as Ztetraol Multidentate (ZTMD) and monofunctional (Mono) perfluoropolyether (PFPE), were recently reported to enhance the performance and reliability of hard disk drive with ultra-low head-media spacing (HMS) [1, 2]. However, ZTMD shows good conformation but bad mobility while Mono exhibits better mobility but worse conformation [3]. The mixture of lubricants with different properties may be one solution to meet the harsh requirements of disk lubricants for ultra-low HMS [4]. In this paper, molecular dynamics (MD) simulations with a bead-spring model were employed to examine the detailed structure, conformation, and dynamics of binary mixture lubricant film.

Figure 1 shows the typical snapshots of ZTMD and Z binary mixture monolayer with different volume fraction using MD simulations. The conformation of the binary mixture monolayers was investigated by analyzing the anisotropic radius of gyration (R_{gxy}/R_{gz} , where R_{gxy} and R_{gz} are parallel and perpendicular components of the radius of gyration, respectively). We found that at the small and large ZTMD volume fraction (ϕ_{ZTMD}) regions, ZTMD as well as Z has flatter conformation than their pure components, which may provide thinner lubricant film thickness. We also calculated the self-diffusion coefficient as a function of volume fraction to quantify the mobility of the binary mixture lubricant. Both self-diffusion coefficients for ZTMD (D_{ZTMD}) and Z as a function of ϕ_{ZTMD} were calculated as shown in Fig. 2. In the region from $\phi_{ZTMD}=0$ to 0.45, D_{ZTMD} gradually decreases. The corresponding snapshots (Figs. 1 (a)) illustrate that ZTMD molecules aggregate together due to strong attraction and form isolated islands. With the increase ϕ_{ZTMD} , more ZTMD molecules stick together and the islands become larger and larger, thus the mobility of ZTMD becomes less due to the strong confinement by the surrounding ZTMD molecules. Note that at certain critical volume fraction, ZTMD molecules are all linked together and form connected network structures (Fig. 1 (c)). The transition point from isolated islands to connected network structures is called “percolation threshold,” which is approximately 0.45. Beyond the percolation threshold, D_{ZTMD} decreases slightly but at a much smaller rate (Fig. 2). This transition indicates the changes in the diffusion mechanism, *i.e.*, from percolation to reptation process. In the percolation process, the mobile molecules diffuse through the bonded molecules with a random distribution, while, in the reptation process, molecules are laterally constrained and can move only along the path between the gaps of the aggregated molecules (Fig. 3). We also found that the binary mixture of ZTMD and Z with the volume fraction from 0.25 to 0.675 have higher mobility than the pure ZTMD monolayer and keep the desirable conformation, which may be better disk lubricants.

Our simulation results of the static and dynamic properties indicate the advantages of binary mixture monolayer as disk lubricants comparing to their single components. The hysteresis effects on the binary mixture films were further studied. Based on the multi-component lubricants simulations, we systematically constructed the database that described the conformation, morphology, surface coverage, mobility, nano-mechanics, and nano-rheology of PFPE films.

A Study on Design and Analysis of New Lubricant for Near Contact Recording.

D. Shirakawa, K. Ohnishi

Asahi Glass Co., Ichihara-shi, Japan

As a hard disc drive is required higher recording density and reliability, the technology of the head-disc interface (HDI) is facing more challenging task regarding its tribological performance. In the phase of near contact recording, the conventional lubricants would cause several issues in HDI. For instance, a conventional PFPE that contains weak “-OCF₂O-” unit in the main chain due to its manufacturing processes is decomposed in the presence of a Lewis acid catalyst.

In the previous work, we had developed a PFPE “TA-30” that had the improved chemical stability by excluding weak unit[1].

But, TA-30 had lower viscosity than conventional PFPE(Lube-B),so It's thin lubricant layer on disk could't endure the harsh interface condition.

New lubricant“QA-40” improved in these properties will be discussed at the conference.

They are expected to be suitable for near contact recording lubricant.

A new contact model for head disk interface (HDI) with ultrathin liquid film and ultra-small spacing.

H. Matsuoka, H. Kokumai, S. Fukui

Department of Applied Mathematics and Physics, Faculty of Engineering, Tottori University, Tottori, Japan

I. Introduction

An ultrasmall spacing between a flying head slider and a magnetic disk is required for higher recording density in hard disk drives. The head-disk spacing is becoming several nanometers in recent years. The head disk interface (HDI) in such an ultrasmall spacing should be designed considering surface forces [1], instabilities of an ultrathin liquid film spread on the magnetic disk as a lubricant [2], intermittent contact between the head and the disk and so on.

In this study, a new contact model between solids with an ultrathin liquid film on a solid surface has been developed and interaction forces between the elastic sphere and the plane in approach and withdrawal processes have been calculated.

II. Interfacial Regimes

Figure 1 shows schematic geometries of a sphere and a plane coated with an ultrathin liquid film. The spacing between the sphere and the plane, h_0 , is assumed to change quasi-statically.

(a) Noncontact regime (see Fig. 1 (a))

Only the van der Waals force, F_{vdW} , is acting on the sphere and the interaction force, F , is given by $F = F_{vdW}$.

(b) Bridged regime (see Fig. 1 (b))

The interaction force, F , consists of the meniscus force, F_m , and the van der Waals force acting through the liquid, $F_{vdW_{liq}}$, and is given by $F = F_m + F_{vdW_{liq}}$.

(c) Solid contact regime (see Fig. 1 (c))

The interaction force, F , consists of the repulsive contact force, F_{cr} , the adhesion force, F_{ad} , and the meniscus force, F_m , i.e., $F = F_{cr} + F_{ad} + F_m$.

III. Modeling of Liquid Meniscus Bridge

When the spacing becomes small quasi-statically in the noncontact regime (Fig. 1 (a)), the van der Waals attractive force acting on the liquid film surface increases, and consequently, instability of the liquid film surface occurs in the vicinity of the minimum spacing between solids. The liquid meniscus bridge can be formed because of the instability at the spacing of about two times of the liquid film thickness [2].

The Laplace pressure, p_{Lap} , and the disjoining pressure, p_{dis} , are assumed to be balanced in this model, i.e., $p_{Lap} = p_{dis}$. Using the geometrical relationship, we can obtain a meniscus shape equation which gives the filling angle ϕ (see Fig. 1 (b) and (c)). The spacing at the break of the liquid meniscus bridge, $h_{0,b}$, is also obtained from the meniscus shape equation.

Once the meniscus shape is obtained, the meniscus force, F_m , can be calculated by $F_m = F_{Lap} + F_{cap}$, where F_{Lap} is the Laplace force and F_{cap} is the capillary force.

IV. van der Waals force and Contact Force

The corrected van der Waals pressure equation between multilayers which has been proposed by the authors [3] is used to calculate the van der Waals forces F_{vdW} and $F_{vdW_{liq}}$.

The repulsive contact force, F_{cr} , is calculated from well-known Hertz theory, and the adhesion force, F_{ad} , is calculated from the DMT contact model [4].

V. Results

Figure 2 shows the relationship between the minimum spacing, h_0 , and the interaction force, F , where the liquid film thickness $T = 1$ nm, surface tension of the liquid $\gamma_L = 24$ mN/m, radius of curvature of the sphere $R = 5$ μ m, and contact angle $\theta_0 = 0$ rad. In the approach process, the liquid meniscus bridge is formed at point B because of the instability of the liquid film. The contact between solids occurs at point D. In the withdrawal process, the solid conjunction breaks abruptly at point F. The liquid meniscus bridge is elongated to point H and the meniscus bridge is broken. This result qualitatively agrees with experimental results obtained by the AFM [5]. Moreover, two hysteresis are found; the first comes from the adhesion of the solid and the second comes from the liquid meniscus bridge.

Density Dependence of Carbon/Magnetic layer for Corrosion/Scratch Resistance on Head-Disk-Interface.

H. Tani, M. Shoda

Head media interface technology, Hitachi Global Storage Technologies Japan, Fujisawa-shi, Japan

1. Introduction

Perpendicular magnetic recording (PMR) disks have increased areal recording density. Generally, PMR disks have the different structure and layer materials including corrosive elements from longitudinal magnetic recording (LMR) disks. Typically, PMR disks have granular magnetic layer with oxide (e.g. SiOx), and soft under layer with soft magnetic metal (e.g. Co, Fe). So, there are some studies about the corrosion behavior of the magnetic disks (1)-(3). On the other hand, scratch resistant of magnetic disks depends on the layered structure of disk (4)-(6).

In this work, we studied about the relationship between the corrosion / scratch resistance and the relative density carbon / magnetic layer derived by TEM-EELS (Electron Energy Loss Spectroscopy). Corrosive metal element extracted on the surface from layers under carbon overcoat generally (3). Scratch damage is affected by the deformation of surface layer and subsurface layer (6). We have suspected the density of carbon overcoat and upper magnetic layer affects both resistance, and we analyzed the relationship between the relative density of both layers and both resistance.

2. Experiment

EELS is the spectroscopic analysis method of electron energy loss through material. Incident electrons generate plasmon by interaction with electrons in material. Transmitted electrons loss energy as same as the energy of the plasmon and we can observe the plasmon energy loss peak. This plasmon energy can be described in the equation (1), where N_e is the valence electron density, ϵ_0 is the vacuum dielectric function, and m^* is the electron "effective mass", m being the free-electron mass. The mass density is derived from the valence electron density N_e by assuming the composition of material is same. We can compare the relative density of each layer of disks by plasmon loss energy spectra as shown in Fig. 1.

3. Results and Discussions

The relationship between corrosion count and plasmon peak energy of COC / upper-mag. layer was studied. Disks with worse corrosion counts had smaller plasmon peak energy of upper-mag. layer. This result must show the density of COC and upper-mag. layer relates with corrosion property, because higher density COC or upper-mag. layer should reduce corrosive metal extraction to disk surface. Next, we evaluated scratch resistance of several disk samples by the particle injection test. These disks were made by the several process conditions. Figure 2 shows the relationship between the scratch count and the plasmon peak energy of up-mag. layer. We can find the scratch count shows good correlation with the plasmon peak energy of upper-mag. layer, but no correlation with the one of COC. These results suggest that the density of upper-mag. layer is more effective for the scratch resistance than the density of COC. PMR disks have granular magnetic layer with segregated oxide, so the segregated oxide should reduce Young modulus along longitudinal direction, because an oxide has the low modulus, generally. And we suspected PMR disks with granular magnetic layer showed poor scratch resistance, because the magnetic layer deformation was larger.

Crystal structure as an origin of high anisotropy field of FeCoB films with Ru underlayer.

A. Hashimoto¹, K. Hirata¹, T. Matsui¹, S. Saito², S. Nakagawa¹

1. Dept. of Physical Electronics, Tokyo Institute of Technology, Tokyo, Japan; 2. Electronic Engineering, Tohoku University, Sendai, Japan

Introduction

Soft magnetic films with high saturation magnetization M_s are promising candidate for storage and high frequency communication devices. A lot of studies on FeCo-based alloy films with high M_s have been demonstrated and FeCoB was found to be a material with low coercivity H_c and high M_s . Further to these parameter, anisotropy field H_k is also a significant parameter to attain high ferromagnetic resonance frequency $f_r = \gamma(H_k M_s)^{1/2}/2\pi$, where γ is gyro magnetic ratio. It has been reported that FeCoB films fabricated with certain deposition method exhibited remarkably high H_k above 200 Oe [1,2]. While soft magnetic properties are frequently discussed, origins of the remarkable high H_k are not well understood. In this paper, the crystal structure in FeCoB layer possessing very high H_k of 500 Oe was examined by X-Ray diffraction and the origin of high H_k was investigated.

Experimental

FeCoB and Ru layers were deposited on glass substrates by DC facing targets sputtering at room temperature, from pure Ru target and $\text{Fe}_{67.2}\text{Co}_{28.8}\text{B}_4$ alloy targets. The thickness of Ru and FeCoB layers were 5 nm and 200 nm. Ar gas pressure for them in deposition processes were 6 mTorr and 1 mTorr, respectively. Magnetic properties were measured with a vibrating sample magnetometer (VSM) and the crystallographic analysis were performed by X-Ray Diffraction (XRD) with Cu-K α radiation. XRD patterns were measured in out-of-plane direction to substrate plane and also in-plane direction for various in-plane rotating angle ϕ .

Results and Discussion

M-H curves of a single FeCoB (200 nm) film directly deposited on a substrate are shown in Fig.1(a). Coercivity for easy axis, $H_{c,EA} = 130$ Oe and that for hard axis, $H_{c,HA} = 100$ Oe, respectively. The curves indicated little magnetic anisotropy but it was insufficient to assess anisotropy field H_k . In contrast, the magnetization curves of substrate/Ru(5 nm)/FeCoB(200 nm) film shown in Fig.1(b) exhibited good soft magnetic properties of $H_{c,EA} = 14$ Oe and $H_{c,HA} = 2.2$ Oe and clear uniaxial magnetic anisotropy with H_k of 500 Oe. Easy axis aligns parallel to the facing direction of FeCoB targets, i.e. the direction related with the oblique incidence of dominant sputtering particles. Out-of-plane XRD patterns of both samples indicated only (110) diffraction line of bcc-FeCo crystallite. By contrast, in-plane XRD patterns of them revealed the difference in 2θ diffraction. Fig.2 shows the in-plane XRD patterns of the Ru/FeCoB film for various measurement angle ϕ , defined from the easy axis direction as indicated in the inset. The (110) diffraction line of the high- H_k Ru/FeCoB film gradually expanded as the angle ϕ increased from 0 to 90 deg., whereas low H_k FeCoB film showed no difference in the diffraction patterns for all angles ϕ . The results indicate that the lattice spacing of FeCo(110) $d_{(110),\text{in-plane}}$ of the Ru/FeCoB film along easy axis direction, which corresponded to the facing direction of FeCoB targets, was larger than that along hard axis direction. The expansion ratio was about 0.5 %. It was also observed that the in-plane (200) diffraction was observed in the direction of ϕ of 0 deg., while the (200) diffraction disappeared in the direction of ϕ of 90 deg. These diffraction patterns imply that an alignment of bcc-based crystallites and a distortion of the unit cell by the internal stress can be schematically illustrated as shown in Fig.3. Basically, the high- H_k film consists of Fe based bcc crystallites. The majority of the cubic unit cells aligns with their $\langle 100 \rangle$ axis transversely to the easy axis and their (110) plane parallel to the film plane. Furthermore, a compressive stress in the film causes distortion of the unit cell, such

as the increase of $d_{(110),\text{in-plane}}$ along the easy axis direction, while the expansion of $d_{(100),\text{in-plane}}$ along the direction transversely to the easy axis is not changed so much. The strain in the distorted cubic model gave the calculated magnetoelastic energy E_{elastic} of 3.8×10^5 erg/cc with measured saturation magnetostriction constant of $\lambda_s = 3.2 \times 10^{-5}$. The E_{elastic} is equivalent to the H_k of 470 Oe which is in good agreement with the measured H_k of 500 Oe.

In conclusion, textured FeCo crystallites as explained above can possibly involve anisotropic magnetoelastic energy which induces the high magnetic anisotropy field H_k in a certain direction.

Introduction

Fe₃Pt related alloys with L12 superlattice have been studied due to their interesting characteristics, such as martensitic transformation [1] and invar structure [2]. In Fe₃Pt thin film system, the excellent soft magnetic properties and magnetic anisotropy were developed recently for application of soft-hard (Fe₃Pt-FePt) exchange spring magnets [3] and recording media [4], respectively. However, the magnetic properties and crystallographic structure of isotropic L12 Fe₃Pt films were seldom reported. In this paper, the disorder-ordered transformation and resultant properties of sputtered Fe₃Pt thin films were investigated by manipulating Fe content, annealing temperature and heating process.

Experimental

Fe_{100-x}Pt_x (x = 20, 25 and 30) thin films were fabricated by rf magnetron sputtering with background vacuum better than 2.0×10^{-7} torr. A composite FePt target was made by overlaying a high-purity (99.99%) iron disk with Pt foils (99.99%). Thin films were annealed at 300-700°C by post-annealing or in-situ annealing. Crystallographic structure was identified by x-ray diffraction using Cu K α radiation. Film thickness was fixed at 51.8 ± 0.5 nm using x-ray reflectivity (XRR) technique. Magnetic properties were measured with a vibrating sample magnetometer (VSM) under a maximum applied field of 12 kOe. Stoichiometric compositions were confirmed by inductively coupled plasma spectroscopy.

Results and Discussion

X-ray diffraction patterns of the Fe₇₅Pt₂₅ samples as a function of annealing temperatures (25~700°C) are shown in Figure 1-(a). Only fundamental (111) reflection can be observed for as-deposited sample, indicating a chemically disordered structure. For films post-annealed above 500°C, the superlattice reflections appear, displaying chemically ordered structure. Moreover, we observed the symmetric profile of (200) reflections in ordered samples, which can be referred to fcc structure. The ordering parameter is close to unity, determined by the integral intensity ratio, indicating a purely ordered fcc Fe₃Pt phase for samples post-annealed at 700°C. X-ray diffraction patterns of Fe_{100-x}Pt_x (x = 20, 25, 30) thin films post annealed at 700°C are shown in Fig. 1-(b). Similar ordered diffraction pattern was found in Fe₇₅Pt₂₅ films. However, for the Fe-rich Fe₈₀Pt₂₀ sample, only disordered reflections were observed.

Hysteresis loops of Fe_{100-x}Pt_x (x = 20, 25, and 30) thin films post-annealed at 700°C are illustrated in Fig. 2-(a). For Fe₇₅Pt₂₅ and Fe₇₀Pt₃₀ samples, the magnetically soft properties with magnetization of 1270 emu/cm³ and coercivity of about 50 Oe were obtained. However, the Fe₈₀Pt₂₀ samples exhibits a paramagnetic properties. Figure 2-(b). shows the hysteresis loops of Fe₇₅Pt₂₅ samples annealed at 700°C by in-situ annealing and by post-annealing, respectively. Comparing to post-annealing sample, the thin films with in-situ annealing present a hard magnetic properties with coercivity of 2.4 kOe, which can responsible to the formation of L10 FePt phase leading to an asymmetrical (200) reflection confirmed by XRD (not shown). This will be discussed in full paper. From the above data, we summarize the results: (i) Threshold temperature of fcc L12 ordered Fe₃Pt phase should be above 500°C, higher than that of L10 ordered FePt phase. (ii) Samples with highly ordered fcc Fe₃Pt phase exhibit magnetically soft properties. (iii) The samples with exceed-

ing Fe content which seems to restrain the formation of ordered Fe₃Pt phase, exhibit paramagnetic properties. (iv) Post-annealing appears to be necessary for formation of pure ordered Fe₃Pt phase, similar to FePt/Fe₃O₄ nanoparticle systems [5].

Suppression Of Sm Segregation And Improvement In Thermal Stability By Introducing Ru Underlayer In Co-Sm Amorphous Films.

K. Ikeda^{1,2}, T. Suzuki¹, T. Sato²

1. R&D center, Taiyo Yuden Co., Ltd., Gunma, Japan; 2. Spin device technology center, Shinshu University, Nagano, Japan

Introduction

We have reported that Co-Sm amorphous magnetic films show a large anisotropic magnetic field (H_k) due to the large magnetocrystalline anisotropy of 3d transition metals and rare-earth metal alloys. However, H_k decreases with an increase in the annealing temperature, depending on the crystallization and its closely related phase separation. The deterioration of H_k can be reduced by introducing a Ru underlayer, which effectively improves the various magnetic properties. In order to analyze the effect of the Ru underlayer, we have evaluated the interface structure of Co-Sm films by high-resolution transmission electron microscopy (HR-TEM).

Experimental

Co-Sm magnetic films with a Ru underlayer were deposited on a surface-oxidized silicon substrate by using inductively coupled radio frequency sputtering systems at room temperature. During the deposition, a magnetic field of 100 Oe was applied parallel to the film plane in order to introduce an in-plane uniaxial magnetic anisotropy. The structures of the films were evaluated by HR-TEM. The magnetization curves were measured by using a VSM. The Co-Sm films were annealed from 250 to 600 degrees C. in vacuum without a magnetic field.

Results and discussion

Figure 1 shows the dependence of H_k of the Co-Sm film (with a Sm content of 7 at.%) on the annealing temperature with and without the Ru underlayer. H_k decreases with an increase in the annealing temperature and almost vanishes at 600 degrees C. However, the H_k value of Co-Sm films with the Ru underlayer annealed at temperatures ranging from 250 to 450 degrees C. is larger than that of the films annealed at the corresponding temperatures without the underlayer films, indicating the effect of the underlayer on the suppression of H_k deterioration with annealing. The cross-sectional HR-TEM images of the Co-Sm films (as-deposited and annealed at 350 degrees C.) are shown in Fig. 2 (with the Ru underlayer) and Fig. 3 (without the underlayer). The Co-Sm film with the Ru underlayer exhibits an amorphous-like contrast without the distinct lattice image despite the annealing (Figs. 2a and b). On the other hand, in the as-deposited Co-Sm film without the underlayer, the existence of a very small Sm-related crystalline precipitation is confirmed by a Fourier-transformed image at the Co-Sm film/SiO₂ interface (Fig. 3a); further, nanosized crystalline Co and Sm₂O₃ phases are present at the interface in the film annealed at 350 degrees C. (Fig. 3b). Such thermally induced phase-separations and the following crystallization of the separated phases can be attributed to the instability of the Sm atoms soluble in the Co metal matrix and the resultant Sm segregation due to a significant difference in their atomic radii; this is one of the reasons for the H_k deterioration during annealing. Although the phase-separation and crystallization are enhanced especially at the interface of without underlayer as clearly confirmed by TEM, the gradual undetectable change in nanometer scale with annealing, such as phase separation and atomistic ordering, is expected to occur in the entire film bulk and can also contribute to the H_k deterioration. Actually, independent of the Ru underlayer insertion, the Co-Sm films annealed at 600 degrees C. were observed to be completely crystallized and show almost zero anisotropy magnetic fields. Within the heat-treatment temperature range below 350 degrees C., the Ru underlayer

effectively prevents the preferential segregation of Sm at the interface, consequently suppressing the thermally induced degradation of H_k in the Co-Sm films.

Magnetic properties of FeCo films prepared by hydrogenous gas reactive sputtering.

X. Liu¹, A. Morisako²

1. Department of Information Engineering, Shinshu University, Nagano, Japan; 2. Spin device technology center, Shinshu University, Nagano, Japan

Soft magnetic thin films with high saturation magnetization are required for magnetic head materials in order to saturate the highly coercive media. The $\text{Fe}_{1-x}\text{Co}_x$ ($0.3 \leq x \leq 0.4$), alloy has the highest saturation flux density of $4\pi M_s \geq 24$ kG in nature [1]. Much effort has been taken to introduce soft magnetic properties in FeCo thin films [2]-[4]. Additives have been considered to be an effective method because suitable additives can reduce the grain size or control the resistivity [5]. So far, additives that induce soft magnetic properties are AlO, N, etc [5],[6]. However, not all the additives can induce soft magnetic properties in FeCo thin films.

In this experiment, additive of C was introduced into the films by two processes; the first is the convenient process of co-sputtering. The second is introducing hydrogenous gas, such as acetylene into the chamber during sputtering. The magnetic properties of the films prepared by the two processes were compared. It is found that films with $4\pi M_s$ of 23.5 kG and coercivities as small as 1 Oe can be prepared by hydrogenous gas reactive sputtering. While films prepared by co-sputtering have coercivities larger than 40 Oe.

Thin films were prepared by a facing target sputtering system. In the case of co-sputtering, carbon chips were placed onto the FeCo targets. In the case of gas reactive sputtering, acetylene gas was introduced into the chamber. The amount of carbon addition was controlled by the acetylene gas partial pressure for the latter case. For both case, the base pressure of the system is better than 1×10^{-6} Torr.

Transmission electron microscopy results show the grain size of the FeCo films decrease with the increase of carbon addition for both processes. Fig. 1 shows the dependence of magnetization on the acetylene gas partial pressure (a) and the dependence of magnetization on the carbon composition prepared by co-sputtering (b). Of particular interest is that as shown in Fig. 1(a), magnetization of films prepared by gas reactive sputtering first increase slightly then decrease dramatically with the increase of acetylene gas partial pressure. However, magnetization of films prepared by co-sputtering, as shown in Fig. 1(b), almost decrease linearly with the increase of the amount of carbon addition.

All the films show in-plane anisotropic magnetic properties with the magnetic easy axis along the stray field direction. The stray field is due to the magnet behind the target. Fig. 2 shows the dependence of coercivity on the acetylene partial pressure (a) and the dependence of carbon composition for films prepared by co-sputtering (b). It is found that coercivity decrease with the increase of carbon addition for both films. However, films prepared by gas reactive sputtering show coercivity minimum of about 1 Oe in both easy and hard axis directions. While films prepared by co-sputtering show coercivity larger than 40 Oe in both easy and hard axis directions.

X-ray photoelectron spectroscopy results show films sputtered without hydrogenous gas have impurities of oxygen of about 4 at%. However, oxygen free films can be prepared by introducing hydrogenous gas into the chamber during the sputtering process. This result can explain the results as shown in Fig. 1 (a).

In conclusion, we have compared the magnetic properties of C doped FeCo films prepared by hydrogenous gas reactive sputtering and co-sputtering. Films with $4\pi M_s$ of 23.5 kG and coercivities as small as 1 Oe can be prepared by hydrogenous gas reactive sputtering. XPS results show that

oxygen free FeCo films can be prepared by reactive sputtering of hydrogenous gas. While films deposited by co-sputtering have impurities of oxygen as large as 4 at%.

Nanocrystalline permalloy thin films obtained by nitrogen IBAD.

P. Prieto¹, J. Camarero², J. F. Marco³, E. Jimenez², J. M. Benayas¹, J. M. Sanz¹

1. Física Aplicada, Universidad Autónoma de Madrid, Madrid, Spain; 2. Física de la Materia Condensada, Universidad Autónoma de Madrid, Madrid, Spain; 3. Instituto de Química Física Rocasolano, CSIC, Madrid, Spain

Permalloy (Fe₂₀Ni₈₀) is well known due to its magnetic properties of high permeability, low coercivity, and small magnetic anisotropy and for its wide use in magnetic recording and sensor industry. Nevertheless, to improve the performance of the permalloy based devices a further optimization of its magnetic properties is required. Several efforts have been performed to optimize the magnetic properties of permalloy thin films by patterning the films or by adding a third element to the FeNi system.

It is also well known that the incorporation of nitrogen by sputtering process on metals induce the formation of fine-grained structures. In the case of Fe, the incorporation of small amount of nitrogen results in a ferromagnetic compound (α' -Fe₃N) with higher magnetic induction and lower coercivity than that of pure α -Fe. In this work we pretend to study the structural changes and the corresponding magnetic effects induced by nitrogen bombardment of Fe₂₀Ni₈₀ during its deposition. With this aim nanocrystalline Fe₂₀Ni₈₀-N films have been deposited on Si (100) substrates at 200°C using a dual ion beam sputtering system. A Fe₂₀Ni₈₀ target has been sputtered with Ar⁺ ions of 500 eV whereas the film is bombarded simultaneously with a controlled mixture of Ar⁺ and N₂⁺ ions of 55 eV energy.

The structure of the films was analyzed using X-Ray diffraction (XRD) at a grazing incidence. The line width at half maximum of the diffraction peaks has been used to estimate the crystallite size using the Scherrer relationship. We have observed a broadening of the diffraction peaks related to the growth of smaller crystallites when the films are bombarded. The composition of the thin films has been studied in terms of resonant RBS. Integral Conversion Electron Mössbauer Spectroscopy (ICEMS) have been used to characterize the deposited films in terms of the grown phases and hyperfine interactions. The magnetic properties were investigated by using vectorial Kerr magnetometry at room temperature.

The ICESM spectra have been recorded in Fig.1 for the non-assisted films as well as for two Fe₂₀Ni₈₀ thin films assisted with 33 and 50% N₂⁺ ions. The spectrum of the non-assisted permalloy film shows a sextet with broad lines that was satisfactorily fitted with a hyperfine magnetic field distribution with a maximum located at 27.5 T. The spectrum recorded for the assisted films is very similar to the previous one, although the distribution is slightly narrower and the maximum of the distribution shifted to smaller values (27.1 and 26.0 T for 33% and 50% N₂⁺ assisted films respectively). The spectrum recorded from the 50%N₂⁺ assisted thin film, in addition to the magnetic sextet pattern, shows also a small paramagnetic doublet (13% of the total spectral area) that can be related with the formation of γ' -(Fe_{0.2}Ni_{0.8})₄N. The small decrease in the magnitude of the hyperfine magnetic field might be due to the presence of some interstitial nitrogen atoms within the permalloy lattice in good agreement with the nitrogen content ($\approx 10\%$ at.) estimated by RBS for this last film.

In-plane magnetization components have been measured to determine the magnetic anisotropy and the magnetization reversal process. Fig.2 shows the easy axis M-H loops for the same films as in previous figures but including the results for that assisted with 25% N₂⁺. It is interesting to observe that those films assisted with 25% N₂⁺ and 33% N₂⁺ reduce the coercive field at the easy axis up to values of 0.19 mT and 0.36 mT respectively with respect to the non-assisted permalloy (i.e.

0.50 mT). On the contrary, the incorporation of excess of nitrogen in the film due to the use of a higher concentration of N₂⁺ ions (i.e. 50%) in the assistant beam, causes an increase of the coercive field up to 1.5 mT, well above that obtained for the non-assisted film. This is probably related with the small amount of paramagnetic γ' -(Fe_{0.2}Ni_{0.8})₄N found to be present by ICEMS in that film.

In summary we conclude that the soft magnetic properties of permalloy thin films are improved after nanocrystallization by the use of low concentrations of N₂⁺ ions in the assistant beam. However, when the nitrogen is incorporated forming a paramagnetic nitride the soft magnetic properties start to degrade.

The demand of the world market leads to magnetic data storage device advancing towards much smaller dimension and higher capacity.[1] In order to achieve a high capacity in a miniature device, an ultra-soft and high magnetic moment material is required for producing high saturation flux density (Bs), so that the necessary flux densities can be preserved on reducing device dimensions, while simultaneously achieving a low coercivity (Hc) to match the high recording density of magnetic media with high Hc.[2] Although a lot of soft or high Bs magnetic films have been achieved via sputtering, evaporation, and casting, most of them cannot be applied to the fabrication of commercial device.[1,3] Electrodeposition is a simple method to achieve various thickness of soft Fe-based materials.[2] But preventing Fe²⁺ from oxidation into Fe³⁺ (which decreases Bs) and minimizing Hc of the metal films are challenges via electrodeposition, hence an ultra-soft (Hc < 5 Oe) magnetic film with high magnetic moment [Bs > 2.4 Tesla (T)] is yet to be achieved.[1] Herein, we report a approach to fabricating ultra-soft magnetic CoFe films from a sulfate salt based solution containing dimethylamine borane (B-reducer) via electrodeposition. In comparison to commonly used strong acidic solutions (pH = 2.4 – 2.8) which contain S-additives (saccharin, Na Lauryl sulfate, etc), the solution containing B-reducer is a semi-neutral medium and has larger process latitude (pH = 3.5 – 4.8). It also does not need a salt-bridge (leading to low efficiency of current) to protect Fe²⁺ from oxidation. The measurements through AFM show that the thickness of the prepared films ranges from tens of nanometers to micrometers. The magnetic characterizations using VSM and SQUID show that the films possess very soft magnetic property with a Hce and Hch of 6.5 and 2.9 Oe, respectively. The films have a high saturation magnetization of ~2.45 T and good anisotropy.

The CoFe films were electrodeposited on 25 nm CoFe/Si(100) wafers. The Fe_xCo_{100-x} (x = 55 – 68) films were fabricated at the temperature of ~40 cel. deg. from a solution of 0.07 mol/l CoSO₄·7H₂O, 0.10 mol/l FeSO₄·7H₂O, 0.5 mol/l NH₄Cl, 0.5 mol/l H₃BO₃, and 2.8 – 3.2 g/l of B-reducer additive. The electroplating system used was a Paddle-Cell with pulse DC power. The atom ratio of Co to Fe in the electrodeposited films was determined by EDS.

Table 1 shows that the addition of B-reducer dramatically decreases the Hc and increases the Bs of Co₄₀Fe₆₀ film (deposited from a current density of 6.0 mA/cm²). The Hce and Hch decreases from 63 and 53 to 6.5 and 2.9 Oe, respectively, while Bs increases from 1.4 to 2.4 T with B-reducer concentration increasing from 0.0 to 3.0 g/l in the electroplating solution. Figure 1 shows that the magnetization curves of the CoFe films from the solutions containing different concentration of B-reducer. It appears that magnetic anisotropy of the films increases with the increase of B-reducer content. Despite no salt-bridge to prevent Fe²⁺ from oxidation for the solution containing B-reducer, the achieved Bs are still very high and the Hc of the CoFe films are much smaller than these obtained from the solution containing S-additive. It is because B-reducer can reduce Fe³⁺ (produced during plating) back into Fe²⁺, which results in a very low content of oxygen in the deposited film. XRD analysis in Figure 2 shows that the added B-reducer leads to a texture structure change of the Co₄₀Fe₆₀ film from CoFe(110) and Fe₂O₃(209) polycrystalline to CoFe(110) single-crystalline. As a result, the film possesses better anisotropy and its Hc dropped drastically while Bs achieved a high level. Further experiments revealed that too much (> 9 g/l) of B-reducer

led to an unstable plating solution. Besides having excellent magnetic properties, our characterizations (in Table 2) indicate that the CoFe films were also good in mechanical and other properties, such as very low surface roughness (Ra) and magnetostriction (λ_s). Thus, the films have potential applications in future ultra-high density and frequency magnetic recording system, biotechnological, and microelectronic devices.[1,3]

Soft-magnetic CoNiFeP alloy films for high frequency applications.

F. M. Rhen, S. Roy

Microsystems Center, Tyndall National Institute, Cork, Ireland

The research in high moment alloy films for high frequency has mostly been driven by applications in magnetic recording heads, microinductors, microtransformers, radars and EMI noise reduction. The basic requirements for materials for high frequency applications are high magnetization saturation, low coercivity, high anisotropy field and high resistivity. High saturation magnetization required for application such as magnetic recording head is to be able to write on magnetic memory elements with high coercivity resulting in higher information density. In case of microfabricated inductors/transformers high saturation magnetization is required to achieve high power density and current handling capability. The most attractive alloy investigated to date is CoNiFe[1], which shows saturation magnetization as high as 2.1 T [2,3]. However, due to low resistivity of CoNiFe (25 $\mu\Omega$ cm) the thickness is limited to submicron when higher operation frequency is required (>100 MHz).

Several approaches have been undertaken to increase resistivity, including the incorporation of sulphur [4,5], and carbon [6] into the deposits. However, these additives also tend to reduce the saturation magnetization. Here, we study the effect of P addition to CoNiFe alloy and its effect on high frequency performance of CoNiFe. We show that films as thick as 10 μm have flat permeability response up to GHz range. The operating frequency is only limited by ferromagnetic resonance of the alloy, which is about 3 GHz (figure 1) depending on the P content.

Spin re-orientation transition in amorphous FeBSi thin-films submitted to thermal treatments.

P. Tiberto, F. Celegato, M. Coisson, F. Vinai
INRIM, Torino, Italy

Ultrathin ferromagnetic films displaying perpendicular anisotropy have been extensively studied in the last decades for practical application in high-density magnetic recording. The magnetic anisotropy governing magnetisation directions is usually strongly dependent on the microstructure and its optimisation turns out to play a key role for thin films application in storage devices [1]. In this frame, magnetic thin films have been obtained by means of RF sputtering technique on Si_3N_4 substrates from a $\text{Fe}_{78}\text{B}_{13}\text{Si}_9$ target. Samples having thickness ranging in the interval 25-300 nm have been produced. X-ray diffraction data indicate that the films have different microstructures varying from fully amorphous to partially nanocrystalline with increasing thickness. In order to relieve the quenched-in stresses during the sputtering, the as-prepared films have been submitted to isothermal furnace annealing in vacuum for temperature varying in the interval 200 – 325 °C. Room-temperature magnetic hysteresis loops have been measured by means of vibrating sample magnetometry on all studied samples. A tailorable spin reorientation transition (SRT) from in-plane single domain-like to out-of-plane multidomain state with increasing film thickness has been observed for samples having thickness higher than 80 nm. These samples are characterised by a two-slope hysteresis loops: a first steep magnetisation jump followed by a linear behavior between remanence and saturation. The lower slope occurring before saturation is related to the development of a perpendicular anisotropy component marking the occurrence of a spin reorientation transition. The magnetic field H_k at which the saturation is reached is connected with the perpendicular anisotropy. Magnetic force microscopy images have been obtained for all studied samples indicating that for films having thickness lower than 80 nm the magnetisation lies in the film plane. Films having higher thickness and displaying the two-slope hysteresis loops exhibit a stripe domains patterns. The domain width increases on samples with a smaller perpendicular anisotropy value, as expected.

In this work, spin reorientation transition have been studied as a function of sample thickness and perpendicular anisotropy. In particular, the effect of furnace annealing on the transition from in-plane to an out-of-plane configuration will be highlighted. Selected in-plane hysteresis loops of the as-prepared and annealed films having thickness 300 nm are reported as an example in Fig. 1. As it can be clearly observed, the magnetisation behavior indicates an evolution from a out-of-plane configuration towards an in plane magnetisation behavior with increasing annealing temperature. Magnetic domain structures of selected samples, whose hysteresis loops are shown in Fig. 1, are reported in Fig. 2 confirming that the complete relief of quenched-in stresses leads to a in-plane magnetisation behavior.

fujitsu ltd, Nagano, Japan

Introduction

Perpendicular magnetic recording (PMR) has become the main technology for hard disk drives. For PMR heads in high areal recording density, improvement in overwrite (O/W) and suppression of pole and side-track erasure are required, so high saturation flux density (B_s) and low coercivity (H_c) are demanded in main pole materials. For that purpose, sputtered magnetically soft FeCo multi-layer and electroplated FeCo/non-magnetic NiP laminate films have been studied [1-4]. Main Pole has been fabricated as reverse trapezoid shape or side-shielded heads [1] have been proposed to suppress the side track erasure at skew angle. But it may be difficult to control 3-dimensional shape of the shielded pole having narrow track width. In this paper, we study electroplated $\text{Ni}_x\text{Fe}_{100-x}/\text{FeCo}$ multi-layer films for the main pole material having lower B_s with low H_c in the leading edge and higher B_s in the trailing edge. We investigate their magnetic properties and crystal structure and designed the materials for the main pole.

Experiment

The electroplated $[\text{Ni}_x\text{Fe}_{100-x}/\text{FeCo}]_2$ films were deposited on a sputtered ruthenium under layer with random crystalline orientation. The electroplated $\text{Ni}_x\text{Fe}_{100-x}$ films were deposited by DC and pulse current in nickel iron electroplating bath. The electroplated FeCo films were deposited by pulse current in iron cobalt electroplating bath. Fig. 1 shows a cross-sectional illustration of $[\text{Ni}_x\text{Fe}_{100-x}/\text{FeCo}]_2$ films. Total thickness was fixed in the range from 350 to 500 nm. The composition and thickness of electroplated films were determined by the measurements of X-ray fluorescence (XRF). The in-plane magnetization curves, H_c , and H_k were measured using a B-H loop tracer. B_s was measured at room temperature using the Superconducting-Quantum-Interference-Device (SQUID). The crystal structures of electroplated films were measured using X-ray diffraction (XRD).

Results and discussion

Fig. 2 shows $\text{Ni}_x\text{Fe}_{100-x}/(\text{Ni}_x\text{Fe}_{100-x}+\text{FeCo})$ thickness rate dependences of H_c in electroplated $[\text{Ni}_x\text{Fe}_{100-x}/\text{FeCo}]_2$ films with various Ni compositions. H_c decreased dramatically in slight NiFe thickness rate and saturated above the ratio of about 50% in electroplated $[\text{Ni}_{35}\text{Fe}_{65}, \text{Ni}_{50}\text{Fe}_{50}, \text{Ni}_{80}\text{Fe}_{20}/\text{FeCo}]_2$ films, whereas it decreased linearly with increasing the NiFe thickness rate in electroplated $[\text{Ni}_{10}\text{Fe}_{90}/\text{FeCo}]_2$ films. It seems that this drastic decrease in H_c is caused not only by exchange coupling between FeCo and $\text{Ni}_{35-80}\text{Fe}_{65-20}$, but also by improvement of the crystalline structure and the reduction of the grain size in electroplated FeCo films on electroplated $\text{Ni}_{35-80}\text{Fe}_{65-20}$ films, because crystal structure contributes to reduction of H_c for easy and hard axis [5].

Conclusions

We have investigated the magnetic properties of electroplated $[\text{Ni}_x\text{Fe}_{100-x}/\text{FeCo}]_2$ multi-layer films for perpendicular write heads in high areal recording density, and found that H_c can be dramatically decreased in electroplated $[\text{Ni}_{35-80}\text{Fe}/\text{FeCo}]_2$ films. These multi-layers are expected to suppress the pole and side-track erasure and improve the O/W in narrow track width when used in perpendicular write heads.

High temperature electrodeposited multilayer amorphous alloy suitable for integrated inductors.

P. McCloskey¹, B. Jamieson¹, T. O'Donnell¹, D. Gardner², M. Morris³, S. Roy¹

1. Microsystems Center, Tyndall National Institute, Cork, Ireland; 2. Circuit Research lab, INTEL Corporation, Santa Clara, CA; 3. Chemistry department, University College Cork, Cork, Ireland

INTRODUCTION: The integration of on-chip inductors with magnetic materials into silicon process technology has been a major challenge in the move towards monolithic solutions for wireless communications, RF IC circuits, radar, power delivery, and EMI noise reduction [1]. The use of a magnetic core in such devices has the potential to significantly reduce the footprint required but requires a material that gives very low losses when operating at high frequency. Electrodeposited amorphous Co-P alloys have the advantage of both high resistivity and low coercivity and consequently can show both low eddy current loss and low hysteresis loss. However in order to achieve a low coercivity an approach other than simple direct current (DC) electroplating must be employed since plane DC plated films exhibit perpendicular anisotropy and hence very low permeability and high values of coercivity. In order to have in plane anisotropy and low coercivity a multilayer structure of alternating compositions must be created using either pulse reverse plating [2] or pulse plating at two different current densities [3] [4].

The temperature stability of the magnetic properties is an important consideration because of the processing steps involved in fabricating an inductor consisting of a magnetic core that encloses the windings. Oda et al [5] used small additions of Tungsten to improve crystallisation temperature of amorphous FeCoP alloys. Tungsten has a large atomic weight of 183.8 and it is thought that its large atomic radii plays a role in bringing about an increase in crystallization temperature. However electroplating baths containing Tungsten have a considerable tendency to be unstable. Rhenium has an atomic weight of 186.2 and Brenner [6] describes how it can be readily co-deposited with Iron group metals. The present work is concerned with the characterisation of a novel electrodeposited alloy CoPre that shows a considerable improvement in temperature stability in comparison with the normal CoP alloy.

EXPERIMENTAL: Plating baths were prepared with the compositions as given in Table 1. The bath composition used in trial 1, was identical to that used in [2] apart from the additions of KReO₄. This was added progressively 0.1g/l at a time so that in all 7 samples were produced, the first having no KReO₄ addition and the last having an addition of 0.7g/l. In trial 1 the cathode used was 20 µm copper foil. In Trial 2 the effect of changing the Phosphorous content was investigated by varying the quantity of H₃PO₃ between 30 g/l and 65 g/l, while keeping the KReO₄ fixed at 0.7 g/l. In the second trial the material was plated onto Cu foil and onto silicon wafers with a top layer of 500 nm of oxide and a conductive sputtered seed layer consisting of 20 nm Titanium and 200 nm Copper. All the trial 2 samples were plated in the presence of a uniaxial magnetic field of around 200 Oe.

Pulse reverse plating was used in both Trials. In all cases the pulse parameters were kept constant at values found to be optimal for CoP [7]; forward on time, T₁=856 ms, forward current density, CD₁=151 mA/cm², reverse on time, T₂= 52 ms, reverse current density, CD₂=62 mA/cm² and off time, T_{off}=80 ms. DC magnetic characterisation was obtained using an ShB Instruments B-H loop tracer. Complex permeability spectra were measured using a Ryowa PMM9G1 permeameter. EDX was used for compositional analysis. DSC analysis was carried out using a Perkin Elmer Pyris 1.

RESULTS: The addition of the Re salt seemed to have no effect on the appearance of the samples. A selection of the samples produced in Trial 1 were subjected to thermal anneals consisting of a 15 minute ramp, a 30 minute dwell at elevated temperature and a 15 minute cooling.

It can be seen that the 300 C anneal dramatically changed the coercivity of the CoP sample but had very little effect on the coercivity of the CoPre. A similar improvement in thermal stability was obtained for all the CoPre samples tested.

CONCLUSIONS: A new electrodeposited multilayer amorphous alloy, CoPre is reported that shows a significant improvement in the thermal stability of its soft magnetic properties in comparison with CoP. The effect of Phosphorous content on the properties of material is investigated.

Magnetic properties of sputtered permalloy/molibdenum multilayers.

M. Romera¹, M. Maicas¹, R. Ranchal², D. Ciudad¹, E. López², P. Sánchez¹

1. ISOM, Universidad Politécnica de Madrid, Madrid, Spain; 2. Física de Materiales, Universidad Complutense de Madrid, Madrid, Spain

Magnetic materials for sensor applications require low internal stress, low coercivity and low magnetostriction while keeping a high permeability [1]. Permalloy (Py: Fe₂₀Ni₈₀) fulfil well with these requirements which makes it a good candidate for magnetic sensor applications. Properties like permeability or linearity of the loops can be controlled by growing Py as a multilayer with alternating perpendicular anisotropies [2]. However for thicknesses over 180 nm sputtered Py films develop perpendicular anisotropy and the magnetic properties degrade notably [3]. Both coercive and saturating fields are nearly 10 times bigger than those measured for thinner films. This anisotropy is induced by the columnar morphology of the sputtered films. Nevertheless, it is possible to obtain low coercivity and high permeability if thick Py films are grown as multilayers with a non-magnetic spacer between magnetic layers. In this work we study the properties of Py films grown as multilayers with thin Molibdenum (Mo) spacers.

The multilayers studied were grown by dc magnetron sputtering and the anisotropy induced was controlled by the angle of incidence of the beam. The anisotropy induced by the deposition angle was measured for a single Py layer (125 nm thick) obtaining an anisotropy constant of $K=1200$ J/m³ which corresponds to an exchange correlation length of 180 nm.

The effect of the sample thickness can be seen in figure 1 which shows the VSM hysteresis loops of Py samples with thicknesses 125, 250 and 375 nm. These loops exhibit quite different behaviour changing from an in-plane anisotropy for the thinner to a clear perpendicular to the plane anisotropy for the others. MFM measurements on the thicker samples show a stripe domain pattern that proves the existence of an anisotropy perpendicular to the sample plane.

A thin Mo spacer of 10 nm results enough to break the magnetic coupling between the Py layers. A Py film with total thickness 250 nm grown as a multilayers with 4 Py layers with Mo (10 nm) spacers was grown. Hysteresis loops show low coercive and saturating fields much lower than those obtained in a Py monolayer with the same thickness (figure 2). The Mo spacer proves to break effectively the magnetic coupling and the columnar morphology maintaining the anisotropy in the plane.

Some authors have found very low coercive field values in Py multilayers for particular thicknesses [3]. In order to study the effect of the thickness in the coercive field of Py/Mo multilayers, 250 nm thick multilayers were grown with a number of Py layers ranging from 2 to 32 with Mo spacers in between. Coercivity was obtained from VSM measurements. Figure 3 shows the coercive field measured as a function of the number of Py layers. A minimum in the coercivity was found for Py layer thicknesses corresponding to 30 nm. This minimum coincides with the transition thickness of a single film where Bloch domain walls change to Néel domain walls. The thickness of Bloch domain walls increases as the Py thickness increases and the thickness of the Néel walls core increases as the Py thickness decreases.

In summary it is observed how the soft magnetic properties of sputtered Py films can be maintained for thicknesses over 180 nm by growing samples as multilayers with thin Mo spacers. The coercivity can be minimized for particular Py thicknesses about 30 nm.

Introduction:

Recently, the amorphous CoFeB is widely used in the MgO-based magnetic tunnel junctions (MTJs) due to its proper magnetic characters. The amorphous CoFeB can also promote the growth of MgO (002), which is very crucial for the high magnetoresistance (MR) ratio. On the other hand, both the magnetic properties and the damping constant (α) of CoFeB are critical factors for spin-transfer or field-switching devices. In this work, we prepared the half-MTJ samples of MgO 1/Co₆₀Fe₂₀B₂₀ 2.5/X 5/Ta 5 (unit:nm) to investigate the properties of CoFeB free layer used in MTJs, where X was Cu, MgO or none. Cu was chosen because it can suppress the spin pumping effect and achieve a low damping constant in the NiFe/Cu bilayer [1]. A low switching current of dual-barrier MTJs was reported and the extra MgO barrier was believed to be the major factor [2], but a systematic study of the MgO effect is still lack. In this work, we study the capping layer effects on properties of CoFeB films after different annealing temperatures.

Experiment results & discussion:

All samples were deposited by using a sputtering system with the base pressure better than 1×10^{-8} Torr. Samples were field-annealed in vacuum ($P < 1 \times 10^{-5}$ Torr) for 2 hours at various temperatures up to 360°C. The α value was obtained from the measurement of the ferromagnetic resonance (FMR) by electron spin resonance (ESR). Magnetic properties were measured by vibrating sample magnetometer (VSM).

A low saturation magnetization M_s of samples of CoFeB/Ta was observed in the as-deposited state, shown in Fig. 1(a), which indicated significant intermixing between Ta and CoFeB layers during deposition. On the other hand, the intermixing seemed to enhance the diffusion of B out of CoFeB for the temperatures up to 300°C, leading to an increase in M_s and reduction of the damping constant [3]. Since the crystallization of CoFeB typically accompanied the increase in coercivity H_c , the almost unchanged H_c up to 300°C annealing, shown in Fig. 1(c), implied the crystallization of CoFeB may not occur until the temperature higher than 300°C. When the annealing temperature reached 360°C, both improvement of crystallinity of CoFeB and serious intermixing occurred, resulting in the slight decrease of M_s and substantial increase of H_c .

High M_s of the as-deposited samples with the insertion of the Cu layer, shown in Fig. 1(a), revealed that the intermixing was suppressed by the capping of Cu. The slight reduction of M_s and almost unchanged H_c were observed after 360°C annealing for samples of CoFeB/Cu/Ta. These results indicated that insertion of a Cu layer would prevent B from diffusing out; therefore, the crystallization of CoFeB might start at temperatures higher than 360°C. In addition, the insertion of a Cu layer led to a low α value even after 360°C annealing, shown in Fig. 1(b). This low α value confirmed that Cu can also suppress the spin-pumping effect in the CoFeB/Cu system, as reported in NiFe/Cu [1]. The limited intermixing also contributed to the low α value. The decrease in M_s and small α may be beneficial to reduce the switching current for spin-transfer devices.

Insulating capping layer, MgO, exhibited quite different behavior from the previous two samples: significantly high M_s and relatively large H_c and α in the as-deposited CoFeB/MgO/Ta samples. MgO capping seemed to completely restrict the intermixing, resulting in high M_s . We expected to observe a low α value due to insulating characteristics of MgO, which should suppress the spin-pumping effect. Other factors may be taken into account to explain the damping behavior. Dramatic

increase of M_s and reduction of α after annealing samples to 300°C were observed, while the H_c change was quite small. It was reported that the diffusion of boron after annealing may form BO_x at the interface of MgO and CoFeB, which diminish FeO_x and CoO_x [4]; therefore, the extra MgO capping layer might substantially speed the diffusion out of B from CoFeB, leading to increase M_s and decrease α . However, the α and H_c raised again accompanied by the decrease of M_s , which may be attributed to the local oxidation of Co or Fe after annealing at 360°C.

In summary, by inserting different capping layers, the α , M_s and H_c of CoFeB can be tuned, which may enable us to adjust the switching current for the spin-transfer devices.

Direct Observation of Barkhausen Avalanches during Nucleation-Mediated Magnetization Reversal on a nanoscale.

M. Im¹, P. Fischer¹, D. Kim², S. Shin³

1. CXRO, LBNL, Berkeley, CA; 2. Department of Physics, Chungbuk National University, Cheongju 361-763, South Korea; 3. Department of Physics and Center for Nanospinics of Spintronic Materials, Korea Advanced Institute of Science and Technology, Daejeon 305-701, South Korea

Since the first discovery of Barkhausen avalanches magnetization reversal phenomena are considered as prototype examples of complex dynamical systems exhibiting non-trivial fluctuations which can be described by well defined scaling behavior [1]. Barkhausen avalanches occur in the magnetization reversal process as discrete and sudden magnetization changes under an external magnetic field. Of fundamental interest are fluctuating quantities such as Barkhausen jump size and duration showing a power-law scaling behavior. Most studies reported so far have been mainly performed by theoretical predictions and indirect probes through a classical inductive technique. Recently, substantial progress was enabled by direct observations of the phenomenon using magnetic microscopies [2]. However, they have been carried out on the micrometer scale and concentrated mainly on the Barkhausen avalanches process during the flexible magnetic domain wall motion.

We investigated the Barkhausen avalanches process under nucleation-mediated magnetization reversal at the nanometer scale utilizing high resolution soft X-ray microscopy at beamline 6.1.2 at the Advanced Light Source in Berkeley CA, which provides a spatial resolution down to 15 nm [3]. Nanogranular CoCrPt alloy thin films which are promising candidates for high-density perpendicular magnetic recording media, were prepared by dc magnetron sputtering at ambient temperature. The magnetic domain configurations were recorded at the Co L3 absorption edge (777eV) with varying applied magnetic fields in full hysteresis cycles. Typical domain configurations taken at applied magnetic fields of +400, +200, 0 Oe in the major hysteresis loop are shown in Fig. 1(a). As demonstrated in the figure the magnetization reversal of the CoCrPt sample is governed by the magnetic domain nucleation process. TEM studies indicate that the nucleation-mediated process of magnetization reversal observed in this system is due to switching of individual grains segregated by higher Cr concentration at grain boundaries. Fig. 1 (b) shows the Barkhausen jump distribution in two-dimensional space, where green and red structures represent the Barkhausen avalanches observed at applied magnetic field of +200 and 0 Oe, respectively. One clearly notes that Barkhausen avalanches vividly illustrate the randomness of size, shape, and location. The random behavior in the locations of the Barkhausen avalanches implies that the numerous pinning sites due to the Cr compositional segregation in this system are randomly distributed and strongly localized. The statistical nature of Barkhausen avalanches was studied by repetitive measurement for magnetic domain configurations at each applied magnetic field of +400, +200, 0 Oe. Through a statistical analysis of jump size from several hundreds of domains, the distributions of Barkhausen jump size are obtained (Fig. 2). They exhibit a non-trivial fluctuation and can be described by power-law scaling distributions of $P(T_0) \sim (T_0)^{-\tau}$ with a scaling exponent ~ 1 . Scaling exponents taken at applied magnetic field of +200 and 0 Oe are found to be identical within the measurement error. They are consistent with theoretical values derived from a random-field Ising model including the effect of long-range dipolar interaction [4]. Our study experimentally supports a long-standing theoretical prediction, namely that long-range dipolar interactions play a decisive roles in the statistical behavior of Barkhausen avalanches in nucleation-mediated magnetization reversal processes

Magnetotransport and exchange-bias in CoCu electrodeposited granular alloys.

M. Plaza¹, L. Perez¹, M. Sánchez¹, A. Fernández-Pacheco^{2,3}, J. de Teresa²

1. Dpt. Física de Materiales, Universidad Complutense de Madrid, Madrid, Spain; 2. Instituto de Ciencia de Materiales de Aragón, CSIC-Universidad de Zaragoza, Zaragoza, Spain; 3. Instituto de Nanociencia de Aragón, Universidad de Zaragoza, Zaragoza, Spain

Granular magnetic materials are composed of ferromagnetic nanoparticles inside a non-magnetic conductive matrix. These materials have been deeply studied due to their interesting properties: giant magnetoresistance (GMR) [1], exchange-bias [2] and superparamagnetic behaviour [3]. The study of these properties has led to the use of granular materials in magnetic sensors and devices [4]. We have produced granular electrodeposited CoCu alloys in powder form using a high current density (~ 10 A/cm²). Electrodeposition was carried out from sulphate-based electrolytes containing 0.5M metal ions and 0.5M boric acid at 20V. The powders were compacted at 120 MPa. A pure Co sample has been also produced following the same procedure.

The figure shows the ω -2 θ XRD scans for Co and Co₁₅Cu₈₅ samples. Whereas Co sample shows the expected hcp structure, all CoCu samples show fcc structure due to the influence of the Cu matrix. The presence of Cu affects also the grain size of the Co clusters, which is significantly lower in CoCu alloys (~ 20 nm) than in pure Co (~ 50 nm). The figure also shows a detail of the Co-fcc(111) and Cu-fcc(111) peaks. The cobalt peak is shifted to lower angles with respect to the normal position (marked by * in the figure) because the Co structure is 0.7% expanded in the Cu matrix.

The thermal evolution of the GMR ratio for three of the studied samples is shown in the right part of the figure. All samples exhibit the same values of GMR at low temperature (1%), whereas, at high temperature, sample Co₁₂Cu₈₈ shows the highest GMR value. At low temperature, scattering at the grain boundaries dominate the GMR effect. Taking into account that all samples present similar structural properties, the same behaviour at low temperature is expected. The thermal dependence of GMR can be fitted with a theoretical calculation based on the model of GMR by Fert et al. [5].

CoCu granular alloys also show exchange bias, most likely due to the antiferromagnetic coupling between the Co clusters and a CoO shell that surrounds them. From these results, comparing with what other authors found in cobalt clusters [2], we suggest that the average particle size may be similar to the grain size (~ 20 nm). Therefore, high-current electrodeposition is a suitable method to produce granular alloys with nanometric ferromagnetic clusters in a non-magnetic metal.

INESC-MN-IN, Lisboa, Portugal; 5. Wolfson Centre for Magnetism, School of Engineering, Cardiff University, Cardiff, United Kingdom

In this paper we describe magnetic thin films prepared by ion beam deposition (Nordiko 3600, INESC-MN) from an alloy target of $(\text{Co}_{70}\text{Fe}_{30})_{80\text{at}\%}\text{B}_{20\text{at}\%}$. The as-deposited films, with thicknesses up to 40 nm, exhibit an amorphous phase and have a spontaneous magnetic moment, as measured by Hall effect, of 1200 emu/cm^3 . An applied field to the substrate, during film growth, induces a uniaxial anisotropy field of 23 Oe, as measured by a B-H loop.

Magnetic flux guides can be used with magnetoresistive sensors to achieve field sensitivities in the picoTesla range and beyond. In those, a non negligible remanent magnetic moment lower the device performance. One way to accomplish null remanent magnetic field in the gap of flux guides consists in integrating a thin, suitable spacer, between two physically identical ferromagnetic layers to provide a long range interlayer antiferromagnetic coupling between the two [1-2] and forming hence a synthetic antiferromagnet [3]. For our purpose, we use thick ferromagnetic layers with a total magnetic thickness in the range of a few hundreds of nanometers, but with high permeability. Ion beam deposition (IBD) is a suitable technique to produce antiferromagnetically coupled films with very smooth interfaces [4], having stabilized single-domain states in the ferromagnetic layers, while maintaining adequate rotational permeability.

The CoFeB has the advantage of having higher spontaneous magnetization than either Permalloy or Co-Zr-Nb (CZN) amorphous alloy, and can have to some degree partial homogeneously distributed crystalline phase by using a suitable buffer layer of Ta 2nm/Ru t_{Ru} . This partial crystalline phase, may have long range interaction through a spacer of Ru and depending upon its thickness, the coupling field between the ferromagnetic layers may be antiferromagnetic. The thickness of Ru of the buffer, on which the multilayer is grown, has considerable effect on the interlayer antiferromagnetic coupling as shown by the M-H curves, presented in Fig. 1, obtained with a vibrating sample magnetometer (VSM). Unlike the CoFeB film deposited directly on a Ta underlayer, films of CoFeB 10nm/(Ru .9nm/CoFeB 10nm)x3 exhibit in the XRD spectra a crystalline peak, around $2\theta = 42^\circ$, as shown in Fig. 2. The peak is more pronounced if the Ru thickness in the buffer, is 3 nm, than if is 1 nm. These structural results correlate well with the antiferromagnetic coupling field strength, obtained from the M-H curves, with values of 200 Oe and 20 Oe, respectively.

The crystalline phase and texture are discussed. The films, microfabricated into flux guides, consisting of long poles and large yokes, have their magnetization processes characterized by anisotropic magnetoresistance measurements and focused beam magneto-optic Kerr effect. The results are compared with analogous multilayer films that use ferromagnetic layers of Permalloy, also prepared by ion beam deposition in a 4-target Commonwealth Scientific ion beam deposition system (IFIMUP).

Controlling Domain Wall Pinning in Planar Nanowires with Transverse Field and its Application in a Magnetic Memory Cell.

D. Atkinson, D. S. Eastwood, L. K. Bogart

Physics, Durham University, Durham, United Kingdom

Introduction

There has been intensive research interest in the behaviour of individual domain walls in nanowires both in terms of the fundamental physics and for potential applications. For memory applications domain walls trapped at features such as notches or prominences create multiple domains and hence memory states. In contrast to conventional single bit per transistor MRAM this approach presents the opportunity to store multiple data bits for each readout transistor. Here we investigate controlling the interactions of domain walls with asymmetric pinning structures by selecting the magnetization state of the domain wall using a small transverse magnetic field. This provides an additional degree of freedom to the control the pinning and may be exploited in future magnetic memory.

Modelling

Micromagnetic simulations were performed using OOMMF developed by NIST. The modelled structure had a triangular notch of depth 176 nm part way along the length of a 496 nm wide, 8 nm thick nanowire with the nucleation pad at one end. Standard parameters for Permalloy, a cell size of 8 nm and a damping factor, $\alpha=0.015$ were used in simulations.

Experimental Details

Magnetic nanowires were made by electron beam patterning, thin-film deposition and lift-off. The thickness was 5 nm. Nanowires were 50 μm long and terminated with a wider rectangular 'nucleation pad' to generate domain walls at one end and a triangular point at the other end to prevent nucleation of walls. A triangular notch was located halfway along the length. The magnetization behaviour of individual nanowires was measured using a focused magneto-optic Kerr effect (MOKE) magnetometer.

Results & Discussion

Figure 1 shows some micromagnetic simulations of domain walls interacting with an asymmetric notch (that is only on one side of the nanowire). The direction of the wall moment is controlled by the application of a small (5 Oe) magnetic field transverse to the long axis of the wire. The domain wall is de-pinned from the pad at 45 Oe and propagates along the wire and is pinned at the notch, figure 1b. The wall is pinned up to an axial field of 60 Oe when it propagates along the remainder of the wire. In contrast, when a transverse head-to-head wall is formed with a wall magnetization in the opposite (downward) direction, figure 1c, the wall de-pins from the pad at 45 Oe, but then propagates along the whole length of the wire at 45 Oe and is not pinned at the notch, figure 1d. The MOKE measurements with the laser spot located after the notch showed the switching behavior resulting from de-pinning of domain walls from the notch. For transverse fields below ± 5 Oe the de-pinning field showed only some small changes, however, above ± 5 Oe the axial switching behaviour changed significantly. For positive transverse fields greater than 5 Oe the negative switching field was reduced while the positive switching field remained the same and for negative transverse fields the opposite behavior was observed with the positive switching field reduced and the negative switching field largely unchanged. Above 5 Oe the transverse field is sufficient to consistently set the magnetization direction of the domain wall that is formed by reversal of the nucleation pad. The transverse field sets the wall magnetization in the same transverse direction for both head-to-head and tail-to-tail domain configurations leading to different domain wall energy states

at the notch resulting from the direction of the wall magnetization with respect to the preferred orientation of the domain magnetization around the notch. Therefore, consistent with the micromagnetic simulations, it is suggested that for a head-to-head domain configuration a low pinning field is achieved for wall magnetization that is pointing away from the apex of the notch while for a tail-to-tail configuration a low pinning field is achieved when the wall magnetization is directed towards the apex of the notch.

The pinning behaviour observed is utilized in a concept for multi-bit memory cells applicable as the free-layer in magnetic random access memory where the domain structure is defined by the location of domain walls that either pin or pass-by pinning structures depending upon the domain wall configuration selected. The pinning results and memory concept are described in more detail [1].

Digital information processing relies on the handling of two states, called bits or “0” and “1”. A Magnetic Random Access Memory (MRAM) is an array of multilayered elements, each one comprising a soft magnetic layer (free layer) and a hard layer (pinned layer) separated by a non-magnetic layer [1]. Both the free and the pinned layers consist on thin and elongated ferromagnetic dots patterned with lithography, and the shape and dimensions of the free layer are chosen in order to achieve single-domain bi-stable behavior. Bits are stored using the two possible orientations of magnetization in these bi-stable ferromagnetic dots. The information is written on each memory element by passing electrical currents through two orthogonal metallic tracks (work and bit lines), which induce an in-plane magnetic field in the free layer to reverse its magnetization by means of precessional switching. Alternatively, the writing process can be also carried out by means of spin-polarized currents flowing perpendicularly to each multilayer cell [2]. In the reading process, the state of the free layer can be determined by magnetoresistance measurements: if both the free and the pinned layers are magnetized in the same (opposite) direction, the multilayer has low (high) resistance. The two equilibrium states of opposite magnetization are separated by an energy barrier which is related to the dimensions and shape of the free layer. In order to achieve higher density storage, the dimensions of the free layer (and therefore, the energy barrier) must be reduced. However, the superparamagnetic effect, which concerns the loss of magnetic stability as a result of thermal fluctuations when the size of the free becomes small, limits the maximum density of storage information: at finite temperature the magnetization of the free layer can switch from one state to the other just by thermal activation.

It has been recently proposed that bits could be stored in dots displaying a flux-closure magnetic state, coded in the chirality of the structure or in the up-or-down magnetic vortex at the center of the dot [4]. These flux-closure magnetic configurations minimize the magnetostatic coupling between adjacent bits, and they are more stable than single-domain states under thermal fluctuations. However, the vortex configuration in soft samples requires a minimum aspect-ratio under which the single-domain configuration is preferred, so that, the maximum density of storage information is also restricted.

In this work, we explore the possibility of using pinned Domain Walls (DW) on a pair of notches placed in a thin ferromagnetic strip as a simple mechanism to storage information. Here, the bits are stored using the two possible DW positions on each of the two notches of the memory element (see Fig. 1(a)-(b)), and the writing mechanism can be achieved both by means of pulses of in-plane magnetic field and/or electrical current. As an example, Fig. 1(c) shows DW position as a function of time under two magnetic pulses of sinusoidal shape with duration of 20ps and two maximum values. Starting from the initial “0” state, a strength of 55mT (54mT) is (is not) enough to promote the jump of the DW to the “1” state.

Several separations between the two notches are evaluated by means of full micromagnetic modeling as well as a one-dimensional model that considers the DW as a rigid object, both at zero and at room temperature [5]. In the presentation we will show that magnetic field or electrical current

pulses can promote transitions between these two well-defined states which are easy, well-controllable, and, faster than previous proposed MRAM devices. Moreover, placing several of these memory elements in the same strip, it will show that the writing mechanism is also highly scalable and selective.

Shingle shot detection of the magnetic domain wall motion by using the TMR effect.

K. Kondou¹, N. Ohshima², S. Kasai¹, Y. Nakatani³, T. Ono¹

1. Institute for Chemical Research, Kyoto University, Uji, Japan; 2. Device Platforms Research Laboratories, NEC Corp., Sagami-hara, Japan; 3. Department of Computer Science, University of Electro-communications, Chofu, Japan

The magnetic domain wall (DW) dynamics has been attracting attention these days, because of its underlying potential applications for new spintronics devices, such as the magnetic racetrack memory [1] and magnetic logic device [2]. The operation speed of these devices depends on the DW velocity [3], but it is limited by the precessional motion of the DW known as the Walker breakdown. Until now, several groups have reported about the DW motion by using anisotropic magnetoresistance effect [4] and magneto-optical Kerr effect [5]. These results clearly show the character of the Walker breakdown, but it requires a large number of sampling to obtain a satisfactory averaging. The motion of the DW, however, has a stochastic nature, i.e. each event is not the same. Thus, single shot detection of the domain wall motion with time- and space- resolution is indispensable.

In this presentation, we demonstrate the real-time and real-space detection of the magnetic DW motion by using a tunnel magnetoresistance (TMR) effect. The relative large resistance change due to the TMR effect enables us to perform the single-shot measurement of the magnetic DW motion.

Figure 1 shows the schematic illustration of the sample and circuits for measurement. A Ta(5 nm)/Permalloy(20 nm)/Al-O(0.82 nm)/CoFe(2 nm)/Ru(0.88 nm)/CoFe(2 nm)/PrMn(20 nm) multilayered film was deposited on the thermally oxidized Si substrate. The wire structure was defined by using electron beam lithography and lift-off method. The length and width of the magnetic wire were 55 μm and 0.9 μm , respectively. The region sandwiched by two Au electrodes forms a TMR junction. The resistance of the TMR junction is modulated by the position of the DW in the Permalloy layer. Thus, the TMR junction acts as a detector of the DW motion. The resistance change was converted to voltage by a DC current and monitored by the real-time oscilloscope.

Figure 2 shows the time dependence of the voltage at the TMR junction at $H_{\text{ex}} = 34.2$ Oe. The voltage starts to increase at $t=t_1$, which means the DW arrived at the left side of the Au electrodes. Similarly, the voltage becomes constant after $t=t_2$, which also indicates that the DW went through the Au electrodes. The linear dependence of the voltage on time suggests the DW velocity is constant. The average velocity can be defined as $v_{\text{ave}} = 40 \mu\text{m}/(t_2 - t_1)$. Detail studies about the average velocity as a function of the magnetic field shows clear Walker distribution, in spite of the large dispersion due to the stochastic nature of the DW motion. These results suggest the universality of the Walker breakdown phenomena, and the importance of the stochastic nature of the DW motion.

Domain wall injection study in spin valve system with different geometry reservoirs.

K. Cheng^{1,2}, C. Yu¹, S. Lee¹, Y. Liou¹, Y. Yao³, J. Wu³, J. Huang²

1. Institute of Physics., Academia Sinica., Taipei, Taiwan; 2. Department of Materials Science and Engineering, National Tsing-Hua University, Hsinchu, Taiwan; 3. Department of Materials Engineering, Tatung University, Taipei, Taiwan

Domain wall injection is a popular topic in Spintronics because it can decrease magnetization switching field (H_s)[1]. In recent studies, it has been demonstrated that the switching field and magnetization reversal process depend strongly on the end shape as well as the width of ferromagnetic wires. The effect of the end shape is attributed to the formation of the end domain or edge domain[2-3]. In this study, we investigate the influence between different shapes of reservoirs and domain magnetization reversal process.

The different geometry patterned wires were fabricated by electron-beam lithography and lift-off process. Five different reservoirs (tip, square, diamond, disk, and ring) on one side of the wires were designed. The other side of the wires was a tip shape. Figure 1 shows a SEM photograph of the wires. The spin valve Co(20nm)/Cu(7nm)/Py(20nm) was used to study the magnetization reversal behavior because the signal of the Giant Magnetoresistance (MR) is much more sensitive in comparison to the Anisotropy MR in a single film. For comparison, a micromagnet simulation software (OOMMF) was used to simulate the spin configurations.

Figure 2 shows typical longitudinal MR curves for all the samples at room temperature. Sample with a tip reservoir is the most difficult one to switch in magnetization reversal process. This indicates that the anisotropic field in the tip shape is the largest, thus it is not easy for domain wall nucleation. On the other hand, domain wall is easy to nucleate in sample with a diamond shape reservoir. For other three kinds of shapes (ring, square, and disk), the value of the switching field H_s is between that of tip and diamond, it is attributed to the domain nucleation process or dipole interaction between the Co and Py films. Diamond and ring shapes have a direct switching, it means the domain wall move quickly through the wires and cause the change easily. The H_s as a function of domain injection angle is plotted in Figure 3. The definition of injection angle is shown in the inset of figure 3. There is a trend that larger injection angle needs bigger switching field. The first group is diamond, square and tip. Diamond has smaller H_s and tip has the biggest value. In diamond shape, magnetic field direction is close to the easy axis, so the domain wall in diamond is easily nucleated than in square. They had similar tendency. The slope of Py is approximately 0.104, and Co is near 0.659. In order to interpret the difference of H_s with the relation to magnetization reversal, the spin configurations were simulated by micromagnet simulation software OOMMF. It is quite consistent with our experimental switching behavior. In tip pattern, the switching behavior is simple and immediate changed. In other structures, it seems like a slowly decrease in the beginning and a suddenly drop off in the next process.

In summary, the diamond shape has the minimum switching field. Results in both Co and Py materials have identical tendency. The spin configurations by OOMMF results also offer good evidence that the different reservoirs have the same magnetic domain, vortex wall, in the sample size we studied. Our experiment provides guidance for taking advantage of different geometry reservoirs.

Magnetization reversal process and domain wall (DW) motion in artificial structures such as sub-micron/nano-scaled or constricted ferromagnetic (FM) wires have been widely researched by magnetoresistance (MR) measurements [1-8]. In this article, different magnetization reversal processes with DW motion in NiFe nanodevices with different pinning sites patterned by ion-milling and FIB milling have been detected and investigated by MR measurements. Two structures have been studied: (a) a 15 nm-thick NiFe micron stripe with a 150 nm-wide nanoconstriction (structure A), and (b) a 15 nm-thick NiFe micron stripe with a submicron triangular element and a 150 nm-wide nanoconstriction (structure B), as shown in the inset of Fig. 1. The ability to control domain wall propagation direction makes them promising for fundamental research and the application of nanowire memory devices.

Structure A: NiFe stripe with a nanoconstriction

For structure A, its longitudinal MR is about -0.17% (Fig. 1-left). When reaching the field of 5.7 Oe, the resistance shows the first jump, indicating that the gradual magnetization reversal in the wide stripe, leading to DWs pinned at the nanoconstriction. When the field reaches the depinning field of the nanoconstriction (20 Oe), the second sharp jump occurs, indicating the depinned DWs annihilate at the nanoconstriction.

The transverse MR magnitude is 0.68% and the MR curve shows a so-called bell-shaped behaviour, that is, an MR enhancement around a zero field [9, 10]. It is argued that this enhancement is due to pinning of the DW at the nanoconstriction near a zero field by reversal from saturation, which can be explained by the DW scattering mechanism [10, 11].

Structure B: NiFe stripe with a triangular element and a nanoconstriction

A negative longitudinal MR curve (MR= -0.16%) (Fig. 1-right). Based on micromagnetic simulation results, the three-step switching behaviour can be explained as follows. The right part of the stripe with a lower coercivity first switches the magnetization, and the DW moves towards the nanoconstriction, and then is trapped there, leading to the first resistance jump. Then the resistance keeps increasing gradually, indicating that the left part gradually switches its magnetization until the DW reaches the base of the triangular element. Then the DW experiences pinning there, and the propagation doesn't continue until the field is high enough to overcome the pinning energy induced by the sharp expansion in width. On reaching the field of 13 Oe, the resistance shows the second small jump, which means that the left DW is depinned from the triangular element, and propagates into the apex area, and then gets pinned at the nanoconstriction. On reaching the depinning field of the nanoconstriction (21 Oe), the resistance returns to its original value in the third jump, owing to the annihilation of DWs at the nanoconstriction.

Similarly, for structure B, the so-called bell-shaped behaviour is shown in the transverse MR curve and the magnitude is 0.66%.

We had taken MR measurement of a FIB pre-patterned structure (a NiFe micron stripe with a 500 nm-wide microconstriction). Comparing MR values of these samples, we notice that the transverse MR magnitude of a pre-patterned structure without the bell-shaped behaviour is 0.56%, lower than those of structures A and B, which are 0.68% and 0.66% respectively. Besides, the longitudinal MR value of pre-patterned structure is -0.09%, which is nearly half as large as those of two patterned

samples, -0.17% and -0.16%, respectively, which cannot be fully explained by the AMR effect and further confirms some contributions from domain wall MR (DWMR).

For structure A, we fabricated a series of samples with different nanoconstriction widths. The longitudinal MR value decreases from -0.15% to -0.22% when the nanoconstriction width decreases from 200 nm to 80 nm. The DWMR plays a more important role when the nanoconstriction is narrower.

Magnetoresistance of transverse and vortex domain walls in permalloy submicron wires.

C. Yu¹, S. Lee¹, K. Cheng¹, D. Chen², E. Haung³, Y. Liou¹

1. physics, academica sinica, Taipei, Taiwan; 2. Materials Science & Engineering, Chiao Tung University, Hsinchu, Taiwan; 3. Materials Science & Engineering, University of Tennessee, Knoxville, TN

Lots of efforts have been studied on how the domain wall affects the magneto-transport in magnetic wires. This local spin modulation in the domain wall causes extra contribution to MR that can not be explained by spin-orbit AMR effect, if the quality factor ($Q=2K/\mu_0 M_s^2$, K: anisotropy energy, M_s : saturation magnetization) is $Q > 1$ [1]. Due to the domain wall MR (DWMR or DWR) is still in debate experimentally— positive[2] or negative [3]. Consequently, more experimental evidences are needed to find out the answer of DWMR.

Submicron s-shape and half-ring wires were fabricated by e-beam lithography. The 25 nm thick Ni80Fe20 film was deposited by sputtering on SiO2/Si substrate. There were 7 half-ring units connected in-series in different way, half-ring wire (up-up) and s-shape (up-down) (Fig.1). Outer radius(r) was 2.1 μm of each half-ring and the line width was 0.2 μm . The AMR loops of three different wires (half-ring, s-shape and straight wires) were measured with 4 different angle ($\theta=0, 30, 60$ and 90 degree) at 77K, θ is the angle between H and the long axis of the wire. Compare with the AMR of straight wire, which is about 1.17 %, the AMR effect was suppressed in s-shape wire (AMR $\sim 0.02\%$) than in half-ring wire (AMR $\sim 0.32\%$). The reason is attributed to the symmetry of geometry structure. For the half-ring wire, there are overlap regions on the corner of two half-ring units, and AMR (0.32%) is mainly contributed from these corners. To reduce the AMR effect as possible is the key issue to measure the MR contributed by DWMR.

Fig. 2 (half-ring wire) shows the MR loops, and from the MR loops the switching fields H_s at different angles were obtained. The H_s of half-ring wire was -230 Oe at 0 degree and -260 Oe at 30 degree, for the s-shape wire H_s was around -295~ -305 Oe for all the angles. The bell shape of half-ring wire MR loops measured at 60 and 90 degree showed only coherent spin rotation during magnetization reversal process. The different magnetization reversal of half-ring wire resulted from discontinuous domain structure-corner, which was not existed in s-shape wire. In remanent state, the resistivities (ρ) of s-shape wire were almost same value at all angles, the maximum differences of ρ at different angles were below 0.002 $\mu\Omega\text{-cm}$ (error of measurement). For the half-ring wire, the ρ of angle 0 and 30 degree were 33.706 $\mu\Omega\text{-cm}$, but the ρ of angle 60 and 90 degree are 33.672 $\mu\Omega\text{-cm}$. The MFM images (Fig.3. (a), (b) half-ring wire and (c) s-shape wire,) shows the domain structures in remanence. There were two domain structures of half-ring wire in remanent state, domain walls (Fig.3.(a)) and magnetic pole (head or tail pole) (Fig.3.(b)) on the corners after magnetized at longitudinal and transverse field. Those different resistivities (0.034 $\mu\Omega\text{-cm}$) in remanent state of half-ring wire were resulted from different domain structures on the corners. There was only one domain configuration of s-shape wire in remanence- magnetic poles on the ends of the wire (Fig. 3 (c)), no matter H was applied in the longitudinal or transverse direction, so no different domain structure to cause different resistivity in remanence. From the MFM images we may interpret the difference of longitudinal and transverse MR in remanence was attributed to two different domain structures on the corners, with domain walls or without domain walls. We calculated the DWMR ratio of half-ring wire was $\sim +0.02\%$ for every domain wall. The domain structures, on the corners of the half-ring wires, were similar to the two magnetic films in GMR which are antiparallel domains (Fig. 3 (a)) and parallel domains (Fig. 3 (b)). And the current we applied was perpendi-

cular to the walls on the corners. We estimate the DWMR by GMR model [4], and the result is 0.01 $\sim +0.05\%$, which is satisfied with our data.

Domain wall magnetoresistance effect in nanobridges.

Y. Chen¹, J. Hsu¹, C. Yu², K. Cheng², S. Lee², Y. Liou², Y. Yao²

1. Physics, National Taiwan University, Taipei, Taiwan; 2. Physics, Academia Sinica, Taipei, Taiwan

The domain wall magnetoresistance(DWMR) in nano-structured films was extensively studied in the past decade due to rich research topics and great potential application in spin-electronics. However, up to now, DWMR is still under intensive discussions because of conflicts in experimental results. Both positive and negative domain wall magnetoresistance effects have been found. And theoretically it has difficulties in explaining the effect satisfactorily. In this presentation, the extended structure, named as nanobridge(NB), combined by a nanowire of well-defined shape and nanocontact was used and the variation of the magnetoresistance under different external magnetic fields with the sizes (width and length) of nanobridge structures was intensively studied.

Electron-beam lithography and lift-off process were used to prepare Permalloy patterned thin films on Si(100) substrates coated with 100nm SiO₂ buffer layers. The Permalloy thin films were deposited by DC magnetron sputtering. The room-temperature magnetoresistance (MR) measurements were made by a four-point technique. The external magnetic field was applied in the in-plane direction. A field of 4k Oe was used to saturate the magnetization and the detailed investigations were carried out from -500 Oe to +500 Oe. The MR results have been compared with the spin configurations obtained by using the micromagnetic simulation software (the Object Oriented Micro Magnetic Framework, OOMMF).

Two sets of NB with bridge lengths 60 nm and 400 nm were used in this study. The width of nanobridge segment of two sets was varied from 40 nm to 100 nm. The samples with long length of 400 nm were denoted as NBL. As examples, three normalized longitudinal MR loops of NBL with widths of 47 nm, 68 nm, and 128 nm were plotted in Fig. 1(a). When the external magnetic field was swept from the saturated magnetic field 4 kOe to zero, the MR value was increased gradually to the maximum value. Further increasing the magnetic field in the opposite direction, the MR value dropped corresponding to a lower resistance state. The total loop can be visualized as the magnetization reversal process from the variation of anisotropy magnetoresistance (AMR) effect. Because the magnetic state at both sides of NB have already switched via domain wall nucleation and domain wall motion, the magnetic state of NB will maintain its original orientation of magnetization leading to the pinning of two domain walls at the connections between the nanobridge and pad. Therefore, the lower resistance state is a meta-state and arises from the AMR contribution of domain wall's transverse magnetized part. When the magnetic field was continued to increase until it reached certain magnetic field, namely switching field H_{sw} , the depinning of two domain walls caused the complete magnetization reversal of NB. Determined from R - H loop in Fig. 1(a) it was found that H_{sw} increased as the width of NBL became narrower due to larger shape anisotropy of NB with larger aspect ratio. Another set of samples with short bridge length of 60 nm was denoted as NBS. Following the same procedure, the normalized longitudinal MR loops of NBS samples having widths of 69 nm, 81 nm and 87 nm were plotted in Fig. 1(b). It was noted that the magnetization reversal process of NBS determined from their MR loops differed from those of NBL markedly. The meta-state (or lower resistance state) in the MR loops of Fig. 1(a) possesses a wider field range than that of Fig. 1(b) and the switching field distribution of NBL was larger by 50 Oe than that of NBS. However, a similar trend has been observed for the switching field, which also strongly depends on the width of nanobridge and follows the inverse-width dependence. Stronger shape anisotropy of nanobridge with narrower width will retard the domain walls against depinning

into the nanobridge. Furthermore, different domain wall structures, such as transverse domain wall and vortex domain wall, can form in the samples of different sizes. The transverse domain wall does not move so easily as the vortex domain wall causing the difference of the switching fields. Additionally, the shape anisotropy of nanobridge will suppress the domain wall.

In order to explore the MR contribution from the domain wall, some calculations have been carried out. For the nanobridge with 70 nm width, an additional positive domain wall resistance (DWMR) about +0.03% was obtained. Following the same way, a larger additional positive DWR change about +0.07% was obtained for the nanobridge with wider width of about 80 nm, which should be explained by the spin-dependent impurity scattering model, so-called the mistracking model. In this model the condition of tracking between spins of conducting electrons and the orientation of moment within the domain wall in NiFe will determine the magnitude of additional MR contribution. Within the framework of this model, the mistracking contribution to the wider domain wall width is more than to the narrower one. Therefore, a larger positive DWMR is presented in the samples with wider line-width.

Introduction

The magnetic behaviour and switching field of thin films is significantly modified by patterning them into arrays of one-dimensional wires. Thin film magnetic wires have a variety of possible applications, such as data storage or data processing[1], and it is therefore important to understand the factors that determine their coercivity and magnetization reversal, and the behavior of domain walls. Here, we explore the properties of arrays of ferromagnetic nanowires made by patterning thin films, and analyze how the magnetic behaviour of the array is modified in a controlled way by magnetostatic interactions between the wires.

Experimental

Rectangular $5 \times 14 \mu\text{m}^2$ fields of Ni₈₀Fe₂₀ parallel nanowire arrays were fabricated on top of commercially available oxidized Si substrates by electron-beam lithography and liftoff processing. Fabricated wires had 25 – 150 nm widths and 350 – 600 nm periods, and were patterned from 20nm-thick polycrystalline NiFe films deposited using ion-beam sputtering, as detailed elsewhere[2]. The present work reports on a thorough study of the room temperature hysteresis loops of arrays with nominally-identical wires, probed using a focussed MOKE magnetometer (Durham Magneto Optics Ltd. NanoMOKE2TM). Hysteresis loops were obtained using an elliptical laser spot close to $5 \times 7 \mu\text{m}^2$ (FWHM) and averaging ~5000 field cycles at a frequency of 27 Hz, sampling the collective magnetization reversal of 14 wires. The samples were mounted on a rotary stage allowing controlled rotation of the nanowire arrays with respect to the applied field.

Results

Scanning electron micrographs (SEMs) of arrays measured are given in Fig. 1, illustrating the edge quality and pattern geometry.

(Fig.1)

While the coercivity of the unpatterned films are below 1 Oe[2], hysteresis loops of arrays of 500 nm period and upwards are square with coercivities ranging from 225 to 345 Oe and a single Barkhausen jump, suggesting that the collective reversal of all the wires occurs within a narrow switching field distribution. However, for the 400 and 350 nm period arrays, the loops show substantial differences in shape, coercivity and remanence on decreasing the linewidth. Fig. 2 a) illustrates the hysteresis loops of arrays with 350 nm period and 50, 80 and 100 nm wire width. Clear Barkhausen jumps in the 80 nm width array suggest that the reversal of individual wires occurs at different fields. (Note that, because of the shape of the MOKE laser spot, the wires contribute steps of different magnitude to the aggregate hysteresis loop). In contrast, the 50 nm wires do not show distinct jumps, suggesting a more gradual change in magnetization as the field varies, possibly due to domain pinning by the edge roughness. For the array with the widest wires, 100nm, the reversal occurs abruptly and resembles that of arrays with 500nm periods and above. Fig. 2 b) shows the variation of coercivity with array period and wire width. For a width of 125 nm, coercivity decreases with period, but for 80 nm width it increases. At a width of 100 nm the coercivity is nearly independent of period. The insets show that coercivity increases with width for the 350 nm period arrays whereas for the 500 nm period, it decreases. For the 500 nm period the variation of coercivity with wire widths is identical to that of isolated wires.

(Fig.2)

These results suggest an important role for magnetostatic interactions in the reversal of closely-spaced arrays. We expect that in closely spaced wires, the stray fields of the transverse 180deg domain walls can stabilise multidomain structures that are not found in isolated wires, and promotes correlation between domain structures in adjacent wires. This leads to a gradual reversal of the array and consequently a hysteresis loop that does not show Barkhausen jumps. A change in reversal process with array geometry has recently been reported in arrays of long wires and attributed to a change in the energy contributions with geometry[3].

Edge Roughness effect on the magnetization reversal process of spin valve submicron wires.

T. Chiang^{1,2}, C. Yu¹, Y. Chen¹, S. Lee¹, G. Guo²

1. Institute of physics, Academia sinica, Taipei, Taiwan; 2. Physics, National Taiwan University, Taipei, Taiwan

Recently, the evolution of nanolithography techniques makes it possible to prepare nano scale pattern with well-defined shapes, which helped us to study the spintronic devices in micromagnetic physics. Magnetic domain wall mobility is one of the interesting topics. Whether the switching frequency of a metallic spintronic device can match up with the modern semiconductor electronic device is decided by the mobility of domain wall. Therefore, determination of domain wall mobilities in submicron or nanometer magnetic wires is a crucial topic of interest not only for fundamental research but also for application.

Theoretically, domain wall mobility for bulk magnetic materials can be calculated by $\mu = \gamma \Delta / \alpha$ (γ : gyromagnetic ratio, Δ : domain width, α : spin damping coefficient). There were many experimental results reported. The discrepancies were attributed to roughness effect. How the surface and edge roughness of the wires affect on domain wall motion in different magnetic materials, such as NiFe, Co80Fe10B10 and Co, are the questions we would like to answer in this study.

Our samples had a spin valve structure, X(24nm)\Cu(10nm)\X(12nm) (X=NiFe, Co80Fe10B10 and Co), and their widths are 400nm. Different edge 'roughness' was designed by e-beam lithography as periodic spikes along both sides of the samples. The height of the spikes and the pitch (period) could be varied systematically. Figure 1 shows three typical NiFe samples with (a) no designed roughness, (b) 33nm spike height, 116nm pitch, and (c) 51nm spike height, 213nm pitch. The magnetoresistance curve was measured and the domain wall velocity was determined under the same applied magnetic field sweeping rate. Thick and thin layers of NiFe, Co80Fe10B10, and Co had different domain wall velocities during magnetization reversal. The domain wall velocity in the thick layers was faster than the thin ones. The shape of magnetoresistance suggested the same results and indicated that the magnetization reversal of thin layer took place by the pinning and depinning of magnetic domain walls. The roughness of wires made the domain wall to slow down. As the spike height got larger, the domain wall velocity reduced. The pitch effect was not obvious.

In Figure 2, we showed the magnetoresistance curves of the three samples in Figure 1. The number of points on the rising part of the magnetoresistance curve increased as the spike height increased. This result suggested that the domain wall velocity in the thick layer was decreased. The roughness created more pinning sites for the domain walls and slowed down the average velocity. As the magnetic materials was varied, our results showed the domain wall velocity in the NiFe was the fastest, the Co was the slowest. In all three different magnetic materials we studied, the spike roughness made the domain wall slower.

Study on domain wall moving in a permalloy ring structure.

D. Chen¹, C. Yu², Y. Yao^{3,1}

1. Department of Material Science and Engineering, National Chiao Tung University, Hsinchu, Taiwan; 2. Institute of Physics, Academia Sinica, Taipei, Taiwan; 3. The Department of Materials Engineering, Tatung University, Taipei, Taiwan

Permalloy (Py) rings were fabricated by electron-beam lithography and the following lift-off technique. The MR measurements were performed at room temperature with applying some constant magnitudes of magnetic field along the direction of the ring plane while rotating the magnetic ring in its plane. Fig.1 shows an SEM image of a Py ring and the configuration in which the contacts of the four-point measurement is arranged. As shown in Fig.2, the rotating MR curves at 4000 Gauss and 100 Gauss reveal obvious difference between the two magnetic configurations. The field at 4000 Gauss hold the most of the local moments parallel to the direction of the field wherever the angle is, hence the resistance is the highest at 0° and the lowest at 90° (or highest at 180° and lowest at 270°). Therefore, the rotating MR signal shows a cosine-like curve. At 100 Gauss, the field is too weak to hold the local moments any more. Instead, the shape anisotropic field forces the local moments aligned to the perimeter of the ring and leave two domain walls at opposite positions in the direction of field. At this magnetization, the field can still drag the two walls in the perimeter of the ring without changing the directions of other moments not present in the walls. Hence, the curve shows more flat region combined with two abrupt sinkages near 90° and 270°. The results of the series of rotating MR measurements by varying magnitude of field reveal a tendency of shift on the angles at which the resistance drops occur with decreasing applied field (Fig.3). The propagation (or moving) of domain wall requires the applied field component tangent to the direction of perimeter at the position where the wall is, thus lower applied field needs larger angle shift to drag domain wall into the region between the two voltage contacts (Fig.4). The tendency of the component changing with varying applied field is shown in Fig.5, in which, the required component to drag domain wall in perimeter, $\sin(\theta)$, increases with decreasing applied field as explained previously.

Fig. 1 SEM image. 1 & 4 serve as current contacts, and 2 & 3 as voltage contacts. The bold arrows indicate the definition of the direction at which the field being applied.

Fig. 3 A series of of rotating MR curves by varying magnitude of field. The angle at which the resistance decrease abruptly shifts toward the direction of angle increasing with decreasing applied field.

In ultrathin weakly disordered Pt/Co/Pt films, structural inhomogeneities create a random pinning potential which impedes domain wall motion, resulting in a type of thermally activated wall motion known as creep [1]. Here we examine how the addition of a spatially periodic pinning potential, produced by the stray field generated by an array of ferromagnetic dots patterned above the film, affects this motion. Introduction of additional pinning via a stray field rather than patterning of the film itself avoids altering the structural properties of the film [2] and hence its intrinsic disorder. A continuous multilayer Pt/Co sample was first sputter deposited with the following structure: [Pt(1.8nm)/Co(0.6nm)]₂ / Pt(5nm) / [Co(0.6 nm)/Pt(1.8 nm)]₄. The top [Co/Pt]₄ multilayer was then patterned into arrays of 200nm wide square dots each separated by 1 μ m (Fig 1a). This was done using ion beam etching with a hard Ti mask created by depositing Ti onto a positive resist patterned via electron beam lithography. The strongly ferromagnetically coupled Co layers in the lower [Pt/Co]₂ bilayer act effectively as one layer and it is this layer in which we measure the domain wall motion. Both the dots and the continuous layer exhibit perpendicular anisotropy.

Hysteresis loops of the sample were obtained using a conventional polar magneto-optical Kerr effect (PMOKE) magnetometer. The dots display a wide switching field distribution between about 2 kOe and 3 kOe. The domain wall velocity under positive applied fields was then measured in the regions of the continuous film under the dot array using a quasi-static PMOKE microscopy technique [3]. The orientation of the dots' magnetization was set before the velocity measurements by applying a positive or negative saturating field of magnitude 4.2 kOe. The field applied to drive the domain wall was kept below 1 kOe to avoid reversing the dots.

The effect of the dots on wall motion is most pronounced at low applied fields, H , for which the velocity is noticeably lower under the dot arrays than in regions where there are no dots. At high field the dots have only a minimal effect on the propagation of the walls which are rather smooth (Fig 1b). Here, the pinning efficiency of the stray field is reduced due to the large driving force of the applied field and the wall's line tension. This is similar to what is observed in ultrathin Pt/Co/Pt films in the high field viscous regime in which the effect of the film's intrinsic disorder becomes negligible [3]. The low field wall velocity, v , in Pt/Co/Pt films can generally be fitted with the creep law which predicts $\ln(v) \propto -H^{-\mu}$ [1,3]. μ is a universal exponent equal to 1/4 for a 1D interface moving in a 2D weakly disordered medium. In Fig 2 we have plotted $\ln(v)$ against $H^{-1/4}$. We observe rather linear behaviour at low field consistent with creep theory despite the addition of the periodic pinning potential.

The creep velocity also depends on the orientation of the dots' magnetization: the velocity is about 2 times larger when the dots are negatively magnetized. In this orientation, the component of the dots' stray field perpendicular to the film plane will be negative directly under the dots and positive around the dots. Although the magnitude of the negative field beneath the dots will be much larger than that of the positive field surrounding the dots, the dots cover only a small portion of the array area. Henceforth, the increased velocity observed when the dots are negatively magnetized is tentatively attributed to the positive stray field in the area located between the dots which reinforces the positive applied field. Indeed, when the dots are negatively magnetized one sees at low field that

the domains do in fact propagate most easily between the dots (Fig 1c). This creates a much more dendritic domain pattern than that which is observed when the dots are magnetized positively (Fig 1d).

The study of domain wall (DW) propagation in ferromagnetic films has long attracted a great interest since it provides both the basis for a wide number of magnetic devices [1] and a good experimental system to analyze the basic physics of an elastic interface in the presence of either ordered or random pinning defects [2,3]. When the pinning potential is asymmetric it can behave as a ratchet, so that DW propagation is favored in one direction. One of the first ratchet potentials that have been used in the field magnetism are “angelfish” patterns that control the sense of propagation of bubble domains in shift registers [4]. Also, asymmetric motion of domain walls (DWs) in nanowires with triangular [5] or notched [6] shapes has been reported recently. However, up to now, in order to ensure a good control of the DW nucleation/propagation process, in all these cases DW motion has been confined to an essentially 1D path (either by narrow guide rails or by the nanowire geometry), so that its transverse wandering can be neglected. On the other hand, in a thin extended film with a 2D array of asymmetric pinning centers, novel ratchet phenomena can appear since a DW behaves as an elastic line that can distort all along its length in response to the 2D pinning potential.

In this work, the propagation of DWs in extended uniaxial magnetic films patterned with a periodic array of asymmetric holes (see Fig.1) has been studied. For the first time, we have experimentally observed and theoretically simulated the existence of two crossed ratchet effects of opposite sign that change the preferred sense for DW motion depending on whether a flat or a kinked wall is moving [7]. This implies a change in the rectification effect on DW motion as a function of magnetic field that has an interesting consequence from the applied point of view: the system keeps memory of the sign of the last saturating state even in a zero magnetization configuration.

When a magnetic field is applied to push a flat DW across the asymmetric holes, the DW moves more easily (i.e. with lower coercivity) in the direction in which the length of the pinned wall between two antidots increases smoothly as shown in the numerical simulations of a ϕ^4 model presented in Fig.2 [7]. This asymmetric pinning for flat walls has been confirmed experimentally and also with micromagnetic simulations with the OOMMF code [8]. The novel ratchet behavior appears as the pinned wall inside the array develops kinks. This provides an extra mechanism for DW motion only possible in a 2D geometry through upward/downward kink propagation. This novel ratchet mechanism has an opposite sign in comparison to the flat DW ratchet and dominates the low field behavior. The interplay between both ratchets implies that the system keeps memory of the sign of the magnetization before a DW enters the array of asymmetric holes. Thus, it is possible to record several magnetic states introducing DWs in the array and to read them with a low amplitude AC field as can be seen in Fig. 3.

Introduction

The investigation of magnetic tunnel junction (MTJ) structures (especially MgO barrier system [1]-[5]) that realizes high tunnel magnetoresistance (TMR) is important for development of advanced magnetoresistive random access memories (MRAMs) and hard disk drives (HDDs). TMR ratio of up to 500% at room temperature (RT) has been observed for sputtered CoFeB/MgO/CoFeB MTJs consisting of pseudo-spin valve (P-SV) stacking structure without antiferromagnetic pinning layer such as MnIr [6]. The optimum annealing temperature ($T_a=450-525^\circ\text{C}$) that results in the maximum TMR ratio for P-SV MTJs is higher than that ($T_a=360-425^\circ\text{C}$) of the exchange biased (EB)-SV MTJs with MnIr layer [7], [8]. The absence of diffusion of Mn into the MgO barrier at high T_a above 450°C is a factor for the high TMR ratios in P-SV MTJs. However, the effect of annealing temperature on the high TMR ratio for P-SV MTJs has not yet been fully clarified.

In this study, we investigated the dependence of the TMR ratio on annealing temperature for P-SV MTJs with various CoFeB compositions and thicknesses.

Experiments

The rf-sputtered MTJs studied here have stacking structure of substrate/Ta(5)/Ru(8)/Ta(5)/(Co_xFe_{100-x})₈₀B₂₀(t_{CoFeB})/MgO(1.5, 2.1)/(Co_xFe_{100-x})₈₀B₂₀(4)/Ta(5)/Ru(5). In CoFeB layer, the B composition was fixed to 20 at% and the composition x of Co was 0 and 75 at%. The bottom CoFeB layer thickness t_{CoFeB} varied from 2.3 to 6.7 nm by using the slide shadow mask technique. All MTJs were fabricated by photolithography and Ar ion milling with a junction size of $0.8 \times 4 \mu\text{m}^2$, and then were annealed at $T_a=270-525^\circ\text{C}$ for 1h in a vacuum under 4 kOe. The TMR ratio was measured using a dc four-point probe method in the magnetic field range of ± 1 kOe.

Results and Discussion

Fig. 1 shows TMR ratios measured at RT as a function of annealing temperature (T_a) for P-SV MTJs with 4.3 nm-thick bottom CoFeB electrodes changed from $x = 0\%$ to 75% . In all samples with different CoFeB compositions, TMR ratio increases with increasing T_a and reaches the maximum at 475°C . When all samples annealed at temperature over 500°C , TMR ratios saturate and then gradually decrease. The maximum TMR ratio is 500% at RT (1010% at 5K) for the MTJ with $x = 25$ and a 2.1nm-thick MgO barrier. The high TMR ratio over 400% was observed for MTJs with $x = 25$ and 50% .

To understand the reasons for the decreased TMR ratios at high T_a for the P-SV MTJs, high resolution transmission electron microscopy (HRTEM) was employed for structural characterization. Fig. 2 shows the cross-sectional HRTEM images of Ta(5)/Ru(8)/Ta(5)/(Co₂₅Fe₇₅)₈₀B₂₀(5)/MgO(2.1)/(Co₂₅Fe₇₅)₈₀B₂₀(4)/Ta(5)/Ru(5) films, which were annealed at (a) 475°C and (b) 600°C . Two features can be pointed out when the samples were annealed at high temperature of 600°C : (i) CoFeB/Ta interfaces become more indistinct and (ii) (001) orientation of CoFeB electrodes deteriorates. Furthermore, energy dispersive x-ray (EDX) analysis (not shown) indicated that Ta diffuses into the CoFeB electrodes and MgO barrier in the sample after annealing at 600°C . Increasing T_a further to 500°C induced the diffusion of Ta into the CoFeB electrodes and MgO barrier, which may be the reason for the drop in TMR ratios in P-SV MTJs. Realization of higher TMR

ratio over 500% is expected by suppression of Ta diffusion resulting from high temperature annealing. The application of the thicker CoFeB electrode suppresses Ta diffusion into MgO barrier and results in a high thermal stability, i.e., high TMR ratio through annealing at high T_a . Perpendicularly magnetic tunnel junctions (pMTJ) have been considered as one of the candidates for high density spintronic applications because of their low aspect ratio. The perpendicularly magnetic anisotropy (PMA) energy constant K_u of free and pinned layers in pMTJ, from which the switching field is mainly determined, is a key characteristics for practical application. In the present work, we fabricated a series of multilayered pMTJs and found that K_u oscillates with respect to MgO barrier thickness with a period of about 0.3 nm.

The pMTJs using (Co/Pd) and (Co/Pt) binary multilayers were deposited on a SiNx substrate at room temperature. The stacking of these structures were SiNx/Pt/(Co/Pd)₁₀/MgO/(Co/Pt)₅. The magnetic and metallic thin films were deposited by dc magnetron sputtering, while the MgO layer was deposited using the radio-frequency reactive sputtering method. The thickness of the MgO layer varied from 0.6 nm to 2 nm. The Co/Pd multilayer was used as the pinned layer and the Co/Pt multilayer acted as the free layer. The magnetic properties were measured using an alternating gradient magnetometer (AGM). The anisotropy constants K_u were obtained by using the extraordinary Hall Effect (EHE) measurements method [1-3]. Under such configuration, the Hall voltage is proportional to the perpendicular magnetization component which, in turn, depends on the strength of in-plane applied magnetic field and the anisotropy constant. The anisotropy constant K_u can be obtained by assuming that the magnetization direction is determined by minimization of the magnetic energy [3]:

$$E = -H_{\text{app}} M \sin\theta - 2\pi M^2 \sin^2\theta + K_u \sin^2\theta, \quad (1)$$

where θ is the angle between the magnetization and the film normal.

Fig. 1 shows the normalized extraordinary Hall voltage versus the applied magnetic field for several MgO layer thicknesses. As the in-plane field increases, the perpendicular magnetizations, and thus the Hall voltages, decrease slowly in the beginning; however, as the field larger than 2 kOe, the Hall voltages decrease abruptly. The suddenly drops could be attributed to the magnetization switching change from coherent to incoherent. Hence, only the data before these abrupt drops are taken to estimate the anisotropy constant. The calculated results of anisotropy constant K_u for various MgO barrier thicknesses are shown in Fig. 2. Interestingly enough, the anisotropy constant K_u oscillates with MgO thickness with values between 1.3×10^6 erg/cc and 2.7×10^6 erg/cc, and the oscillation period is about 0.3 nm, which is close to the oscillation period of magnetoresistance observed in epitaxial Fe/MgO/Fe MTJs [4]. An discussion on the effect of oxidation layer thickness from the AGM and CIPT (Current In-Plane tunneling) measurements are also presented in Worledge and Trouilloud [5].

Introduction

Magnetic tunnel junctions (MTJs) with perpendicular anisotropy can increase the memory density of magnetic random access memory (MRAM) by avoiding the magnetization curling phenomena in the low aspect ratio scheme [1]. Co/Pt multilayer with the perpendicular anisotropy was shown to be exchange biased using a conventional FeMn antiferromagnet [2]. In the previous study, we obtained tunneling magneto-resistance (TMR) ratio of 12.6% at R.T. in a pseudo perpendicular magnetic tunnel junction (pMTJ) but a very low TMR ratio in the top exchange biased (TEB)-pMTJ [3]. In this study, we fabricated the bottom exchange biased (BEB)-pMTJ based on Co/Pd multilayers and investigated the effect of multilayer structures, such as underlayer materials and number of bilayers, on the magnetoresistance and perpendicular exchange coupling of the BEB-pMTJs.

Experiments

SiO₂/Pd 9/(Co 0.2/Pd 0.7)_x/Co 0.5/Al 1.6 + oxidation/Co 0.5/(Pd 0.7/Co 0.2)₃/IrMn 8/Pd 2 stacks and SiO₂/underlayer/IrMn 8/Pd 0~0.7/(Co 0.2/Pd 0.7)_n/Co 0.5/Al 1.6 + oxidation/Co 0.5/(Pd 0.7/Co 0.2)₃/Pd 2 (numbers in nm) stacks were sputter-deposited on Si substrates for the TEB-pMTJ and the BEB-pMTJ, respectively. The tunnel barrier was formed by oxidizing the Al layers in an RF plasma environment (2.16 W/cm² RF power density, 100 mTorr O₂ partial pressure). Junctions were patterned using a set of metal shadow masks with a 200×200 μm² opening. The magnetoresistive and magnetic properties of the pMTJ samples were measured using a dc-four point probe and a vibrating sample magnetometer (VSM). The temperature dependence of the TMR was measured using a cryogenic Dewar at temperatures from 10 to 300 K. The surface roughness was measured using atomic force microscopy (AFM) and the scan size was 1×1 μm².

Results and Discussion

TMR ratio of the TEB-pMTJ was reduced as compared with the pseudo-pMTJ because in-plane anisotropy of the Co/antiferromagnet (IrMn) interfaces deteriorates the anti-parallel state between the bottom and the top electrodes.[3] When we used the Pd as an underlayer in the BEB-pMTJ stack, the TMR ratio increased a little compared with the TEB-pMTJ. However, the perpendicular exchange coupling and perpendicular anisotropy decreased because the IrMn induced the in-plane anisotropy. To improve the TMR ratio and perpendicular exchange coupling in the BEB-pMTJ, we modified the multilayer structure and the materials, such as underlayer materials, Pd insertion in between the IrMn and the bottom (Co/Pd)_n layer, and the number of bilayers in the bottom (Co/Pd)_n. When the Pd layer was inserted, the TMR ratio was improved but the spin polarization and the perpendicular anisotropy were degraded. TMR, R, and ΔR increased as the number of bilayers in the bottom (Pd/Co)_n increased as shown in Fig. 1. Although the perpendicular anisotropy increased as the number of bilayers increased, the perpendicular exchange coupling with the IrMn was not observed in this stack. When we used the NiFe as a buffer layer, the in-plane anisotropy was induced and hence the IrMn coupled with the NiFe in the plane direction. To solve this problem, we replaced the Ta/NiFe with the perpendicular magnetized (Pd/Co)_n as a buffer layer. The perpendicular exchange coupled pMTJ with the moderate TMR was obtained using the buffer layer

of (Pd/Co)_n as shown in Fig. 2 and the exchange coupling field was 147 Oe. In summary, we could improve the TMR ratio in the BEB-pMTJ. A perpendicularly magnetized buffer layers, such as (Pd/Co)_n multilayers should be used to induce the perpendicular exchange coupling with antiferromagnet such as IrMn in the BEB-pMTJ.

Improvement of (100) orientation of MgO films deposited at room temperature for perpendicular MTJ.

H. Ohmori, S. Nakagawa

Dept. of Physical Electronics, Tokyo Institute of Technology, Tokyo, Japan

Introduction

MTJs with perpendicular magnetic anisotropy (p-MTJ) are expected to be high density integration and reduce electrical power consumption of MRAM^{[1],[2]}. We fabricated p-MTJ with rare-earth transition metal (RE-TM) amorphous alloy and 3nm-thick MgO(100) tunneling barrier prepared at room temperature and observed 64% TMR ratio^[3]. However, large TMR ratio above 100% was not observed despite using Fe(100)/MgO(100)/Fe(100) tunnel junction. We particularly focused the crystallinity and crystallites orientation of MgO(100) textured films and tried to improve MgO crystallinity. Since high temperature treatment such as annealing may cause degradation of perpendicular magnetic anisotropy of RE-TM films, we investigated the appropriate process by changing sputtering condition. MgO crystallinity was improved by the epitaxial growth depended on the crystallographic structure of Fe buffer layer by low MgO deposition rate. Crystallinity of 3nm-thick MgO tunneling barrier prepared at total gas pressure of 0.5 mTorr and low deposition rate was improved compared to that of the 3nm-thick MgO tunneling barrier prepared in the previous condition.

Experimental

Fe films were deposited by facing targets sputtering system at 0.4 mTorr of Ar gas pressure. Fe films exhibit (100) orientation when these films were deposited directly on glass substrate at low deposition rate below 0.7 nm/min. MgO films were prepared at room temperature by reactive facing targets sputtering system using Ar+O₂ mixture gas and Mg target. MgO deposition conditions were changed by total gas pressure (0.50-1.0 mTorr) and sputtering power (17-130 W). MgO deposition rate were controlled in the range from 0.20 to 1.45 nm/min. Fe(3 nm)/MgO(20 nm) bilayer on glass substrates were prepared at room temperature in order to evaluate MgO crystallinity and crystallites orientation. Gd_x(Fe₉₀Co₁₀)_{1-x} and Tb_x(Fe₉₀Co₁₀)_{1-x} were prepared by ion beam sputtering method using 0.10 mTorr of Kr gas pressure. MgO crystalline orientation was evaluated by X-ray diffractometer (XRD).

Results and Discussion

Fig.1 (a) shows the variation of MgO crystallinity for various total gas pressure. Integrated intensity, FWHM and $\Delta\theta_{50}$ indicate that total gas pressure of 0.75 mTorr was optimal condition for the crystallinity and crystallites orientation of MgO(100) textured films. Since each input power was almost constant (85-90 W), MgO crystalline were not influenced by input power. However, MgO deposition rate dropped with increase of gas pressure. We think that the improvement of MgO(100) crystalline was caused by increase of collision probability and decay of MgO deposition rate. The distance between the center of targets and the center of substrate was about 15 cm in our sputtering system and mean free path of MgO particle was about 5-8 cm in this gas pressure condition. Therefore, the sputtering particle which can reach substrate decrease with the increase of gas pressure and the deposition rate was dropped. Most particles collide with other particles on the way to the substrate by the increase of gas pressure and the particles which collide once or more lose their momentum. As a result, they depended on the interfacial energy of Fe buffer layer and MgO films exhibited better (100) orientation. Fig.1 (b) shows the change of crystallinity of MgO films for various input power at the same total gas pressure. In the region below 88 W, integrated intensity, FWHM and $\Delta\theta_{50}$ indicate that the crystallinity and crystallites orientation of MgO films improved

with the decrease of input power. Interfacial energy was smaller than surface energy with the decrease of input power. In the result, MgO particles depended on the crystallographic structure of Fe surface by the decrease of input power and deposition rate^[4]. In conclusion, since the crystallinity and crystallites orientation of MgO films prepared at room temperature were improved by the decay of MgO deposition rate with the change of total gas pressure or input power, the control of deposition rate can be possible to reduce the annealing temperature.

Fig.2 shows the XRD diagrams of 3nm-thick MgO tunneling barrier which was prepared at total gas pressure of 0.5 mTorr and input power of 17 W was improved compared to 3nm-thick MgO in previous condition that revealed 64% of TMR ratio^[3]. MgO(200) integrated intensity prepared in this condition was 1.5 times larger than that prepared in previous condition. The further increase of TMR effect can be expected with the improvement of MgO crystalline prepared at room temperature.

When Parkin et. al.[1] and Yuasa et. al. [2] published the first results for MgO-TMR's with values above 200 % in 2004 the resonance was enormous. The high signal amplitude which had been predicted previously by Butler et.al. [3] opened the path to improved performance in magnetic random access memories (MRAMs) as well as magnetic sensor applications and enabled new concepts based on spintronics.

One reason, why it took relatively long to achieve the breakthrough in MgO-barriers was that the approach of oxidizing the metal which is commonly used for the formation of Alox barriers did not seem to be applicable. Achieving a well ordered crystalline layer by first depositing a metallic Mg-layer and then incorporating oxygen atoms is not straightforward. Consequently, the first successful approaches used either reactive deposition of MgO [1] or epitaxy [2].

Results for MgO-barriers formed by oxidation of metallic magnesium have been less encouraging [4], although values of up to 60% have been demonstrated [5]. The gap to the results obtained with the above mentioned methods was attributed to the poor texture present in the MTJ formed by oxidation.

In this work we present results for MgO-based magnetic tunnel junctions formed by radical shower oxidation that show TMR effects of almost 200%. Despite a strong dependence on the Mg-thickness in a single deposition step the process is shown to be scalable to any resistance area product needed in a given application.

MTJ-stacks of the form seed/PtMn/CoFe/Ru/CoFeB/xMg(t_{ox})/CoFeB/cap were deposited using DC-sputtering. The wafers were deposited up to the Mg layer, then oxidized using a radical shower oxidation process. The stack formation was completed by depositing the freelay and the cap material. The wafers were annealed in a magnetic oven at 350°C for 1 h with a field of 1 T.

Figure 1 shows CIPT results for MR and RA as a function of initial Mg-thickness.

Obviously, a high signal is obtained only for a very thin Mg-layer of 5 Å thickness. Even an increase of only 0.5 Å leads to a significant increase in RA and a decrease in MR. A further increase of the Mg-thickness results in an even stronger degradation of the barrier properties. On the other hand, Mg-layers thinner than 5 Å do not result in a functional barrier either, which indicates that the window for obtaining the right texture is indeed very small.

The observed properties of the 5 Å barrier stack are, however, very attractive for spintronic applications: 90% MR at an R*A-product of 13 Ωμm². Characterization of the magnetic properties confirm the integrity of the barrier. Despite the above described small window significantly larger R*A can be realized. This is achieved by simply repeating the barrier process as often as needed to obtain the desired resistance. Figure 2 shows the results obtained for up to five iterations. The R*A trend follows the exponential law expected for the thickness dependence of a tunnelling process. High MR is obtained throughout the series with maximum values of 180 % and more. The structural homogeneity is astonishing as is observed with HRTEM for fourfold barrier (Fig.3).

Introduction:

MgO-based magnetic tunnel junctions (MTJs) using amorphous CoFeB ferromagnetic electrodes have attracted much attention not only due to their huge tunnel magnetoresistance (TMR) effect but also to their suitability for mass production. In this system, the influence of Co/Fe ratio on TMR effect has been investigated, and the Co/Fe ratio of about 25/75 has been found to be an optimum composition to obtain the largest TMR effect [1-2]. In past reports, however, boron concentration had always been constant at about 20 at.%, and thus the influence of boron concentration on TMR effect is still unclear. Therefore, in this study, we prepared CoFeB/MgO/CoFeB MTJs with different boron concentrations under a constant Co/Fe ratio, and investigated the influence of boron concentration on TMR effect.

Experimental:

The MTJs consisting of bottom electrode/Pt49Mn51/Co70Fe30/Ru/(CoFe)100-xBx reference layer (RL) /MgO/(CoFe)100-xBx free layer (FL) /top electrode were prepared on a thermally oxidized silicon wafers using an ultra-high vacuum magnetron sputtering system (Canon ANELVA C-7100). All the metallic layers were deposited by dc sputtering in Ar or Kr atmosphere, and the insulating MgO layer was deposited by rf sputtering directly from a sintered MgO target. The Co/Fe ratio in the (CoFe)100-xBx layers was maintained at around 75/25. When boron concentration of one CoFeB layer was varied, that of another CoFeB layer was fixed at 20 at.%. After deposition, the MTJs were annealed at various temperatures for 2 hours in a magnetic field of 8 kOe.

Results:

Figures 1 and 2 show the dependence of MR ratio on annealing temperature for MTJs with (CoFe)100-xBx RL and (CoFe)100-xBx FL, respectively. It is noted that all MTJs show a local minimum of MR ratio in the annealing temperature dependence experiments. This MR drop is caused by thermal degradation of the synthetic antiferro (SAF) pinned layer and not by degradation of the tunnel junction. The dashed lines in the figures indicate the critical temperature until which the properties of the SAF pinned layer are retained. For the MTJs with (CoFe)100-xBx RL, the critical temperature depends on boron concentration x. Furthermore, when x = 0-5 at.%, the MR ratio is significantly low, only 50-70%, which is equivalent to that of MTJs using an amorphous Al₂O₃ tunnel barrier. On the other hand, for the MTJs with (CoFe)100-xBx FL, the critical temperature is almost constant between 360°C and 380°C. The MR ratio is always over 100% below the critical temperature and gradually increases with increasing boron concentration x. The low MR ratio in the MTJs with (CoFe)100-xBx RL when x = 0-5 at.% is caused by the lack of (001)-texture of the MgO layer deposited on top of the RL and by the partial oxidation of the the (CoFe)100-xBx RL after high temperature annealing.

Following theoretical predictions, very high tunnel magnetoresistance (TMR) ratios have been achieved in epitaxial Fe/MgO/Fe MTJ structures [1]. The TMR ratio exhibits both temperature and bias voltage dependences, which play critical roles in device applications. In the present work, we analyse the temperature dependence of TMR of fully epitaxial Fe/MgO/Fe/IrMn MTJs grown by MBE. The temperature dependence of TMR ratio, which rises to over 300% at 10K, is fitted using a model based on the effect of magnetic disorder of the electrodes on the spin polarized tunnelling current.

Structural characterization (RHEED, XRD, HRTEM, see ref [2]) established the epitaxial structures as Fe(001)[100]/MgO(IrMn)(001)[110] with sharp interfaces. Junctions (6x8 μm^2 area, 36 per sample) were patterned by optical lithography combined with Ar ion-beam milling. The magneto-transport properties at different temperatures were measured in a PPMS system using a standard four-probe technique with a magnetic field applied parallel to the [100] Fe easy axis. Figure 1 shows loops of the junction resistance R as a function of magnetic field at 300K, 100K, and 10K, measured for an MTJ composition Fe(25)/MgO(3)/Fe(10)/IrMn(10) (thicknesses in nm). A TMR ratio of 170% is found at room temperature which increases to 318% at 10K. Note also in Figure 1 the strong temperature dependence of coercivity and exchange bias field, unlike results of other groups [1], which is attributed to the fully epitaxial nature of the FM/AFM structure in this study. The temperature dependence of the TMR ratio is shown in Figure 2(a) for two different junctions from the same sample as Figure 1. We find a reproducible departure from linearity of the TMR vs T relationship, and the solid lines in Figure 2(a) are fits based on the model to be described. Figure 2(b) shows the resistances of junction-2 in the P and AP configurations as a function of temperature. R_p is seen to be nearly independent of temperature, which is a characteristic of high quality MgO barriers, while R_{AP} increases monotonically with decreasing temperature.

In order to describe the temperature dependence of TMR we have used Slonczewski's [3] expression for the conductance of a tunnel junction: $G = G^0(1 + P_1 P_2 \cos\theta)$, where P_1 , P_2 are the effective polarizations of the FM electrodes and θ is the angle between their magnetisations. This definition is now modified by replacing polarization with magnetization (M) and introducing individual angular terms to define the directions of magnetisation in the two electrodes with respect to the direction of the applied field. The close link between polarization and magnetization has been emphasised by previous authors [4]. At temperatures $T > 0$, the direction of the magnetisation in each electrode will deviate from exact alignment with the applied field according to the minimum of the Zeeman plus exchange energies, and the energy terms are different for the P and AP configurations. Taking R_p to be constant, and using the Bloch relation to describe the temperature dependence of magnetisation [4], the TMR ratio can be expressed as :

$$TMR = (R_{AP} - R_p)/R_p = R_{AP}^0/R_p^0 [1 - \beta M_1^0 M_2^0 (1 - \alpha_1 T^{3/2})(1 - \alpha_2 T^{3/2})] - 1 \dots\dots(1),$$

where the fitting parameter β includes the proportionality factor between polarization and magnetization, and α_1 , α_2 are the Bloch constants for the two FM layers.

The fits, using Eq. (1), of the experimental TMR data are shown by the solid lines in Figure 2(a). The parameters $\alpha_{1,2}$ were obtained by fitting the magnetization curves of reference Fe and Fe/IrMn

layers according to the Bloch equation. The temperature dependence fitting of the TMR ratio has been repeated successfully for MgO barrier thicknesses of 2 and 3 nm. We conclude that the temperature dependence of TMR in epitaxial MgO tunnel junctions is well described by a model based on the magnetic disorder of the two FM electrodes on each side of the barrier.

Two sets of MTJs: pseudo spin valve (PSV): glass/Ta50/Ru180/Ta30/(Co₅₂Fe₄₈)₇₅B₂₅150(50)/MgO150(12)/(Co₅₂Fe₄₈)₇₅B₂₅150(40)/Ru50/Ta50 and exchange biased spin valve (EB-SV): glass/Ta50/Ru180/Ta30/Pt₄₆Mn₅₄200/Co₈₂Fe₁₈20/Ru9/(Co₅₂Fe₄₈)₇₅B₂₅150(30)/MgO150(12.5)/(Co₅₂Fe₄₈)₇₅B₂₅150(30)/Ru50/Ta50 (thicknesses in Å) have been investigated in order to characterize microstructure using XRD methods. Layer thicknesses of MTJs for TMR measurements are given in brackets. The samples were annealed in high vacuum at 340°C, for 1 hour in a magnetic field of 4 kOe applied along the easy axis, and furnace cooled in the field.

Figure 1 shows θ -2 θ diffraction profiles in wide 2θ range for PSV (a) and EB-SV (b) measured for as deposited and annealed samples. It was found for both PSV and EB-SV samples that seed layer 50 Å Ta is amorphous. Buffer layer 180 Å Ru is strongly textured in [002] direction. CoFeB ferro-magnetic electrodes are amorphous in as-deposited state and crystallize to bcc(200) CoFe phase after annealing. The PtMn antiferromagnet in EB-SV sample transforms after annealing from single fcc(111) to single fct(111) phase. The rocking curves of (002) Ru and (200) MgO show that the texture of these materials essentially increases after annealing.

Figure 2 shows θ -2 θ experimental and simulated diffraction profiles in narrow 2θ range for annealed PSV (a) and EB-SV (b), and simulated structure of EB-SV imaged by one dimensional grains (c). The intensities of θ -2 θ profiles were calculated from kinematical diffraction theory using the Monte Carlo simulation method. In this approach polycrystalline multilayer structure is generated with the assumption of the Gaussian distribution of crystallite sizes in the perpendicular to the film plane direction. The calculated intensity profiles are in very good agreement with experimental data. The results of simulations are collected in Table 1. Diffraction θ -2 θ profiles of the annealed PSV and EB-SV (Fig.3) show that amorphous (Co₅₂Fe₄₈)₇₅B₂₅ crystallizes to the CoFe bcc (200) phase. Intensity of CoFe (200) peak in PSV sample and texture coefficient is higher than that of EB-SV sample (Table 1). It means that CoFeB layers adjacent to MgO (200) barrier crystallize more effectively when grown on Ta50/Ru180/Ta30 buffer layers in comparison to those which are separated from buffer layers by PtMn200/CoFe20/Ru9. TMR and RA product of MTJs with layer structure equivalent to the samples for XRD investigation are collected in Table 1. Higher TMR for PSV than that of EB-SV sample is probably due to effective crystallization process of amorphous CoFeB layers in the case of PSV stack layers.

In summary, it can be concluded that after annealing CoFeB amorphous layers, which are adjacent to MgO barrier, crystallize coherently with (200) MgO planes.

The electrical properties of the radically oxidized MgO prepared in different oxidation condition.

Electronics and Optoelectronics Research Lab (EOL), Industrial Technology Research Institute (ITRI), Hsinchu, Taiwan

The improvements of the magnetic tunnel junctions (MTJs) with MgO barriers represent the capability of the MRAM device and spin transfer memory because of their high magnetoresistance ratios (MR) and good resistance-area product (RA) control. High MR results above 200% could be realized in the RF sputtered MgO-based MTJs in recent reports[1]; furthermore, reactively sputtered Mg in radical oxidation process also showed good MR behavior about 100% and better resistance-area (RA) and MR uniformity[2]. Although the MR ratio in the post-oxidized MgO MTJ is only half of that in the RF sputtered MgO MTJ, the RA and MR uniformity and distribution are the main points for mass production. Therefore, in this report, the development of uniformity and film properties of the MTJs with post-oxidized MgO barriers has been studied and the MTJ stacks of Ta/PtMn/CoFe/Ru/CoFeB/Barrier Layer/CoFeB/Ta are deposited on the thermally oxidized Si substrate in UHV sputtering system. The barrier layer was prepared by first depositing the Mg metal layer and then radical oxidized it at the atmosphere of oxygen or argon/oxygen mixed gas. All films were vacuum-annealed ex-situ in a field of 1 Tesla at 360C for 2 hours.

The preparation of the MTJs with radically oxidized MgO is very complicated because there are too many conditions need to be concerned, like deposition power, gas condition, etc.. In this work, we found that the oxidation atmosphere is an important factor for the cell quality. In Figure 1, the MTJs with the MgO barrier made by oxidizing Mg layer under argon/oxygen mixed gas (type A,B,C) or pure oxygen (type D) showed similar MR ratios about 90% and RA about 300 ohm-um². However, for the barriers oxidized in mixed argon/oxygen gas, the MTJ device showed the bad performance and large amount of bad dies. Those dies were short and resulted in no MR and RH loops which may be come from the worse oxidization quality by adding the argon gas. In addition, all dies are short when the argon/oxygen ratio was increased to 1 (Type C, 200/200). For type D, oxidizing in the pure oxygen gas, the device showed higher good dies and similar MR ratio.

Furthermore, compared the radically oxidized MgO MTJs with RF sputtered MgO MTJs, we investigated that the MR and RA uniformity in RF MgO MTJs are 8% and 14%. Both of those could be improved to about 3.7% and 8.5% in radically oxidized MgO MTJs. The uniformity is defined as standard deviation per average value.

Consequently, we have demonstrated that the oxidation atmosphere has greatly affected the MTJ device and the radically oxidized MgO MTJs could possess the better uniformity. In the following work, the influence of the oxidation atmosphere on the MgO texture and device performance will be discussed in detail and the uniformity still continued to be improved.

INTRODUCTION

Magnetic tunnel junctions (MTJs) composed of a crystalline MgO barrier and amorphous CoFeB layers have attracted much attention due to their high TMR values more than 200% at room temperature [1]. Most recently, the pseudo-spin-valve MTJs with rf-sputter-deposited MgO showed that the TMR could reach 500% at room temperature [2]. Magnetic layers of CoFe with B contents over 20 at% followed by high temperature annealing have been required to achieve such high TMR values since they help develop the (001) texture and crystallize the MgO barrier. In our presentation, we discuss changes in the chemical states with different annealing temperatures in the CoFeB free layer and the MgO barrier, and at the interface between CoFeB/MgO/CoFeB.

EXPERIMENTS

We have prepared $\text{Co}_{40}\text{Fe}_{40}\text{B}_{20}/\text{MgO}/\text{Co}_{40}\text{Fe}_{40}\text{B}_{20}$ MTJs by a UHV sputtering system whose base pressure was lower than 2×10^{-9} Torr and annealed them in vacuum at 275 °C and 380 °C for 2 h each. The MgO was rf-sputter-deposited. We performed the photoemission spectroscopy depth profile on the U7 beamline at the Pohang Light Source, which provides a highly brilliant and monochromatic linear-polarized soft x-ray for high-resolution spectroscopy. We used Ne ions to minimize the ion sputtering damage during the depth profiling, and a beam energy of 635 eV for oxygen and 270 eV for boron and magnesium to improve surface sensitivity. We calibrated the binding energies using the valence-band maximum in valence spectra. The base pressure of the experimental chamber was less than 1×10^{-10} Torr.

RESULTS AND DISCUSSION

As expected, the TMR values of MTJs annealed at 380 °C were much higher than those annealed at 275 °C; 124% vs. 56%, more than double increase. However, changes in the chemical states were not as significant as those in the TMR values. The photoelectron spectra of B, O and Mg did not show great differences in chemical states with the annealing temperatures, except for the relative fraction of oxide phases existed in the CoFeB free (top) and MgO barrier layers, and at the interface between CoFeB (top)/MgO. We found not only the metallic B phase but also two distinguishable boron oxide phases, stoichiometric B_2O_3 and oxygen-deficient BO_x , in the CoFeB layer, which is also confirmed by others [3]. On the other hand, we could not see noticeable evidence of the formation of Co and Fe oxides, irrespective of the annealing temperature. We think that the oxygen sources for B oxides in the free layer were probably originated from our sintered CoFeB target. As we get closer to the interface of CoFeB/MgO, the oxygen-deficient BO_x and the metallic B phase started to decrease and finally disappeared in the MgO barrier, as shown in Fig. 1. However, the stoichiometric B_2O_3 phase remained even inside the MgO barrier, confirming the diffusion of B into the MgO barrier during the deposition and the annealing. The relative fraction of B_2O_3 inside the MgO was found to be large when the MTJ was annealed at 380 °C, which indicates that the diffusion of B into MgO was significant at high temperature. In this presentation, we discuss how the chemical states were changed in the CoFeB free layer and the MgO barrier, and at the interface between CoFeB/MgO/CoFeB with different annealing temperatures based on the depth-profile results by high-resolution photoelectron spectroscopy with the synchrotron radiation.

Ab initio calculations of the TMR in magnetic tunnel junctions (MTJ): application to Fe/MgO/Fe.

I. Arias, J. I. Cerdá, M. Muñoz

Intercaras y crecimiento, Instituto de Ciencia de Materiales de Madrid, Madrid, Spain

Magnetic Tunnel Junctions (MTJ) consisting of two ferromagnetic (FM) metal layers separated by a thin insulating layer exhibit a large change in the Tunneling Magneto Resistance (TMR) depending on the relative orientation of the magnetization at the FM layers[1]. The origin of the TMR lies in the dependence of the tunneling probability across the MTJ on the spin state. It is now well established that TMR is determined by the electronic structure of the entire junction, and not only by the properties of the FM. Thus, a realistic and reliable description of the TMR must consider the character, symmetry and spin polarization of the electronic states at the FM, but also any interfacial localized states or any evanescent waves inside the insulator which may be expected due to the chemical bonding at the FM/insulator interface. The Fe(001)/MgO(001)/Fe(001) MTJ can be considered as a model system for TMR studies

since it can be fabricated fully epitaxially providing large TMR ratios[2].

The theoretical study of TMR across MTJ is, however, problematic.

Most of current DFT based codes are restricted to the so called “supercell” approach, whereby a 3D periodicity is always assumed for the system to be studied. Low dimensional structures (e.g. clusters or surfaces) are also treated within this framework by simply inserting large vacuum regions along the non-periodic directions. However, the supercell approach is not well suited for electron transport calculations, since semi-infinite leads are required in order to emit or receive electrons into or from the junction. The presence of the leads breaks any periodicity along the transport direction and hence, the “supercell” approach cannot be employed anymore.

To overcome this shortcoming, we have implemented an interface between the DFT-LCAO based SIESTA package[3] and the GREEN code[4], the latter being designed to solve the Green's functions of non-periodic systems such as the MTJ. As depicted in the figure, we first perform two independent SIESTA calculations, one for the bulk part of the leads and another one for the MTJ interface, which is defined as a 2D slab comprising the oxide layer sandwiched by several metallic planes (see figure). Full atomic optimizations may be performed at this stage in order to account for any relaxations at the metal-oxide interface. However, in the relaxation process the metal atoms far from the interface are fixed to the bulk positions -this is essential to ensure that selfconsistency is preserved in the matching process described below. From the DFT calculations we extract and save the Hamiltonian matrix elements for both the leads and the MTJ. Our next step consists on constructing the Hamiltonian for an infinite MTJ by attaching the bulk leads to the MTJ interface. To this end we split the system into principal layers (PLs), each PL containing several atomic planes so that only nearest neighbor interactions are taken into account. The Hamiltonian hence becomes block tridagonal and infinite. We may use the Hamiltonian matrix elements obtained from the slab calculation (H_{slab}) for all the interactions involving the MTJ interface (PL number 0 in the figure), while those obtained from the bulk DFT calculation (H_{bulk}) may be used for the rest of blocks in the infinite Hamiltonian matrix. The Green's function of such a system is solved exactly via matching techniques[4] and the spin resolved elastic conductance across the junction can then be easily obtained after integration over the 2D Brillouin Zone[4].

We have applied the current approach to the calculation of the TMR across the ideal (epitaxial) Fe/MgO/Fe junction systematically varying the oxide thickness. Although our results are somewhat similar to previous theoretical works on the same system, we also find important issues which differ qualitatively (e.g. the role of atomic relaxations at the interface) and that may provide new insights into the magnetotransport across metal-tunnel junctions.

Substrate biasing effect on the MgO (001) growth in CoFeB/MgO/CoFeB TMR junctions.

G. Choi, W. Lim, T. Lee

Department of Materials Science and Engineering, KAIST, Daejeon, South Korea

After the theoretical prediction of coherent tunneling in Fe/MgO/Fe MTJ[1,2], high TMR ratio were reported by two groups[3,4]. More recently similar results were reported in CoFeB/MgO/CoFeB MTJ after annealing, which is easier to fabricate. However, good (001) oriented MgO layer on CoFeB layer in thin thickness is not so easy task and reports on high TMR and low RA are limited by several groups. In this work we have studied effect of substrate bias voltage during MgO layer deposition on TMR ratio and RA of CoFeB/MgO/CoFeB MTJ as a function of target-substrate (T-S) distance.

A homemade multi-target UHV sputtering system with back ground pressure of better than 5×10^{-9} Torr was used for the deposition. Si/Ta/NiFe/IrMn/CoFe/Ru/CoFeB/MgO/CoFeB/Ta stacks were deposited and fabricated to $10 \times 10 \mu\text{m}^2$ cells by a photolithography and ion beam etching. The patterns were annealed at 400°C in vacuum of 3×10^{-6} Torr with an applied field of 1000 Oe. MgO layer was kept at a constant thickness of 2nm in all experiments. During MgO layer deposition substrate bias was applied.

As sputter power increased from 60W to 200W at 10mTorr with T-S distance of 5cm, TMR was a nearly constant of 250% but RA increased. This suggests some parts of the bottom electrode may be oxidized by O ions or radicals. When the T-S distance was varied from 5 to 10cm. TMR rapidly decreased and RA increased more drastically as shown in Fig. 1. The reason of this behavior can be explained by formation of weaker (001) texture of MgO layer as the T-S distance increases as shown in Fig. 2. Deterioration of the MgO (001) growth must be associated with lower ad-atoms' mobility on the substrate surface as the T-S distance increases. If mobility of ad-atoms is high enough MgO will grow to (001) orientation as (001) surface has the lowest surface energy. It is concluded that in order to get high TMR and low RA high mobility of ad-atoms and reduction of oxidation of the bottom electrode by reducing flux of O ion and radical are needed. As population of ion species decreases faster than that of neutral atom species as T-S distance increases, we increased T-S distance while applying substrate bias voltage to increase ad-atom mobility via Ar ion bombardments. The results are appeared in Fig. 3. In both cases, as bias voltage increases, TMR increases and RA decreases. However, it should be mentioned that when negative bias voltage exceeds -50eV for 20mTorr, TMR was not detected due to strong etching effect on growing MgO surface. High RA must be associated with two major factors; misoriented MgO (001) growth by which broken lattice matching between CoFeB and MgO during post-annealing for coherent tunneling and partial surface oxidation of bottom electrode. In the case of the specimens of TMR beyond 200 or 250% range, the major reason of high RA must be associated with partial surface oxidation of bottom electrode. In this paper, role of H_2O during sputtering process was not studied as we have used a constant back ground pressure condition. The TMR ratio achieved was 352% at RT but RA was $100 \text{ k}\Omega\mu\text{m}^2$ range. The RA is much higher value than the previously reported one [5,6].

Applying substrate bias voltage during MgO layer deposition is effective for increasing TMR and lowering RA especially when T-S distance increases. This is due to increased ad-atom mobility by Ar ion bombardment via substrate bias and reduced O ion population as T-S distance increases.

The bias voltage dependence of inverted magnetoresistance on the annealing temperature in MgO-based magnetic tunnel junctions.

J. Feng, G. Feng, J. Coey

CRANN and school of physics, Trinity College, Dublin, Ireland

MgO-based magnetic tunnel junctions (MTJs) with a main layer sequence Ir₂₂Mn₇₈ (or Fe₅₀Mn₅₀, 10 nm) /Co₉₀Fe₁₀ (2 nm) /Ru (0.85 nm) /CoFeB (0 < t < 3 nm) /MgO (2.5 nm) /CoFeB (3 nm) have been fabricated. The inverted tunneling magnetoresistance (TMR) as high as -55% has been observed at zero bias for these MTJs at t = 1.5 nm. More details can be found in Ref. 1. TMR is defined as (RAP-RP)/RL, RP and RAP are the resistances of MTJs when the magnetizations of the ferromagnetic electrodes in contact with tunnel barrier are parallel and antiparallel, and RL is the lower one. Here we give a detailed description about the bias voltage dependence of the TMR as a function of the annealing temperature (Ta) in these MTJs with a thin CoFeB layer in the pinned synthetic antiferromagnetic CoFe/Ru/CoFeB stack.

Experimental results show that a possible discontinuous CoFeB film may form on Ru when the pinned CoFeB layer in the synthetic antiferromagnetic stack is thin (t < 1.5 nm), and the TMR ratio changes its sign from inverted to normal at a critical bias voltage (VC) without any annealing process. VC is the bias voltage at which TMR = 0, as shown in Fig.1. Figure 1 (a) shows the bias voltage dependence of the TMR ratio for one FeMn- MTJ with t = 0.75 nm, the sign change of the as-grown TMR happens at VC = -0.28 V. The inverted and normal TMR curves at VC = +0.2 and -0.4 V are shown in Figure 1 (b) and (c), respectively. However, no VC can give at as-grown state and Ta = 150 oC for the MTJs with t = 0.5 nm due to no appearance of the obvious TMR. At Ta > 150 oC, the magnetotransport behavior happens, which may be due to certain Ru diffusion in the annealing process.¹ It is easy to find that the annealing effect has a key influence for these MgO-based MTJs.

The VC at different CoFeB thicknesses increases largely by increasing the Ta and starts to decrease at a certain Ta (see Fig. 2), which has a similar change compared to that of TMR versus Ta.¹ The VC at higher Ta was not attained for the MTJs with t ≥ 0.75 nm because the larger bias voltage was needed to apply and the MTJs were easy to be destroyed. These VC values in Figure 2 are much changed for different CoFeB thicknesses and Tas, which suggests that a strong density-of-states modification at bottom oxide/ferromagnet interface appears.^{2, 3}

In the far infra red (IR), the dielectric response of a metal is directly related to its d.c. electrical conductivity with the result that the refractive index is a function of the electrical resistivity. This is exploited in remote techniques for measuring giant magnetoresistance (GMR) by sensing a change in reflection, transmission or emission in an applied magnetic field [1,2]. In spectral magnetorefractive effect (MRE) measurements, the percentage change in reflected intensity in an applied magnetic field is measured as a function of wavelength. The effective medium approach normally used to model metals breaks down when studying magnetic tunnel junctions (MTJ) due to the presence of the insulating tunnel barrier through which IR transmission is high. Previous work has concentrated on thick film granular tunnelling materials such as Co-Al₂O₃ which contain large volume fractions of insulator, the dielectric properties of which are modified by the magnetic inclusions [3]. Spin dependent effects have been seen in thick granular films in which multiple reflections occur, enhancing the changes which occur in a magnetic field [4,5]. We report the detection of a significant MRE in a patterned tunnel junction, enhanced by the presence of an absorption edge associated with MgO.

The sample (Fig. 1) was prepared by molecular beam epitaxy on an MgO substrate and patterned into 3mm arrays of square pillars of dimensions: 50µm and 5µm. The structure of the MTJ is: MgO(100)/MgO_{20nm}/Fe_{20nm}/MgO_{1.5nm}/Fe_{5nm}/Co_{3nm}/Au_{3nm}. The MRE spectra from 2-20µm were measured with randomly polarised IR radiation using a Fourier Transform Infra red Spectrometer in applied fields up to 1.25T, shown in Figs. 2 and 3 for the 5µm pillars. As the film is thin compared to the skin depth of the IR radiation, the raw IR spectrum is dominated by the spectral response of the MgO substrate which contains the longitudinal optic (LO) and transverse optic (TO) phonon modes at 24µm and 13.5µm respectively. This results in a sharp increase in reflectivity as the wavelength is increased at approximately 12.5µm. In 1.25T, the size of the MRE is approximately 0.2% at long wavelengths with a prominent step of magnitude 0.6% at the absorption edge. The MRE scales with the applied field, and has not yet saturated at 1.25T. Control experiments carried out on MgO substrates and the sample holder confirm that the MRE originates from the sample. Fig. 2. is an average of 10 very similar spectra demonstrating the repeatability of the measurement. No significant differences were observed between the 5µm and the 50µm pillars. The origins of the spin-dependent effect are not yet clear; they may result from bulk spin dependent scattering within the magnetic layers, or the more direct effect of spin dependent tunnelling on the dielectric response. The results demonstrate the effectiveness of using a resonant feature in the underlying reflectivity spectrum to enhance an otherwise small MRE, opening the way to using the technique to study a wider range of materials or using the step edge as a magnetic switch.

Low Frequency Noise in MgO Magnetic Tunnel Junctions: Hooge's Parameter Dependence on Bias Current Density.

J. M. Almeida^{1,2}, P. P. Freitas^{1,2}

1. INESC - MN, Lisbon, Portugal; 2. Physics, IST, Lisbon, Portugal

Single (SB) and double barrier (DB) magnetic tunnel junctions (MTJs) were deposited with the stacks presented in Figure 1a and 1b. These samples were processed with areas of $200 \mu\text{m}^2$ (elliptical junction shape), presented RA products ranging from 20 to $60 \text{ k}\Omega \cdot \mu\text{m}^2$ and TMR values up to 110% (Figure 1c).

At low frequencies and for samples showing no Random Telegraph Noise (RTN), $1/f$ noise dominates: $S_V^{1/f}(\text{V}^2/\text{Hz}) = \alpha V_b^2/(A \cdot f)$

where α is the Hooge parameter, A stands for the junction area, S_V the noise power spectrum and V_b the junction bias voltage. Non-magnetic α values depend on barrier properties (RA product), and MTJs low or high resistance states). This work demonstrates that the Hooge parameter, measured on magnetically saturated MTJs, also shows a dependence on the current density flowing through the junctions for both single and double barrier MTJs.

Noise measurements were made for both types of MTJs. Permanent magnets were used to saturate the junction's free layer with an applied field of $\pm 250 \text{ Oe}$ during measurement. Figure 2 shows a set of noise measurements made for a DB MTJ vs. bias current. The Hooge parameters obtained from these curves are plotted in Figure 3. " α " varies from $\approx 9\text{E-}9 \mu\text{m}^2$ near zero bias to $\approx 1\text{E-}9 \mu\text{m}^2$ at $j = 1.5 \times 10^3 \text{ A/cm}^2$. Similar measurements on SB MTJs show a weaker but still significant decrease of α with bias current (from $\approx 1\text{E-}9 \mu\text{m}^2$ to $\approx 3\text{E-}10 \mu\text{m}^2$ in the HR state). The reproducibility of this bias current dependence was verified measuring for both increasing and decreasing current densities.

Introduction:

Over the last decade, the magnetic tunnel junction (MTJ) devices have been extensively studied due to great potential for spintronic devices. For the aspect of memory application, a good unit cell must possess low field leakage and reversible switching process to enhance storage density and operating mode, respectively. As a result, ring-shaped element was firstly proposed to be the best candidate for magnetic random access memory (MRAM) cell due to its unique shape [1]. The advantage of using the ring-shaped cell is the lack of the energetic core in the center of circular element, giving rise to a simple and reproducible switching behavior [2-3]. In addition, a recent publication has shown nanostructured MTJ rings with current-induced magnetization switching method and thus the storage density is expected to be dramatically increased [4]. However, the mechanism for having many different intermediate states taken place in the free layer switching process in the previous publications is still unclear. Herein, we present a study of a series of nanostructured MTJ rings to investigate the magnetization reversal processes. The concerns are focused on the size dependent free layer switching process and coupling effects.

Experiments:

Stack films consisting of Si/SiO₂ 50-substrate/ Ta 5/ Ru 40/ Ta 5/ (Co₅₀Fe₅₀)₇₈B₂₂ 4/ Mg 0.4/ MgO 1.8/ (Co₅₀Fe₅₀)₇₈B₂₂ 4/ Ru 0.85/ Co₇₀Fe₃₀ 3/ MnIr 7.5/ Ta 5/ Ru 7 -cap (thickness in nm) were first prepared by magnetron sputtering system. Various MTJ rings with outer diameter/linewidth of 0.7 μ m/100nm and 1 μ m/100 nm were fabricated using a top-down technique. Firstly, a hard mask of Cr was created by standard electron beam lithography through a lift-off process. Subsequently, a two-step ion-milling was utilized to transfer the ring pattern into the MTJ stack films. A 40 nm SiO₂ insulating layer was then sputtered on the whole devices area, followed by an etch-back technique for making the top electrodes. The magnetization reversal processes was investigated using four-terminal magnetoresistance measurements with the external field applied in the film plane.

Results and discussion:

Figure 1 (a) shows the R-H major loop of a MTJ ring with outer diameter/linewidth of 0.7 μ m/100nm. A significant reduction of biasing field, from 1600 Oe extracted from the AGM data of the sheet film down to 250 Oe measured from the ring device, indicates a strong anisotropy effect in this small ring. Figure 1 (b) presents the minor loop of the abovementioned MTJ ring, in which the magnetoresistance ratio (MR) is about 50 % and the resistant-area product (RA) is about 6400 $\Omega\mu$ m². Double transition process is examined with fixed magnetization configuration in pinned layer and field-switching process in free layer. A simpler magnetization reversal process in comparison with micronstructured MTJ rings [3] within free layer, i.e. onion to vortex to reversed onion state, was observed. Figure 2 represents the minor loop of the other MTJ ring with diameter/linewidth of 1 μ m/ 100nm, in which the MR ratio is about 70 % and the RA is about 3100 $\Omega\mu$ m². In contrast to the smaller outer diameter MTJ ring, the same transition process is also revealed. The

antiparallel coupling, showing the shift of minor loop, are both observed in these patterned MTJ rings, implies that the dipolar coupling of the pinning system of synthetic antiferromagnet structure is strikingly reduced. Moreover, different transition fields, i.e. Hc1 of onion to vortex and Hc2 of vortex to reversed onion, are also perceived. Notice that the Hc1/Hc2 of 70/120 Oe and 30/125 Oe are observed in diameter/ linewidth of 0.7 μ m/ 100nm and 1 / 100 nm MTJ rings, respectively. Details of the fabrication and characterization will be discussed.

First-principles calculations of structural and magnetic properties of Fe/MgO/Fe with interfacial Mg vacancy.

C. Kim, G. Yoon, Y. Chung

Materials Science and Engineering, Hanyang University, Seoul, South Korea

Magnetic tunnel junctions (MTJs) utilizing tunneling magnetoresistance have been strong candidates for the application of spintronic devices. Because the thickness of each thin film is in a few nanometer scale, understanding the influence of the imperfections upon a magnetic properties is becoming increasingly important. We demonstrated theoretically that the electronic structures in Fe(001)/MgO(001)/Fe(001) MTJ are strongly affected by the interfacial Mg vacancy. Using Vienna ab-initio simulation package code, density functional theory calculation was performed. The projector augmented wave-generalized gradient approximation method was employed.

Calculation yielded 1.74 Å of Fe-O distance.(Fig. 1) The Mg-interface atoms positioned 0.19 Å lower than the O atoms while the Fe-interface atoms kept their position. This reconstruction led the consequent fluctuation of the second MgO layer, so that the half of O atoms displaced upwardly whereas another half displaced downward. There were no lateral displacements in the plane parallel to the (001) for both layers regardless of lateral lattice mismatch of 5.5% between the electrode and barrier layers. The layer density of states (DOS) profile for Mg and O atoms in barrier layer showed very large unexpected band in the energy range between the conventional valence band and conduction band.(Fig. 2) Specifically, band gap for interfacial atoms of MgO layer was nearly vanished because of the noise states induced by the hybridization. Most of DOS peaks for Mg- and O-interface atoms consist of s and p. However, there also exist considerable $d_{x^2-r^2}$ and $d_{x^2-y^2}$ orbital states. Although the noise of DOS was negligible at Fermi energy of MgO-center, strong enhancement of spin polarization at the energy range from -0.25 eV to -0.1 eV was found. Because of non-symmetric occupancy between spin-up and spin-down states the magnetic moment became 0.20 μ_B .

The absolute amount of both majority and minority DOS was approximately zero as shown in Fig. 3. However, it was clearly seen that the distribution of spin polarization values of MgO was spread in almost same range of the polarization of Fe layers. It can be reasonably inferred that the induced DOS and unexpected polarization for atoms in the barrier layer resulted from the hybridization of 2p states of Mg and O ions with 3d band of Fe atoms, which involved in the junction formation. Furthermore the third and fourth slabs of Fe layer exhibit the negative polarization. Consequently, relatively small magnetic moment for those two atomic slabs was predicted.(Fig. 3)

The energy gap between the valence and conduction bands yielded 7.5 eV commonly to both spin channels.(Fig. 4) At approximately -2.5 eV, single impurity state was induced for majority channel, and additional sub band at -3.0 eV was found for minority channel. Contrary to existence of 1.3 eV of energy mismatch between both spin channels of the Mg-interface atom, the bands of Mg-center atom positioned at same energy level. The small gap opened in majority channel of interfacial O atom, but the unexpected noise exists, which remained in O-center layer as well. Among the noise states there were only negligible d states whereas the other band region contains significant d_{yz} and d_{xz} states for valence, and d_{xy} , d_{yz} , and $d_{x^2-r^2}$ for conduction band. It was obvious that the electronic structure of Fe layer propagated into the barrier layer, and the influence on the O atoms was much stronger than the Mg atoms.

The tunneling magneto resistive (TMR) head [1,2] is widely used as HDD read sensor. Although several barrier materials were studied for its application, MgO-TMR leads to great success to achieve large MR ratio over 200% [3-7]. On the other hand, in terms of sensor resistive, the MR head whose resistance-area product (RA) is around 0.1 Ohm micron², is needed for 1 Tbit/in² recording [8]. Thin barrier layer under 1nm in thickness has low-RA under 1 Ohm micron² [8], however, it is difficult to sustain high-MR ratio and high-breakdown voltage. Therefore, insulators of high MR ratio and low barrier height are needed for next breakthrough beyond MgO-TMR. In this study, we report ab-initio electronic transport calculations for new magnetic tunneling junction (MTJ) structures with low band-gap insulator.

We performed transmission calculations based on NEGF method [8] formulated by linear combination of pseudo atomic orbitals(LCAO) [9]. All results are calculated by OpenMX which is electronic structure calculation code based on DFT [10]. As insulating materials for a barrier layer sandwiched between ferromagnetic layers, we examined MgO, ZnO and CaO, which are insulating oxides with rock salt structure. These materials are suitable to replace the MgO layer and to make a good interface with (001) aligned bcc Fe layer.

Table 1 shows calculated electronic transport properties of MTJ in the cases of six atomic layers of MgO, ZnO and CaO sandwiched between bcc Fe ferromagnetic layers. The MTJ with the MgO layer has the large MR ratio over 1000% [3,4], because the MgO layer can transmit mainly delta 1 electrons which construct the eigen-state of majority spin near the Fermi level. On the other hand, MTJs with ZnO and CaO layer have low RA and low MR ratio. This reason is investigated by transmission and spectral function [8]. Fig. 1 shows the transmission in k-space of MTJ with ZnO layer (a) and CaO layer (b). In the case of ZnO, the delta 1 electron near gamma point in k-space tunnels through the insulator layer similar to MgO's result, however, this result indicates that MTJ has lower RA than that of MgO, because ZnO has delta 1 eigen-state as LUMO state with low excitation energy. On the other hand, MTJ with CaO layer has different transmission whose peak are located near k=(0.5,0.5). Because CaO has delta 5 eigen-state as LUMO at k=(0.5,0.5), MTJ with CaO can transmit only delta 5 electrons. These results show that ZnO has same symmetry filtering effect similar to MgO, and ZnO is a candidate to be compounded or formed multi-layer with MgO for low RA and high MR ratio. Next, we examined the MTJ with ideal tri-layer structure MgO(1L)/ZnO(4L)/MgO(1L). Fig. 2 shows transmission of majority spin at parallel configuration and spectral function at anti-parallel configuration which is compared with that of ZnO mono-layer. In ZnO mono-layer case, interfacial resonant state is observed and decreases the MR ratio. The tri-layer suppresses this resonant state by inserting MgO at the interface, has a large MR ratio, calculated value is 1300%.

Inhomogeneity and magnetism in diluted magnetic semiconductors.

B. Sanyal, R. Knut, O. Granas, D. M. Iusan, O. Karis, O. Eriksson
Department of Physics, Uppsala University, Uppsala, Sweden

In semiconductor spintronics [1], the spin of the electron is manipulated by the control of charge carriers. Two major tasks are involved in the realization of a successful diluted magnetic semiconductor (DMS) to be used in future spintronic devices: a well characterized sample without inhomogeneities and the occurrence of ferromagnetic order at room temperature and above. However, a wide variation of experimental results [2] showing strong or weak ferromagnetism or paramagnetism, exists for Co doped ZnO diluted magnetic semiconductor indicating the absence of homogeneity in the samples. Recently, it was shown from experiments [3] that the high temperature ferromagnetism in DMS materials without charge carriers can originate from the nanocrystals of magnetic ions. The increased density of magnetic ions in certain regions of the samples reflects inhomogeneities.

Here, we have studied the chemical and magnetic interactions in Co doped ZnO diluted magnetic semiconductor by *ab-initio* density functional calculations. We have performed electronic structure calculations using a Green's function Korringa-Kohn-Rostoker (KKR) method [4]. The chemical and magnetic disorder were simulated by the use of coherent potential approximation (CPA). The Heisenberg pair-exchange parameters were determined using the theory of Liechtenstein *et al.* [5]. The chemical pair interactions were calculated using the generalized perturbation method. To generate the atomic configurations, we performed Monte-Carlo simulations (MCS) on an Ising model Hamiltonian. To allow for different stages of growth, we terminated our simulations after different number of Monte-Carlo steps. The corresponding atomic configurations were used for the calculation of magnetization using the calculated magnetic exchange interaction parameters. These simulations were done by a single spin flip Metropolis algorithm. Curie temperatures were estimated from the magnetization vs. temperature plots.

The calculated first neighbor chemical interaction is very strong indicating a strong tendency of clustering between the Co atoms hence paving the way towards a phase separation commonly known as spinodal decomposition. Both chemical and magnetic pair interaction parameters are short-ranged with a large first neighbor interaction.

Magnetization is strongly dependent on the configurations of magnetic atoms. For 10 % of Co, at an early stage in the annealing process, the spins can interact with each other and a long-range ferromagnetic order is established. So, a well defined magnetization vs. temperature curve is obtained showing a finite T_C (Fig.1). However, after 2000 MC steps, the Co clusters have become so large so as to effectively absorb all Co atoms in the simulation cell. We are left with a system with clusters of Co atoms which are separated far from each other, which has the consequence that they cannot interact with each other to establish a magnetic percolation path. As a result, we do not observe ferromagnetism in the system. Any magnetic response from such materials should rather be referred to as super paramagnetic.

The situation is different for 30 % Co. Here a consistent increase in T_C with an increase in MCS step is clearly observed in Fig.1. For a homogeneous distribution of Co atoms in the beginning of the annealing process, the estimated T_C is around 200K. At a very large number of MCS step 20000, one observes an extremely high T_C indicating the formation of a metallic Co in a big spanning cluster throughout the system. As the Co atoms are close to each other in a spanning cluster, it is very easy to interact with each other with this strong ferromagnetic interac-

tion. This phenomenon explains qualitatively the wide variation of results on the ordering temperatures obtained in experiments.

Interface magnetism in Fe_2O_3 - FeTiO_3 heterostructures.

S. Sadat Nabi, R. Pentcheva

department of earth and environmental sciences, section crystallography, Ludwig Maximilian University of Munich, Munich, Germany

Charge mismatch at complex oxide interfaces can give rise to properties and functionality distinct from the bulk [1,2,3,4]. The unique magnetic behavior of the hematite-ilmenite system [5] has received revived interest as a possible cause for magnetic anomalies in the Earth's crust and on other planets [6]. In addition, Ti doped hematite is a potential material in the search of a room temperature (RT) ferromagnetic semiconductor for spintronic devices [3,7,8]. To explain the strong and stable remanent magnetization in nanoscale exsolutions of the canted antiferromagnet (AFM) hematite and the RT paramagnet ilmenite, Robinson et al. [9] proposed a mixed Fe^{2+} and Fe^{3+} contact layer. This so called lamellar magnetism (LM) hypothesis is based on bond valence arguments and kinetic Monte Carlo simulation with empirical parameters, but a microscopic understanding from first principles was lacking so far.

To this end we have performed DFT calculations on solid solutions and heterostructures of hematite and ilmenite using the FP-APW method in the WIEN2k-code [10].

As a starting point we have modelled the end members $\alpha\text{-Fe}_2\text{O}_3$ and FeTiO_3 in a hexagonal primitive unit cell containing 30 and 60 atoms, respectively (Fig.1). We find that the inclusion of electronic correlations within the LDA+U method [11,12] is decisive to obtain the correct ground state and band gap of the bulk materials i.e. AFM coupling of Fe layers in $\alpha\text{-Fe}_2\text{O}_3$ with Fe in the Fe^{3+} oxidation state and a Fe^{2+} and Ti^{4+} ground state configuration in FeTiO_3 .

varying systematically the concentration, distribution and charge state of Ti (Fe) incorporated in a $\alpha\text{-Fe}_2\text{O}_3$ (FeTiO_3) host we explore different scenarios for the charge compensation mechanism in this system and its consequences for the magnetic and electronic behavior. A phase diagram of the different configurations showing the stability with respect to the end members as a function of Ti-doping is shown in Fig.2. Each Ti ion, irrespective of the charge state ($3+$ or $4+$) adds a defect magnetic moment of $4\mu_B$ to the system. Ti incorporation in the same spin-sublattice which maximizes the net magnetic moment is slightly preferred to substitution in different spin-sublattices in agreement with previous LDA+U results [13]. However, we find a clear preference to form layered arrangements as opposed to solid solutions. When Ti substitutes for Fe^{3+} in the hematite host, it is not inert as commonly assumed but plays an active role in charge compensation and the emergence of magnetism: in a single Ti layer in hematite the preferred charge state is Ti^{3+} , Fe^{3+} . The spatial distribution of the majority spin density with an occupied d_{z^2} orbital at the Ti^{3+} -sites across the interface is shown in Fig. 1a. As soon as a thicker ilmenite-like block forms, the most favorable compensation mechanism is through Ti^{4+} and a disproportionation in the Fe contact layer in Fe^{2+} , Fe^{3+} (Fig.1b) giving first theoretical evidence from correlated band theory for the lamellar magnetism hypothesis [14].

The band gap reduces to 0.7-1.0 eV and in some cases (at 66% Ti-doping) to half-metallic behavior, making this system a promising candidate for spintronics applications.

Transition metal oxides exhibit a rich spectrum of properties such as ferroelectricity, magnetism, superconductivity, Mott insulator-metal transition and colossal magnetoresistance, to name only a few. Oxide heterostructures offer not only the possibility to combine these properties in one material, but also to generate novel functionalities that do not exist in the parent compounds. The conductivity measured at the interfaces between the Mott insulator LaTiO₃ and the band insulator SrTiO₃ [1] but also between the two simple band insulators LaAlO₃ (LAO) and SrTiO₃ [2] has triggered intensive research and excitement both on the theoretical and experimental side. Recently LaAlO₃/SrTiO₃ interfaces were reported to be magnetic [3] and even superconducting [4]. To explain these results we have performed density-functional theory (DFT) calculations including a Hubbard U on a variety of LaTiO₃/SrTiO₃ and LaAlO₃/SrTiO₃ superlattices where we have varied the number of layers of each material. We find that the charge mismatch at the LaTiO₃/SrTiO₃ as well as the n-type LaAlO₃/SrTiO₃ interface (a LaO layer next to a TiO₂-layer analogous to the Mott insulator LaTiO₃) is accommodated by charge disproportionation on the Ti-sublattice in the interface layer in Ti³⁺ and Ti⁴⁺. The charge density distribution of the occupied d-states in Fig 1a) shows that this state is not only charge ordered (CO) with Ti³⁺ and Ti⁴⁺ arranged in a checkerboard manner, but also orbitally ordered with an occupied dxy-orbital at the Ti³⁺-sites. These results point at additional compensation mechanisms in complex oxides with multivalent cations that are not available in conventional semiconductor heterostructures. We find a slight preference for an antiferromagnetic (AFM) alignment of the Ti³⁺ spins [5,6], but with a periodicity that is different than in bulk AFM-G type LaTiO₃. This result is particularly interesting for the n-type LaAlO₃/SrTiO₃ interface, because here the corresponding bulk materials are not magnetic. First experimental evidence for localized magnetic moments in this system is given by Brinkmann et al. [3].

While for the ideal positions of the atoms a 1LTO/5STO superlattice is insulating in the strong interactions regime ($U=8\text{eV}$, $J=1\text{eV}$), lattice relaxations lead to a metallic behavior (cf. Fig 1b) and c)). We also discuss the influence of lattice relaxation on the electronic and magnetic properties of more isolated interfaces in a 5LAO/5STO-heterostructure.

An enhanced complexity with respect to orbital occupation is observed at the LaVO₃/SrTiO₃ interface. The charge mismatch at this d₂-d₀ interface can be accommodated either by Ti³⁺ or promote V⁴⁺. Both compensation mechanisms and the resulting magnetic and orbital order will be discussed in the context of recent experimental findings [7].

Magnetism of conduction band, exchange interactions and magneto-caloric effects in pure hcp Gd: a first-principles calculations.

S. Khmelevskyi¹, A. V. Ruban², I. Turek³, P. Mohn¹

1. Center for Computational Materials Science, Vienna Technical University, Vienna, Austria; 2. Royal Unicersity of Technology, Stockholm, Sweden; 3. Charles University, Prague, Czech Republic

The pure Gd metal exhibits an example of model system where a strongly correlated and well-localized magnetic 4f-electronic subsystem interacts with broad spd-conduction band. The intensive spectroscopic studies of the last decade have revealed a highly non-trivial behavior of the conduction band at finite temperatures due to increasing thermal disorder of the localized 4f-moments. We present a first-principles theoretical framework, which gives a description and physical explanation of microscopical photoemission probes as well as macroscopical behavior such as the anomalous thermal expansion and a value of the Curie temperature. In order to describe an electronic structure of the conduction band we model thermal disorder of 4f-moments using Disordered Local Moment approach. The calculations are püerformed within the Korringa-Kohn-Rostokker band structure formalism in the framework of the Local Spin Density Approximation. The local moments associated with 4f-states are treated by an open core model. We find that the local splitting of the conduction band remain finite in paramagnetic state, but order of magnitude smaller than in FM ground state. We also show that changes in the electronic structure of conduction band lead to the strong temperature dependent renormalization of magnetic interactions between localized 4f-moments. The magnetic interactions have been calculated using first-principles magnetic force theorem and then used to derive the Curie temperature of hcp Gd from statistical Monte-Carlo simulations. Having estimations of the exchange constants in paramagnetic state and their dependence on the total magnetization, we calculate also a magnetic specific heat dependencies on the external magnetic field and thus a give a first principles description of the magnetocaloric effect in pure Gd.

Ab-initio magneto-optical properties of bcc Ni/Ni(100).

C. Etz¹, A. Vernes¹, L. Szunyogh^{1,2}, P. Weinberger¹

1. Center for Computational Materials Science, Vienna University of Technology, Vienna, Austria; 2. Department of Theoretical Physics, Budapest University of Technology and Economics, Budapest, Hungary

By using the Luttinger formula and the spin-polarized relativistic screened Korringa-Kohn-Rostoker method, the inter- and intra-layer contributions $\sigma^{pq}(\omega)$ to the complex optical conductivity have been computed for a photon wave length $\lambda = 633$ nm and both bcc Vac_Nvac/Ni_Nlay/Ni(100) and Ni(100)/Ni_Nlay/Ni(100) respectively, layered systems showing an in-plane magnetization. By comparing the layer-resolved permittivities with that of the semi-infinite bulk substrate, it is shown that with the exception of the xy components all other permittivity tensor elements are dominated by contributions arising from the surface.

Ab-initio Kerr angles obtained via the 2x2 matrix technique for an arbitrary linearly polarized light at oblique incidence within the 0yz plane prove that the appropriate formulas for Kerr angles, widely used in the literature, are valid for a relatively large range of incidence angles.

The calculated Fresnel coefficients show that besides the magnitude of the average magnetization, they only depend on the angle of incidence θ . Within the range of validity of the appropriate formulas

$$\theta_K = \theta_K^l m_l + \theta_K^q m_l m_l \quad (1a)$$

$$\epsilon_K = \epsilon_K^l m_l + \epsilon_K^q m_l m_l \quad (1b)$$

the θ -dependence of the linear Fresnel coefficients was found to scale as $\sin\theta$ confirming the experimental expectation, whereas the quadratic Fresnel coefficients are almost independent of θ . (see Fig.1)

With these highly accurate Fresnel coefficients, the appropriate formulas in Eqs.(1) can be applied to determine Kerr angles for any arbitrary direction of a uniform in-plane magnetization. A comparison of the calculated Kerr angles obtained via the 2x2 matrix technique with those determined by using the two-media approach (see Fig.2) evidences that the latter only applies for a normal incidence, whereas for arbitrary oblique incidences about 75% of the magnitude of Kerr rotation angles comes from surface contributions.

FIG. 1: Fresnel coefficients for p -polarized light incident within the 0yz plane ($\lambda = 633$ nm) in bcc Ni/Ni(100) as a function of the angle of incidence θ , see Eqs.(1). $\sin\theta$ -scaled linear and plain quadratic Fresnel coefficients are shown by open and full circles, respectively.

FIG. 2: Differences in the Kerr angles for oblique incidence of p -polarized light in 0yz plane ($\lambda = 633$ nm) and bcc Ni/Ni(100), when using the 2x2 matrix technique and the two-media approach as a function of the incidence angle θ (left) or the polar angle ϕ_M (right). In the left panel circles, squares, diamonds and triangles (up, left and down) refer to Kerr angles obtained for a polar angle $\phi_M = 15^\circ, 30^\circ, 45^\circ, 60^\circ, 75^\circ, 90^\circ$ (open symbols), in the right panel circles, squares, diamonds and triangles (up, left, down and right) represent Kerr angles obtained for an angle of incidence $\theta = 0^\circ, 10^\circ, \dots, 60^\circ$ (open symbols), stars, pluses and crosses stand for $\theta = 70^\circ, 80^\circ, 90^\circ$.

Influence of external magnetic field on the resistivity of a one-dimensional Neel type magnetic domain wall in presence of Rashba spin-orbit coupling.

M. Ghanaatshoar¹, V. Fallahi¹, M. M. Tehranchi¹, A. Phirouznia²

1. Laser and Plasma research institute, Shahid Beheshti University, Tehran, Iran; 2. Department of physics, Azarbaijan University of Tarbiat Moallem, Tabriz, Iran

Magnetic nanowires offer new prospect for spintronic devices such as sensor, switch and data storage memory. In these systems spin-dependent scattering makes accountable role in the electrical resistance. In addition, the long dephasing time of electron's spin and easy manipulation of the spin polarization by an external magnetic field, have made these kinds of materials to be one of the suitable candidates for information transmission devices. Spin relaxation time can be affected by various interaction mechanisms. It is well known that the domain walls (DWs) in the nanowires cause spin-flip scattering via coupling of two spin states [1]. Furthermore, presence of Rashba spin-orbit interaction which arises due to asymmetry of confining potential in the low dimensional systems can decrease the relaxation rates of electrons and consequently change the DW resistance [2]. However, by applying external magnetic field, one can eliminate the spin-flip scattering via Rashba spin-orbit interaction.

In this paper, we systematically investigate how the interplay between the Rashba spin-orbit interaction and Zeeman coupling affects the electron transport through the 1-dimensional (1-D) DWs. Confinement of the electrons in one dimension eliminates the magnetic part of the Lorentz force which is exerted on electrons, but the magnetic field still contributes in collision term through the Zeeman interaction. The studies have been carried out on the ideal 1-D linear Neel type DWs which are shown in Figure (1). For a smooth linear DW, the local direction of magnetization can be described by $\theta(z) = \pi z/d$ in which d is the DW width and θ is the angle between the local direction of magnetization and wire axis (z axis). We suppose that the magnetic field do not affect the DW configuration.

The Hamiltonian of the system can be written as

$$H = H_0 + H_{sf} + H_Z + H_R$$

where H_0 contains periodic potential and kinetic energy, H_{sf} is the s-f exchange between the conduction electrons and the localized magnetic moments, H_Z is the Zeeman interaction and H_R represents the Rashba coupling Hamiltonian. The appropriate spin-orbit coupling Hamiltonian operator for electrons moving with a well-defined k along the DW can be written as

$$H_R = 2\pi\gamma_R/\hbar \sigma \cdot (n \times p)$$

where \hbar is planck's constant, p is the momentum of the electron, n is the induced electric field direction due to structure inversion asymmetry and σ is the spin operator. We have considered that the asymmetry of electrical potential in the z direction is negligible in compare to the transverse direction. In the limit of $\epsilon_F \gg \Delta$ in which ϵ_F is Fermi energy and Δ is the exchange interaction constant, it is straightforward to show that only the terms of H_R which are proportional to σ_y , can contribute to elastic scattering. By introducing transverse external magnetic field along the $\pm y$ direction, one can control the strength of Rashba spin-orbit interaction.

To determine the eigenstates of $H_0 + H_{sf}$, we apply an approach based on the perturbation method [3]. In this approach, for a linear DW and up to any order of approximation, the s-f interaction can not produce any mixing between different k -states. Treating of the Rashba and Zeeman scattering mechanisms has been based on Boltzmann transport equation, within the relaxation time approximation. Through this formalism, we can determine the relaxation times and the resistivity of the DW. Figure (2) indicates the DW resistivity versus applied magnetic field. As can be seen, when the

scattering amplitude associated with the Zeeman interaction is comparable to that of the Rashba interaction at the Fermi level, the contribution of the external magnetic field to the DW resistivity can be canceled out.

***Ab-initio* study on the magnetic structures in the ordered Mn₃Pt alloy.**

Y. Kota, H. Tsuchiura, A. Sakuma
Applied Physics, Tohoku University, Sendai, Japan

1) Introduction

Geometrically frustrated antiferromagnetic (AF) systems have been extensively studied because they show many unusual behaviors in magnetic and thermal properties. Their classical ground state has a thermodynamic degeneracy with a potential instability to various magnetic phases. In general, thermal fluctuations may drive symmetry breaking to the phase with the largest entropy, and leads to the possibility of phase transitions between different magnetic phases. The magnetically ordered Mn₃Pt alloy has long been studied [1-4], and considered to be such a system, which shows an order-order phase transition between two AF phases. The magnetic structures of these two phases are determined by neutron scattering measurements. In the low temperature phase (D-phase) realized below $T_i = 400\text{K}$ [2], the spin moments of the three Mn atoms in the unit cell order in a triangular arrangement in the (111) plane, each spin pointing to the center of the triangle, shown Fig. 1 (a). In the high temperature phase (F-phase) in the temperature range of $T_i < T < T_N = 475\text{K}$, in contrast, a collinear magnetic structure shown in Fig. 1 (a) is realized. A peculiar feature of the F-phase is that one third of Mn atoms on the sites where the magnetic mean-field is cancelled have no magnetic moments. Recently, it has been suggested experimentally that the spins of these one third Mn atoms are not paramagnetic but strongly fluctuating [4]. Motivated by these backgrounds, we study the stabilities of various magnetic structures in the ordered Mn₃Pt alloy by using *ab-initio* calculation techniques based on the density functional theory (DFT).

2) Calculation method and model

In this work, DFT calculations have been carried out in conjunction with the generalized gradient approximation (GGA) projector augmented-wave (PAW) potentials, by using the Vienna *ab initio* simulation package (VASP) [5,6]. The lattice constants are set to experimental values of $a=b=c=3.833\text{\AA}$ for the D-phase [1], while $a=b=3.882\text{\AA}$ and $c=3.876\text{\AA}$ for the F-phase [4].

3) Results and Discussion

First, let us look at the ground state of the Mn₃Pt. Taking account of the spin-orbit interaction, we actually obtain the D-phase magnetic structure as the lowest energy state of the system. The magnetic moment obtained here is $3.09\mu_B$ per Mn atom, which is in fairly good agreement with the experimental value $3.0 \pm 0.3\mu_B$ [2]. This non-collinear magnetic structure has been theoretically proposed for Mn₃Pt within a spin-wave theory for the classical Heisenberg model [3]. We note here that, the spin structure of the D-phase is now unambiguously determined from the theoretical point of view.

Next we study the magnetic structures with higher energies, which may be relevant to the F-phase. We find that the structure with one third of Mn atoms having no magnetic moment is energetically so much unfavorable that it may be irrelevant to the F-phase. Instead, we introduce noncollinear magnetic structures with additional spins on the one third Mn atoms shown in Fig. 1 (b). Although this structure appears different from the collinear structure experimentally proposed for the F-phase (Fig. 1 (a)), we confirm that it is energetically much lower (about 1.7eV per unit cell) than the collinear structure. It should be noted that this magnetic structure has four-fold symmetry around the *c*-axis and can easily rotate within the *c*-plane, which leads us to suggest that the spatially or thermally averaged magnetic structure can be equivalent to the structure of Fig. 1 (a). Moreover, we also confirm that if the relative angle between the additional spins and the *c*-axis change from 0 to 90 degrees, the energy of the system per unit cell varies only in order of 0.001eV. This implies the

possibility that the additional spin moments can thermally fluctuate in the temperature range $400 < T < 475\text{K}$, where the F-phase is realized. This result may support the experimentally proposed model [4]. We will also discuss the thermal fluctuation effects in more detail by estimating the exchange interaction constants for Mn₃Pt within the *ab-initio* calculations.

Half-metallicity of the bulk and the (001) surface for full Heusler alloy Co_2HfSi : a first-principles study.

Y. Jin, J. Lee

Physics, Inha University, Incheon, South Korea

Introduction

One of the crucial issues in recent rapidly developing field of spintronics is to obtain efficient spin-injections from ferromagnets into semiconductors. Half-metallic ferromagnets are regarded as promising sources for spin-injection due to the complete spin-polarization at the Fermi level. Many of the Co_2 -based full Heusler alloys Co_2YSi ($Y=3d$ and $4d$ transition metals) were predicted to be half-metallic by band structure calculations [1,2,3]. On the other hand, the measured spin-polarizations for several half-metallic ferromagnets from the surface sensitive techniques such as point contact Andreev reflection spectroscopy are lower than 100% [4] and it was suggested that the atomic disorder or surface effects were responsible for the discrepancies between the theoretical predictions and the experimental observations [5].

In this work, we predicted that the Co_2HfSi compound, the Co_2 -based full Heusler alloy containing $5d$ transition metal, is half-metallic by the first-principles band structure calculation. We also calculated the surface electronic structure of Co_2HfSi (001) and discussed the half-metallicity at the surface.

Model and calculational method

We first found that the bulk Co_2HfSi is half-metallic at the equilibrium lattice constant of $a = 11.317$ a.u. In order to investigate the surface electronic structure, we have considered two types of surface terminations along the (001) plane: the Co atoms terminated (Co-term) and the Hf and Si atoms terminated (HfSi-term) surfaces. The Co-term and HfSi-term were modeled by two single slabs with 11 and 13 atomic layers, respectively. The two-dimensional (2D) lattice constant was taken to be 8.002 a.u. and the interlayer distance was taken to be 2.829 a.u. which is a quarter of the calculated equilibrium lattice constant. The Kohn-Sham equation was solved by means of the all-electron full-potential linearized augmented plane wave method within the GGA [8]. Lattice harmonics with $l \leq 8$ were employed for describing the wave functions, charge, and potential inside the muffin-tin (MT) spheres. Core states were treated fully relativistically and valence states were treated scalar relativistically.

Results and discussions

The calculated atom-resolved density of states (DOS) for the Co-term and HfSi-term (001) slabs are presented in Fig. 1. The results for bulk Co_2HfSi are also given for comparison. The minority spins are factored by -1 and the Fermi levels are set to zero. As we can see in Fig. 1, there is a band gap of 0.69 eV in the minority states for bulk Co_2HfSi which indicates that the bulk Co_2HfSi is a half-metallic ferromagnet. The calculated magnetic moment of Co_2HfSi is an integer value of $2.00 \mu_B/\text{f.u.}$ which follows the Slater-Pauling rule [9]. For the HfSi-term of the $\text{Co}_2\text{HfSi}(001)$, the surface retains the half-metallic character as in the bulk, while the minority spin band gap was much reduced compared to that of the bulk. On the other hand, the surface of the Co-term loses the half-metallicity because the occupied minority states shift to higher energy region. The magnetic moments of the Hf(S) in the HfSi-term and the Co(S) in the Co-term, calculated to be -0.05 and $0.98 \mu_B$, respectively, were slightly smaller than those of the bulk (-0.07 and $1.05 \mu_B$ for the Hf and Co atoms, respectively).

Ferromagnetic transition metal nitrides are technologically interesting materials which are more and more applied in the areas such as a high density magnetic recording. Especially cobalt nitride films are considered to be promising materials for the application because of their high chemical stability and a large saturation magnetization. It is known that the cobalt-nitrogen system may contain many phases, among them is the richest in cobalt Co_4N [1]. The structure of Co_4N may be thought as face-centered-cubic (*fcc*) cobalt with N atom inserted in the center of the cube. In such structure two types of Co atoms may be distinguished: one positioned at the corner of the cube (denoted as Co^{I}) and the other placed in the center of the cube face (Co^{II}). Recently, an *ab initio* study has been undertaken in order to understand the electronic and magnetic properties of such structured bulk Co_4N [2]. It was shown that the magnetic properties of cobalt atoms in the structure are strongly correlated with the atoms chemical surrounding, i.e. Co^{II} , which are involved in creation of a bond with N atom, have smaller magnetic moments, while Co^{I} at the corner sites retain their isolated character, similarly to the atoms of *fcc* Co.

For further applications of Co_4N , a comprehensive study of the electronic and magnetic properties of its surfaces is equally essential as the understanding of the bulk properties. In this paper we discuss the electronic and magnetic properties of the antiperovskite $\text{Co}_4\text{N}(001)$ surfaces based on a first-principles method.

The calculations were carried out for a single slab representing the (001) surface of Co_4N . We considered two possible surface terminations, that is Co- and CoN-terminated surfaces (denoted as Co-Term and CoN-Term, respectively). In the first system, the slab consisted of 13 layers cut from the bulk structure, which lattice constant equal to 6.7788 a.u. was taken from experimental data [3]. In the CoN-Term slab there were 11 layers. We employed the all-electron full-potential linearized augmented plane wave (FLAPW) method [4,5] with the generalized gradient approximation (GGA) [6].

The calculated atom-resolved local density of states (DOS) for the Co-Term and CoN-Term (001) surface of Co_4N are shown in Fig. 1. Four layers are concerned in each of the two systems: the surface (S), the first sub-surface (S-1), the center (C), and next to the center (S-4 in Co-Term and S-3 in CoN-Term) layer. We found that the DOS for $\text{Co}^{\text{I}}(\text{S})$ in the Co-Term surface is narrower than the DOS for Co^{I} in the bulk. The exchange splitting in the $\text{Co}^{\text{I}}(\text{S})$ is larger compared to the center layer due to the surface effect, which suggests an enhancement of the magnetic moment. The calculated DOS for $\text{Co}^{\text{II}}(\text{S})$ of the CoN-Term shows no increase of exchange splitting, which is due to the hybridization with the surface N atom. The surface states are found around -1 eV of the spin-down states in both $\text{Co}^{\text{I}}(\text{S})$ atom of Co-Term and $\text{Co}^{\text{II}}(\text{S})$ atom of CoN-Term. The surface states of $\text{Co}^{\text{II}}(\text{S})$ atom of CoN-Term split into two peaks, which are thought as the effect of the surface nitrogen bands.

The calculated magnetic moment (MM) on Co atoms in the most inner layers of the two investigated slabs are 1.91 and 1.37 μ_B on Co^{I} and Co^{II} , respectively, which is consistent with the results reported for bulk Co_4N [2]. The magnetic properties of the surface Co atoms depend strongly on the atoms surrounding. In the Co-Term slab the value of MM on $\text{Co}^{\text{I}}(\text{S})$ is 2.03 μ_B , considerably larger than that on $\text{Co}^{\text{I}}(\text{S-4})$. In contrary, the calculated MM on the $\text{Co}^{\text{II}}(\text{S})$ atom in CoN-Term slab is reduced to 1.27 μ_B , which is even lower than the MM on Co^{II} atoms in inner layers. This behav-

iour may be explained by an enhancement of the surface N *p* and Co *d* states hybridization, which is confirmed by the split surface states for Co^{II} atom in the CoN-Term slab. A similar reduction of Co^{II} magnetization is seen also in the (S-1) layer of the Co-Term structure, which confirms the importance of the presence of nitrogen for tailoring the magnetic properties of Co^{II} atom in the nitride.

A first principles study of Thiol-Capped Au Nanoparticles.

R. Cuadrado, J. Cerdá

Intercaras y Crecimiento, Instituto de Ciencia de Materiales de Madrid, Madrid, Spain

I. Introduction

During the last years, nanoparticles (NPs) have become a subject of major research due to their new optical, electronic and/or magnetic properties which may be controlled by varying the NP size or shape. Functionalizing these NPs with adequate organic capping layers further provides chemical specificity to the clusters, thus becoming highly interesting for biological applications. Gold NPs have received great attention because bulk gold is inert and, most surprisingly, several experiments recently reported on the ferromagnetic nature of these Au Nps [1]. There exist, however, conflicting results regarding the conditions required for achieving such magnetic clusters; whereas the first experiments required sulfur based capping ligands (alkane-thiols), subsequent theoretical and experimental works point to the existence of a permanent magnetism in bare gold clusters [2]. In this work, we address precisely the role that an alkane-thiol capping layer plays on the properties of Au NPs by means of ab initio Density Functional Theory (DFT) based calculations.

II. Theoretical

We have modeled Au clusters of different sizes ranging from just 1 up to 38 gold atoms. The two largest clusters considered, Au38 and Au14, were chosen with octahedral shapes preserving the bulk fcc arrangement. In order to reduce the computational load, we considered short alkane-thiols of just two C atoms (S-C2H5) and systematically varied the thiol coverage for each of the Au clusters. In order to generate initial configurations for the thiol-capped clusters, we first performed Molecular Dynamics (MD) calculations at a fixed temperature of 300 K (Nosé thermostat) employing simple two-body Lennard-Jones potentials. Following a recent XRD structural study of thiol films on an Au surface [3], a different set of initial configurations was additionally created by attaching an extra gold atom to the thiol (Au-S-C2H5) and performing further MD runs. The structure of these clusters was then studied with the DFT based SIESTA code under the Local Density Approximation (LDA) employing scalar relativistic pseudopotentials [4]. All the clusters were fully relaxed and their electronic and magnetic structure were determined by inspecting the resulting atom projected Density of States (PDOS) together with any net magnetic moments.

III. Results

Figure 1 shows several relaxed clusters for the Au38 cluster and for different thiol coverages. The optimized structures show that the S atoms are predominantly 2 fold coordinated to the surface gold atoms, although structures having 1 and 3 coordination numbers were also found. The highest coverage considered here were 24 thiols, which amounts to a 3:4 ratio between the number of gold surface atoms and the number of thiols. As the coverage is increased, the reconstruction at the NP surface becomes more prominent. Figure 2 shows the distribution of Au-Au distances as a function of coverage. A shift in the first peak from 2.75 Å to 2.85 Å can be clearly followed as the coverage increases, in good accordance with the experimental findings[1].

As our main result, we have not found any evidence for magnetism in any of the large clusters studied; the spin polarization vanished in all cases.

Figure 3 shows the evolution of the DOS for the Au38 cluster and for different thiol coverages. We include the projections on the gold and sulfur atoms as well as on the organic ligands (C3H5). As the coverage increases, the peaks are smeared and bands are formed implying that electrons become delocalized. Most interestingly, any peaks related to the gold atoms and close to the Fermi

level disappear thus reducing the number of d-holes. We thus conclude that thiol capping does not help the development of any spin polarization in the Au NPs.

Rare-earth metals as Sm combines with iron metal to form intermetallic Fe₂Sm compound and its crystallizes in the MgCu₂ (Fd3m) Laves phase. In this structure the Sm atoms are equivalent to Mg atoms, occupying equivalent sites with cubic point symmetry and this intermetallic compound behaves ferromagnetically. Then, in this context, motivates us to investigate theoretically the magnetic behavior of the Fe₂Sm compound. We used the self-consistent spin-polarized energy band calculation, using full potential linearized augmented plane waves method (FP-LAPW) with APW + lo [1]. These calculations are based on the first-principles functional-density theory (DFT) with the general gradient approximation (GGA) for exchange and correlation potential [2] and provide total density of states, total energy as function of volume and band energy dispersion. The calculated magnetic spins moments are 5.41 μ_B for samarium atoms and 2.90 μ_B for iron atoms, respectively. Figure 1 shows the ferromagnetic behavior of the material by the the difference observed between the total density of states of spins up and spins down [3] and figure 2 shows the behavior of the total energy as function of volume with an equilibrium volume of 643.2910 (bohr**3) and a bulk modulus of 33.988 GPa [4].

Energy spectrum of S=1/2 Heisenberg systems via a recursive diagonalization method.

F. C. Souza, V. L. Líbero

Departamento de Física e Informática, Instituto de Física de São Carlos, Universidade de São Paulo, São Carlos, Brazil

Introduction. Quantum spin systems are among the most important subjects in condensed-matter physics and recently have motivated many applications, for instance in the new area of spintronics [1]. An example is the work at IBM, using low-temperature scanning tunneling microscopy were able to measure the exchange interactions between individual spins in small manganese chains [2]. A Heisenberg like Hamiltonian was used to analyze the experimental results. They also measured the spin excitation spectrum of these structures, constituting of linear chains of one to ten atoms. The most striking features of these systems are found in the antiferromagnetic compounds, generally the hardest to diagonalize. The difficulties arise especially when the system presents broken symmetry. In this case even well-established methods like Lanczos [3], or Monte Carlo [4], encounter serious limitations. In this work we propose a new numerical diagonalization method which works even in the absence of translational invariance. **The recursive method.** We applied this method to the isotropic spin-1/2 Heisenberg model. Besides conservation of the z-component of the total spin, S^z , we also exploit conservation of the square of the total spin, S^2 , a much more complicated procedure that renders an additional block diagonalization. Moreover, we diagonalize a chain with N spins using the eigenvectors obtained from previous diagonalization of a chain with N-1 spins. The N-site Hamiltonian, H_N is built using basis-vectors generated from the direct product of the eigenvectors of the H_{N-1} and the states up and down of the added N-th spin, by means of suitable Clebsch-Gordan coefficients. The matrix elements of the H_N are then expressed in terms of invariant matrix elements through the Wigner-Eckart theorem. The procedure is easily adapted for the two-leg ladder, an experimentally relevant system with a chain as a particular case. **Results.** Using a desktop microcomputer we were able to obtain the entire energy spectrum for chains with up to 20 spins 1/2 (10 rungs for ladders) with fourteen figures of precision. For larger chains, the recursive diagonalization allows a simple truncation scheme that reduces the size of the basis with some controllable reduction of accuracy. The key idea is, to build at each iteration the basis-vector not using all eigenstates from the previous iteration, but a fraction of them. The more eigenstates kept at each iteration, the higher accuracy the spectrum will have. For instance, for an open chain with 128 spins 1/2 the exact ground-state energy is known as $e_0/J = -0.441683$. Using our recursive procedure, we obtain $e_0/J = -0.44166(3)$, with a maximum of 10000 states kept at each iteration. The number in parenthesis means the deviation from a simulation keeping 5000 states. The deviation from the exact result is just 0.005%. The iterative procedure is also easily implemented for spin-1/2 chains with few spin impurities S located at any position along the chain. It is also straightforward to code the procedure for spin ladders for any ratio of the rung and leg exchange couplings. Having the entire spectrum evaluated with controlled accuracy, we are now investigating thermodynamical quantities for the same systems. **Summary.** We have proposed an iterative diagonalization method exploiting the conservation of S^2 and S^z , and implemented it for the Heisenberg model. The method is also adaptable to other strong correlated systems like the Hubbard model. It is time and memory intensive, but still more economic than Lanczos exact diagonalization or Monte Carlo methods. For large chains, the low-lying energy levels are obtained with high accuracy after an energy cutoff. The presence of spin impurities, bond defects or borders does not pose any additional problem.

Density Functional Theory for Heisenberg Spin-1/2 Chains With Bond Defects.

V. L. Libero, P. H. Penteado

Departamento de Física e Informática, Instituto de Física de São Carlos, Universidade de São Paulo, São Carlos, Brazil

Introduction. The development of new magnetic materials is close related to our comprehension of the fundamental models of magnetism. As could be expected, the pioneering theoretical studies were in magnetic chains or lattices with complete translational invariance, i.e., systems without impurities, bond defects or border effects. The Bethe ansatz solution for the infinite Heisenberg chain of spin 1/2 is the best example of such a system. We learned a lot from those clean chains, but even a superficial inspection reveals that real materials unavoidably have impurities or defects. Frequently, to obtain special properties impurities or defects are insert even in clean materials. Thus, in material science, models and techniques developed for systems with broken symmetry are crucial.

The model. The most important spin model is the Heisenberg model, defined to describe a collection of localized spins coupled by exchange interactions, usually restrict to nearest neighbour spins [1]. Its aplicability goes beyond Physics and extends to Chemistry and Biology as well. In particular for antiferromagnetic ordering, its comprehension is far from complete and becomes even more challenging for inhomogeneous systems.

The procedure. Density Functional Theory (DFT) in the local-density approximation allows to obtain estimates for ground-state properties of inhomogeneous systems by exploiting many body calculations for homogeneous systems [2]. Although created for electronic systems, recently, DFT was formulated for the Heisenberg Model, and a local-spin approximation (LSA) to the ground-state spin functional was proposed [3,4]. This approximation permits the study of inhomogeneous systems with impurity spins in chains or lattices of arbitrary size with uniform exchange interaction. Ref.[5] presented a local functional applicable to nonuniform bond interactions, that improved on the mean-field approximation. Here we present a non-local functional of the bond interactions that further improves the results. This is relevant for instance in the study of the $S=1/2$ alternating-bond Heisenberg chain, in which the exchange coupling alternates (values or even sign) from site-to-site [6].

Consider a chain of spin 1/2 with alternating bonds J and αJ . A precise estimate for the ground state $E_0(\alpha)$ is known from Ref.[6] for $\alpha < 1$. For $\alpha > 1$ we may use the relation $E_0(\alpha) = \alpha E_0(1/\alpha)$. The DFT-LSA approach first looks for a homogeneous system as a starting point. Our alternating chain is homogeneous if seen as made of pair of bonds J and αJ . After that, we define the correlation energy $E_c(\alpha) = E_0(\alpha) - E^{MF}(\alpha)$, where E^{MF} is the well known mean-field energy term. Now, for a chain with arbitrary exchange interactions J_i , i.e., an arbitrary set of $\alpha_i = J_{i+1}/J_i$, a local approximation for the correlation is obtained by replacing $E_c(\alpha)$ by $E_c[\alpha_i]$. Therefore, $E_0[\alpha_i] = E^{MF}[\alpha_i] + E_c[\alpha_i]$. Note that the only approximation is in E_c , since E^{MF} is known exactly. This local functional of α_i is in fact non-local in the exchange coupling J_i ; this is the first non-local functional of bond coupling for Heisenberg models and provides much better estimates than the previous local approximation presented in Ref.[5].

Results. We compare results from our DFT procedure to exact numerical diagonalization of the model Hamiltonians for chains with 24 spins and periodic boundary condition. We illustrate the method in the case in which all bonds have the same exchange interaction J ($\alpha_i = 1$) except one bond with $J' = \beta J$. Note that this case represents a very inhomogeneous situation relative to the alternating chain. The following table contains representative results:

β	$-E_0/J$	Exact
0.2	0.43596	0.43598
0.5	0.43692	0.43775
0.9	0.44005	0.44282
1.5	0.45459	0.45560

For β close to unity, the agreement is not expect to be as good as for β much less than one or β much bigger than one, since the expression for the ground-state energy for the homogeneous system, $E_0(\alpha)$, is an approximation valid for α nonequal to one.

Summary We developed a non-local functional of the bond exchange interactions for the ground-state energy of quantum spin chains. We obtain good estimates for large chains with arbitrary distribution of bond interactions, at no extra computational costs as compared to a simple mean-field calculation. The agreement with exact numerical diagonalization is very good even for many bond defects.

The extensive half-metallicity studies in double perovskite materials are related with the technological applications in *spintronic* devices, such as spin valves, sources for spin polarized electrons and magnetic information storage systems. The aim of this work is to carry out a *ab-initio* study of the complex perovskite $\text{Sr}_2\text{CoReO}_6$, which was reported as antiferromagnetic with low Néel temperature $T_N = 65$ K[1].

Calculations of electronic structure for $\text{Sr}_2\text{CoReO}_6$ were performed with the FP-LAPW method, in the framework of the Density Functional Theory [2,3] as implemented in the wien2k code[4]. We have used the following parameters for the program: RMT×Kmax=8, the muffin-tin radii (in u.a.) of 2.5, 1.96, 1.96 and 1.69 for Sr, Co, Re, and O respectively. 196 k-points were used in the irreducible Brillouin zone. Calculations were performed with the structure I4/m (space group #87). The total energy versus volume of unit cell was fit to the Murnaghan state equation. From this fitting, we obtain the lattice parameters $a=5.533$ Å and $c=7.859$ Å, which correspond to $c/a=1.42$, which are in a good agreement with experimental results [1].

As it is shown in figure 1, the Density of States (DOS) shows a clear half-metallic nature for the material: the spin up channel has a semiconducting behavior, with a gap of 0.27 eV, and the spin down evidences a conductor behavior.

In the $\text{A}_2\text{BB}'\text{O}_6$ complex perovskite, the effect of oxygen on the B and B' (transition metal cations) produces a splitting in the bands due to the crystalline field. It is known that for no cubic structures, d_{xz} and d_{yz} behave as a single level d_{xz+yz} . It is because of the lost of symmetry in the structure, due to the deformation of a cubic cell to create a tetragonal structure. Another explanation is related to the possibility that usual states are not divided in d_{eg} (high energy) and d_{t2g} (low energy) but in d_x (high energy) and $d_{x^2-y^2}$ and d_{xz+yz} (low energy) levels. Due to the magnetic characteristic of B and B' cations, an exchange splitting has place. It is observed as a difference between up- d_{eg} and down states, and a difference between up- d_{t2g} and down states. In order to study these effects, calculations of projected DOS on the like atomic-orbitals have been performed for Co and Re. In figure 2, it is observed that spin-down-low-energy states (which is extended from ~ -1.88 eV to ~ -0.84 eV) contribute to the conduction band, while high energy levels contribute to the unoccupied states above the Fermi level (from ~ -0.9 to ~ 2.5 eV). On the other hand, spin-up-high-energy states contribute below the Fermi level from ~ -1.69 eV to ~ -0.16 eV.

Low energy states are observed below -3.00 eV. We have determined that up and down high energy states do not contribute significantly to the density of states and appear above ~ 3.5 eV. Up-spin-low energy states are located close and above the Fermi level at $E > 0.15$ eV. Down-spin-low energy states belong to the conduction band. It is expected from the possible valences of Re, +5 or +6, which represent an effective magnetic moment due to the $5d^1$ or $5d^2$ electronic configurations.

In summary, structural and electronic properties of the $\text{Sr}_2\text{CoReO}_6$ material were investigated. Our study reveals that this material is half-metallic. As expected for such systems, effective magnetic moment of cell, predominantly due to Co, is an integer number of Bohr magneton. Additionally, we use the partial densities of states of electronic orbital to discuss some aspects of the underlying physics in these systems and to correlate our results with reported methodologies, which consider a new mechanism as responsible of the magnetic interactions in perovskite compounds.

Combinations of decoding algorithm for LDPC codes by tensor product decoding.

H. Kamabe

Information Science, Gifu University, Gifu, Japan

1. Introduction

A power constraint of electronic circuits for encoding and decoding is rather severe in storage devices in mobile systems. We combine bit flipping decoding algorithms (simple, fast but not good enough), denoted by $SD_{\{1\}}$ below, and the sum-product decoding algorithm (complex, power consuming but very good), denoted by $SD_{\{2\}}$ below, by using the concept of Tensor Product Codes[1] in order to save the power for decoding retrieved signals without much code rate loss.

2. Method

We use 3 error correcting codes as constituent codes of our coding scheme, say, $SC_{\{1\}}$, $C_{\{2\}}$ and $SC_{\{3\}}$. Here, $SC_{\{2\}}$ is a repetition code of length 3 and $SC_{\{3\}}$ an LDPC code. We explain our coding scheme using a single parity check code as $SC_{\{1\}}$ for simplicity. A code word generated by our coding scheme is schematically given as follows

$c_{\{11\}} c_{\{21\}} \dots c_{\{k1\}} c_{\{(k+1)1\}} \dots c_{\{n1\}},$
 $c_{\{12\}} c_{\{22\}} \dots c_{\{k2\}} c_{\{(k+1)2\}} \dots c_{\{n2\}},$
 $c_{\{13\}} c_{\{23\}} \dots c_{\{k3\}} c_{\{(k+1)3\}} \dots c_{\{n3\}}.$

2.1 Encoding

We assume that $SC_{\{3\}}$ is a systematic code.

- (1) We encode $c_{\{11\}} c_{\{21\}} \dots c_{\{k1\}}$ by $SC_{\{3\}}$ and obtain parity bits $c_{\{(k+1)1\}} \dots c_{\{n1\}}$.
- (2) We calculate a syndrome $s_{\{1\}}$ of $c_{\{11\}} \dots c_{\{k1\}}$ for the single parity check code $SC_{\{1\}}$.
- (3) We determine $c_{\{1j\}}$ so that a syndrome bit of $c_{\{1j\}} \dots c_{\{kj\}}$ for $SC_{\{1\}}$ is equal to $s_{\{1\}}$ for $j=2,3$.
- (4) We encode $c_{\{1j\}} \dots c_{\{kj\}}$ by $SC_{\{3\}}$ and obtain parity bits $c_{\{(k+1)j\}} \dots c_{\{nj\}}$ for $j=2,3$.
- (5) We record or transmit $c_{\{ij\}}$ but do not record $s_{\{1\}}$. We call $c_{\{1i\}} c_{\{2i\}} \dots c_{\{ni\}}$ the i -th block.

2.3 Decoding

Let $y_{\{1i\}} \dots y_{\{ni\}}$ be retrieved signals.

- (1) We apply the decoding method $SD_{\{1\}}$ to each block $y_{\{1i\}} \dots y_{\{ni\}}$ and obtain $z_{\{1i\}} \dots z_{\{ni\}}$.
- (2) We calculate a syndrome bit $t_{\{i\}}$ of $z_{\{1i\}} \dots z_{\{ki\}}$ for $SC_{\{1\}}$.
- (3) We decode $t_{\{1\}} t_{\{2\}} t_{\{3\}}$ as a code word of $SC_{\{2\}}$.
- (4) If we find an erroneous bit in the previous step, say $t_{\{i\}}$, we try to decode the i -th block again by the decoding method $SD_{\{2\}}$.

Note that the error correcting performance of $SD_{\{2\}}$ is better than that of $SD_{\{1\}}$.

3. Results

We show simulation results of the above decoding scheme where we use a Hamming code as $SC_{\{1\}}$. In Fig.1 we show error correcting performance of our coding scheme. 'mQBF' is a decoding algorithm based on the bit flipping. It uses only integer values in each iteration process but has a relatively better error correcting performance. $SC_{\{3\}}$ is an 's2.94.594' code available from the Mackay's database for LDPC codes. When we use the Hamming code as $SC_{\{2\}}$, we can have some variants of our coding scheme because a syndrome of the code is a vector of length

greater than 1. 'TP-Hamming-1Correct' and 'TP-Hamming-AllCorrect' mean two of these variants. Our coding scheme is far better than mQBF and the probability for invoking the Sum-product decoding is low when the SNR is large enough. This may imply that the power consumption of our coding scheme may be low. Our coding scheme can be modified so that the information about erroneous block is used in the first decoding process by $SD_{\{1\}}$. We must investigate better combinations of $SC_{\{1\}}$, $C_{\{2\}}$ and $SC_{\{3\}}$.

4. Properties

(1) Code rate

We use $SC_{\{2\}}$ to find errors in outputs of $SD_{\{1\}}$. A similar mechanism can be implemented by a serial concatenation coding scheme of $SC_{\{2\}}$ and $SC_{\{3\}}$. But we can reduce the rate loss by our coding scheme.

(2) Error detecting capability

Our coding scheme can find an erroneous block correctly when the number of erroneous blocks is at most one.

(3) Error Propagation

Our decoding method is analogous to the decoding procedure for a Tensor Product code[1] which we use to reduce the code rate. An integrated interleaving error correcting(IIEC) is another technique to reduce the code rate[2]. Although a lot of errors in integrated parity bits in the IIEC propagate through a block, there is no error propagation in our decoding scheme because integrated parity bits are used only to find erroneous blocks.

(4) Power consumption

From Fig. 2 we note that our coding scheme reduces the power consumption while keeping the better error correcting performance of $SD_{\{2\}}$.

Introduction

We proposed a post-processor without parity check code for PRML channel[1]. The post-processor targets the likely error patterns due to jitter-like medium noise which depends on the recording sequence, and corrects without support provided by parity check. It requires a write pre-compensator (WPC) to offer good performance in perpendicular magnetic recording (PMR) channel with nonlinear transition shift (NLTS) [2]. Furthermore, it introduces parity check (PC) code to decrease the mis-correction in error pattern targeting and to correct the uncovered error patterns. In this study, the PRML channel with the combined post-processor (CPP) is evaluated under WPC in PMR channel with NLTS and is compared to PRML-AR channel with a complex autoregressive (AR) model [3] as channel estimator.

PRML channel with write pre-compensator and post-processor

Fig.1 shows the block diagram of PRML channel with CPP. The system employs the 4-interleaved PC code with coding rate of 128/132. The data sequence is recorded after the WPC in the PMR channel with NLTS. The amount of NLTS is measured by using 5th harmonic method [4] for R/W experimental data obtained by a sprinstand. We use a hyperbolic tangent like function defined by the saturation level A and the rising time T_{50} as the isolated reproducing waveform for the step-like recording waveform [5] in computer simulation. We adopt a generalized partial response (GPR) channel [6] based on PR1 channel which requires a Viterbi detector (VD) with 16 states. The VD estimates the detector input sequence using a simple signal estimator, or it does not use a complex noise estimator like AR model. The CPP consists of two classes of error correction units. The first unit called PPE corrects the particular decision errors of GPRML channel due to jitter-like medium noise [1]. The second unit called PPP corrects the remaining errors composed of the other uncovered error patterns and the mis-corrected errors by PPE. The PPE and PPP units use the squared distance increase [7] as the reliable information. It is calculated by a simple signal estimator which is the same as the VD.

BER performance comparison

Fig.2 shows the bit error rate (BER) performance of proposed GPRML-CPP, GPRML-PPE, simple GPRML and GPRML-AR channels with symbols \circ , \triangle , \bullet , and \blacksquare , respectively. The parameters are set to the normalized linear density $K=T_{50}/T_b=1.2$ by a bit interval T_b , SNR=19.5dB defined by the saturation level A and the rms value of total noise at the reading point, the percentage of jitter-like noise $R_f=80\%$, the normalized cut-off frequency of low-pass filter $x_h=0.4$ by a bit-rate f_b , and the tap number of transversal filter $N_t=15$. The amounts of NLTS normalized by a bit interval T_b are 0.031, 0.133, 0.139, and 0.142 for the respective transition intervals of T_b , $2T_b$, $3T_b$, over $4T_b$. The WPC shifts the transition with longer interval than T_b from the previous transition to the post direction by L_{comp} [%] of T_b . From the figure, the optimum amounts L_{comp} of pre-compensation which provide the lowest BERs are different for respective GPRML channels. Though the performance of GPRML-PPE is inferior to that of GPRML-AR, GPRML-CPP shows the slightly better performance than GPRML-AR in spite of rate loss due to PC code.

Conclusion

The PRML channel with CPP has been evaluated under WPC in PMR channel with NLTS and compared to PRML-AR channel with an AR model as a channel estimator. The results show that GPRML-CPP shows the slightly better performance than the complex GPRML-AR in spite of rate loss due to PC code.

Performance comparison of various error correcting strategies using perpendicular magnetic recording data series.

S. Mita, H. Matsui

Toyota Technological Institute, Nagoya, Japan

Introduction

The choice of error correcting strategy is a key point in implementing HDD with high data reliability. We have evaluated the performance of the following typical three error correcting methods that have nearly the same code rate of 0.93 at a bit error rate of around 10^{-3} and higher using real perpendicular magnetic recording channel data series. This bit error rate may be expected as the worst case for practical use.

(a) Finite geometry LDPC codes [1]

(b) Parity product codes

(c) Reed-Solomon codes with hard decision decoding

Measurement

Figure 1 represents a performance evaluation process. 6 bit quantized data series sampled at adequate timing instants are fed into a simple DC restoration process using signal envelope detection and equalized to partial response class 1 waveform by using

9-tap transversal filter. Then, LLRs are calculated by applying BCJR algorithm to PR1 trellis structure (PR1 detector). We have adopted two types of PR1 detector such as a conventional 2-state PR1 detector and our proposed 4-state PR1 detector [2] using multi-chip structure. These LLRs are provided to various error correcting decoders above mentioned. Hard decision bits generated from LLRs are provided for the Reed-Solomon decoder. The number of error included in retrieved data series are counted in correspondence with original data series.

Structure of error correcting codes

(a) Finite geometry LDPC code

We have used a Type-2 Projective Geometry-LDPC code (PG-LDPC) whose code length is 5797 and code rate is 0.949. Moreover, we have estimated another code length, the shortened PG-LDPC code whose code length is 4296. The code rate of the shortened PG-LDPC codes is set to 0.931. As well known, these LDPC codes do not include 4-cycle. These encoders have the form of quasi-cyclic structure adequate for easy implementation. We have used sum-product algorithm as a decoding algorithm.

(b) Parity product code

We have attempted to evaluate the parity product codes of 83×51 matrix including 4100 data bits, 82 horizontal parity bits and 51 vertical parity bits. This code rate is approximately 0.968. Moreover, we have adopted a random inter-leaver of 4100 bits that can cover an entire sector data.

(c) Reed-Solomon code

RS code over a field $GF(2^{10})$ are selected, which can cover one sector of 512 bytes with redundant part for 15 correctable errors. Thus, the total code length must be 440 symbols. Its redundant part is 30 symbols, which is equal to 300 bits. Its code rate is approximately 0.931.

Comparison of error correcting capability

(a) Figure 2 shows one example of the decoding performance of both PG-LDPC code and the shortened code. LDPC decoding of small noise data (bit error rate of approximately 10^{-3} with 2-state PR1 detector) is completed after 3 iterations. Furthermore, the error rate of PG-LDPC code with a code rate of 0.949 is 10 times greater than that of shortened PG-LDPC code. On the other hand, LDPC decoding of large noise data (bit error rate of approximately 5×10^{-3}) can not correct errors

even after 9 iterations. Proposed 4-state PR1 detector halves number of errors of 2-state PR1 at a bit error rate of 10^{-3} . Table 1 shows the number of residual errors included in 4296 bits after iteration. This small improvement is useful in high error rate area.

(b) A combination of parity product codes with code rate 0.97 and 4-state PR1 detector can improve bit error rate by two orders at a bit error rate of 10^{-3} . Residual errors can be corrected by using RS codes with a code rate of 0.96. Total code rate of the combination is approximately 0.93.

(c) The maximum number of symbol errors included in one sector was 6 for the 4-state PR1 detector and 12 for the 2-state PR1 during total 2000 sectors. Therefore, surprisingly, Reed-Solomon codes with hard decision decoding can correct these errors completely.

Concluding remarks

Consequently, increasing RS codes redundancy and adding soft decision capability for a part of redundancy as well as hard decision capability could be one of the best choices for the worst error rate of around 10^{-3} in future HDD.

EPCC-based Channel-Optimized LDPC coding.

H. S. Alhussien, J. Moon

CDSLAB, Electrical and Computer Engineering, University of Minnesota Twin Cities, Minneapolis, MN

Low density parity check (LDPC) codes are gaining wide interest in the implementation of the perpendicular magnetic recording (PMR) read channel. The PMR read signal is corrupted by inter-symbol interference (ISI) and a mix of Gaussian electronic and media noises. For this kind of environment, even state of the art soft decoding of the currently implemented Reed-Solomon (RS) codes shows a significant gap to the binary constrained channel capacity. On the other hand, turbo equalization (TE) based on the iterative exchange of soft information between the channel detector and the message passing decoder (MPD) of LDPC can potentially close the gap to channel capacity. Moreover, the gap to capacity can be reduced by optimizing the LDPC matched to the channel using density evolution techniques. However, the resulting random irregular parity check matrix requires high encoding complexity.

To design a channel optimized high-rate TE system with low encoding complexity, we propose to concatenate a very high-rate specialized inner error pattern correction code (EPCC) to an outer structured LDPC code. This is motivated by the sector error rate (SER) gains observed when EPCC serves as an inner code for RS at a manageable added complexity [2]. Furthermore, EPCC enhances the overall bit error rate (BER) of TE systems for a wide range of operating rates [3].

We compare the BER and SER performance of TE based on a standalone quasi-cyclic (QC) LDPC [3] iteratively decoded with the channel, to the performance of the same TE with an EPCC soft-in soft-out (SISO) decoder standing at the output of the channel detector and LDPC MPD input. In this presentation, we show results for a 1+D ISI channel corrupted by additive-white-Gaussian-noise (AWGN) experiencing a noise penalty proportional to $10 \times \log_{10}(1/R)$, where R is the coding rate. In the final version of this work, we will study the performance in a jitter dominant environment with $10 \times \log_{10}(1/R^2)$ noise penalty.

The EPCC proposed in [1] and [2] is designed such that for a given set of dominant error patterns, inherent in an ISI channel, any single dominant error pattern occurrence as well as a significant portion of their multiple occurrences can be corrected. Here, We design a 0.98 rate (630, 616) EPCC targeting the 10 most dominant error events of the 1+D channel, those are of length 1 to 10 and are of the form $\pm[2, -2, 2, -2, \dots]$. Details on the design of the EPCC algebraic single pattern correcting code can be found in [2], the correction capability of the algebraic decoder is extended through list decoding [2][3] by using a parallel bank of such decoders. The list decoder uses channel observation in addition to *a priori* soft information generated by the maximum *a posteriori* (MAP) channel detector to build a list of candidate codewords through algebraic decoding of 25 most probable test patterns, where a test word is constructed by corrupting the maximum likelihood word at the output of the MAP detector by a predetermined combination of the most probable error events. Then, by the utility of error-event-matched *local* correlators to evaluate candidate codeword probabilities, bit-level soft output information is calculated and passed to the LDPC MPD, which in turn, generates extrinsic information to be fed back to the MAP channel detector [3]. The system block diagram is shown in Fig.1.

The outer QCLDPC is designed using the algebraic structured technique in [4] to have performance that rivals the best comparable random codes. We construct a regular (4251, 3926) QCLDPC of rate 0.92, and column and row weights of 3, and 39 respectively. Each sector-wide LDPC codeword is

encoded into 7 EPCC codewords and 10 LDPC iterations are implemented per turbo iteration where the overall EPC-QLDPC coding rate is 0.9.

As can be seen in Fig.2, simulation results show that with only 5 turbo iterations of EPC-QCLDPC, a SER of 10^{-4} is achievable at an SNR that is more than 1 dB less than that of standalone QCLDPC.

On Imposing an RLL Constraint without Explicit RLL Coding.

J. Park, J. Moon

Electrical and Computer Engineering, University of Minnesota, Minneapolis, MN

In most recording systems, the maximum runs of consecutive like bits and alternating bits are respectively limited to $(k+1)$ and $(g+1)$, based on the non-return-to-zero (NRZ) convention. The k constraint provides adequate timing information to the clock recovery circuit while the g constraint limits the path memory length in the implementation of the Viterbi algorithm. While run-length limited (RLL) coding is typically employed to impose this $\{k, g\}$ -constraint, the rate loss associated with the RLL code results in a significant loss of effective signal-to-noise ratio (SNR). A large codeword length can be utilized to mitigate the rate loss effect but this would require reverse concatenation between the error correction code and the RLL code. In this work, we propose a different approach to imposing the $\{k, g\}$ -constraint. Our approach does not utilize an explicit RLL coding. The idea is to make use of an error-pattern-correcting code (EPCC) that is highly tailored to a set of dominant error patterns [1]. This code has been shown to provide a significant coding gain [1][2], but here we show that it can also be used to completely eliminate the need for explicit RLL coding. The specific approach is to force a short error pattern in the middle of a prolonged absence of bit transitions as well as a long string of consecutive transitions, after EPCC encoding is done. In the read side, the combined action of EPCC decoding and typical error correction code decoding eliminates the forced error patterns with high probability. This scheme is reminiscent of the method based on the insertion of a detectable pattern with a cyclic redundancy check (CRC) code [3]. The difference is that the present method utilizes a more aggressive error-pattern *correcting* code that can handle multiple occurrences of error patterns including the inserted pattern. Obviously, the inserted pattern must be detected/corrected by the EPCC, and any pattern that contains relatively short transitions can be chosen for this purpose. The inserted pattern is removed whenever it appears at the channel detector output, by using a pattern removal block, as seen in Fig. 1. Afterwards, the error between the detector input and the pattern-removed detector output convolved with the known intersymbol interference (ISI) channel drives the local pattern correlator bank. In this way, when the error flag is raised, the forced pattern and its possible positions can be identified based on the captured syndrome, and the local correlator matched to that pattern will successfully produce a high output at the inserted position. With both the algebraic information and the pattern-level reliability measures provided by local error-pattern correlators matched to the targeted error patterns, including the inserted pattern, the EPCC list decoder based on a set of test word-error events [2] can correct multiple occurrences of error patterns. For the ISI channel response $5+6D-D^3$, a (630,616) EPCC based on the generator polynomial $g(x) = (1+x^3+x^5+x^8)(1+x+x^6)$ has been constructed in [1][2] to identify ten dominant error patterns. Assuming a 20-symbol-correcting outer (450,410) Reed-Solomon (RS) code, the sector error rates (SERs) of the proposed scheme are compared for various $\{k, g\}$ values (Fig. 2). In order to attain the given $\{k, g\}$ constraints, a single-bit error pattern, which is one of the targeted dominant error patterns, is chosen as the insertion pattern. Here, the SERs above 10^{-5} represent actual counts, whereas the lower SERs were computed based on the block multinomial distribution. The employed EPCC list decoder attempts to correct up to triple error patterns within the codeword using 26 test words. It is seen that there is virtually no performance penalty in inserting patterns to impose the $\{k, g\}=\{20, 20\}$ compared to the no-insertion case, i.e., $\{k, g\}=\{\infty, \infty\}$. Compared to the case of the Viterbi detector plus RS code only (no EPCC), the $\{20, 20\}$ -imposed EPCC system yields about 0.5 dB coding gain at $\text{SER}=10^{-7}$ while completely eliminating the need for explicit RLL coding.

On the use of averaging to estimate the dibit response.

M. Ting
Seagate Technology, Pittsburgh, PA

I. INTRODUCTION

The dibit response of a magnetic recording system is useful in various ways: for example, its width is an indication of the amount of inter-symbol interference (ISI) in the magnetic recording channel. In the magnetics literature, the dibit response is typically estimated assuming knowledge of the written bit sequence and the noiseless readback signal [1], [2]. Magnetic recording systems, however, have various sources of noise. These include transition and additive noise [3]. In [2], a method to obtain the noiseless readback signal was proposed in which one used spatial and temporal averaging to reduce the transition and additive noise respectively.

This work considers the effect of independent and identically distributed (i.i.d.) transition position jitter and additive noise in the readback signal. We assume that a second-order Taylor series expansion can be applied to the transition response terms with position jitter. We then show that the averaging method of [2] results in a biased estimate of the noiseless readback signal. Assuming that the position jitter has zero mean, the bias in the estimate is proportional to the position jitter variance. Suppose that a transition sequence is written I times around a track, and J rereads of the I sequences are obtained. Application of the Central Limit Theorem shows that the variance of the estimate due to the additive noise decreases by a factor of $(IJ)^{-1}$. The variance of the estimate due to the transition position jitter decreases by a factor of I^{-1} . Explicit forms for the distributions of the transition jitter and additive noise are not used: the result therefore has the appeal of being broadly applicable to various noise distributions.

II. READBACK SIGNAL MODEL AND NOISELESS ESTIMATOR

Denote the transition bits $b_n \in \{0, \pm 1\}$. The readback signal $y(t)$ is oversampled at $R \in \mathbb{N}$ times the data rate. Let T be the bit period and T_s the sampling time period: note that $RT_s = T$. We consider transition position jitter and additive noise, so that the sampled readback is $y_n = \sum_k b_k h(nT_s - kT + e_p(k)) + e_a(n) \dots$ (1), where $h(\bullet)$ is the transition response; $e_p(n)$ is the transition position jitter; and $e_a(n)$ is additive noise [3, (1)]. Assume that

 $e_p(n)$ is an i.i.d. sequence with $E[e_p(n)] = 0$ and finite second and fourth order moments.

 $e_a(n)$ is an i.i.d. sequence with $E[e_a(n)] = 0$ and $E[e_a(n)]^2 < \infty$.

For a continuous time signal $x(t)$, let $x_n(n) := x(nT_s)$ denote the sampled discrete time signal, e.g., $h_n(n) = h(nT_s)$, etc. For a sequence $x(n)$, $x_{(R)}(n)$ is $x(n)$ upsampled by R . Define $x(n) * y(n) := \sum_k x(k)y(n-k)$ and $s_n := b_{(R)}(n) * h_n(n)$. Note that s_n is the noiseless readback signal.

Let s_n^o be the estimator of $s(n)$ proposed in [2]. It is formed as follows: denote by $y_{ij}(n)$ the j th readback of the i th track location, for $1 \leq i \leq I$ and $1 \leq j \leq J$. Then, $s_n^o = (IJ)^{-1} \sum_{ij} y_{ij}(n) \dots$ (2).

III. ASYMPTOTIC RESULTS

Define σ_{ep}^2 to be the variance of $e_p(n)$. One can show that $s_n^o \rightarrow s_n + \frac{1}{2} \sigma_{ep}^2 [b_{(R)}(n) * h''_d(n)]$ (a.s.) as $I, J \rightarrow \infty \dots$ (3), where "a.s." denotes almost sure convergence. The variance results are omitted for lack of space.

IV. SIMULATION

The readback signal model (1) is simulated with: the perpendicular recording channel at normalized density $D_n = 2$ and $R = 10$; $e_p(n)$ being i.i.d. Gaussian $N(0, \sigma_{ep}^2)$ truncated to $[-T/2, T/2]$; and $e_a(n)$ i.i.d. $N(0, \sigma_{ea}^2)$. T denotes the bit period. The data bits $a_n \in \{\pm 1\}$ are taken to be three periods of a pseudorandom (PRB) sequence generated by the primitive polynomial $x^2 + x^4 + 1$, and $b_n = (a_n - a_{n+1})/2$. The signal to noise ratio (SNR) is 15 dB in the oversampled domain with a noise mix of 50% jitter and 50% additive noise: see [4].

The empirical and theoretical asymptotic bias of s_n^o are illustrated in Fig. 1 for one PRB period. The transitions in the signals match well; however, the amplitudes of the peaks and valleys do not. There are two possible reasons. The first is that the theoretical bias term is derived in the asymptotic regime: a larger value of I may be required. The second is that a second order Taylor series expansion may be insufficient, and higher order terms need to be considered.

I. Introduction

Bit-patterned media (BPM) is one of the promising technologies that is being considered for storage densities of 1 Tbit/in² and higher. In BPM, in order to achieve high densities, the bits or magnetic islands should be very close to each other, i.e., both the track pitch and the bit period must be very small. As a result, there will be inter-track interference (ITI) in addition to inter-symbol interference (ISI) [1], [2]. In other words, in BPM, the interference is in 2D. Also in BPM, the media noise is different from that in conventional magnetic recording systems [3]. In BPM a major part of the media noise is due to the fabrication imperfections, therefore the media noise is correlated and affects both the along-track pulse response and the track profile. In this work, to obtain a more realistic channel model, we develop a 2D pulse response to model the 2D interference and the media noise. We also fit an analytical model to the 2D pulse response of BPM to simplify the channel model.

II. Channel modeling

We obtain the 2D pulse response using the three-dimensional (3D) reciprocity integral based on the magnetic potential of the magneto-resistive (MR) read head. We apply the MR read head surface magnetic potential approximated by Weisen et al. [4], to obtain the head magnetic potential [4], [5]. In this work, we use the numerical approach to calculate the 3D reciprocity integral and the head magnetic potential. From the 2D pulse response, we obtain the readback signal by applying 2D linear superposition to model both the ITI and the ISI. We consider fluctuations in island locations and sizes as the sources of media noise [3]. Fluctuations in the location are modeled by using suitably random sampling points of the 2D pulse response. Because the size fluctuations change the shape of the 2D pulse response, we use the first-order Taylor series expansion to approximate this media noise. The correlated noise is obtained by applying a digital filter to white Gaussian noise. To find an analytical or closed-form expression for the 2D pulse response, we fit a surface to the numerical 2D pulse response. A 2D Gaussian pulse appears to be a good candidate for an analytical model of BPM pulse response.

III. Simulation results

An example of a numerical 2D pulse response for a square magnetic island with length 11 nm, height 10 nm, and fly height 10 nm and with soft under layer (SUL) is shown in Fig. 1. For this pulse, the MR element has a thickness of 4 nm and width of 20 nm and the shield-to-shield gap is 20 nm. In this work, we focus on the density of 1.5 Tbit/in², corresponding to a bit period and the track pitch of 21 nm. A generalized partial response (GPR) equalizer and corresponding Viterbi detector are employed in the channel simulator. The results of modeling the media noise for different values of noise are shown in Fig. 2, where SNR_c is the inverse of electronic noise power in db when using normalized 2D pulse response. It seems that to achieve reasonable bit error rates (BERs), the size fluctuations and the location fluctuations should be smaller than 8% of the bit period. The simulation results also show that correlated noise degrades the performance of the channel even more. The mean square error between the numerical pulse response and the 2D Gaussian pulse response with the same along-track and cross-track PW50s is of the order of 10⁻⁴. Also the BER

performance of the channel modeled by the 2D Gaussian pulse is very close to that based on the numerical pulse.

Soft Feedback Equalization for Patterned Media Storage.

M. Keskinöz

Electronics Engineering, Sabanci University, Istanbul, Turkey

Patterned Media Storage (PMS) has recently got a lot of attention since it has a potential to provide ultra-high recording densities of 1 Tb/in² and beyond [1]. In PMS, the information is stored in the isolated single domain magnetic islands and islands are distributed both along the track and across the track directions. The 2D discrete noisy readback signal of PMS can be expressed as $r_{ij} = a_{ij} \odot h_{ij} + n_{ij}$ where a_{ij} represents the i th binary information bit of the j th track, h_{ij} is the 2D island response sampled at island period along track direction, T_x , and island period across-track direction, T_y , and n_{ij} is the receiver electronics noise which is modeled additive-white Gaussian noise (AWGN) with zero mean variance σ^2 .

In this work, we consider only PMS with a SUL and generate the 2D island response to produce similar characteristics as in reference [1] using a square island of length of 12.5 nm. For a high areal density PMS, both inter-track interference (ITI) and inter-symbol interference (ISI), and noise severely degrade the bit error rate (BER) performance of the system. To mitigate the effects of these adverse effects and obtain a capacity increase, in literature, the linear minimum mean squared error (LMMSE) equalization following by threshold (TD) detection, pseudo-decision feedback equalization (PDFE) has been proposed [2]. Under severe 2D-ISI, the performance of PDFE has been shown to be quite better as compared to LMMSE in the numerical experiments since PDFE uses self-iterations to improve hard decisions obtained after the LMMSE equalization followed by threshold detection. To further improve the performance of the PDFE, we develop a method called soft feedback equalization (SFE) that produces soft information rather than hard decisions after the LMMSE equalization and exchanges that between its self-iterations. In SFE, the LMMSE equalizer output is used to calculate the soft information called “extrinsic information” about a particular symbol a_{ij} as shown in Fig.1 Therefore, we first design a simple extrinsic information calculator which outputs the extrinsic log likelihood ratio (LLR) of each information symbol. The calculated extrinsic LLRs are then used to determine the mean of the channel outputs which is later subtracted from the channel outputs to perform LMMSE estimation. To initialize the SFE equalization, we set a priori information of all information bits to zero. After the first iteration, we obtain the extrinsic LLR at the output of the equalizer and it can be used as a priori information for the next iteration of the equalization process.

We also compare the performance of SFE with LMMSE and, PDFE and SFE for different recording densities that equal to $1/(T_x T_y) \text{ bits/unit area}$. In our numerical experiments, for this aim, we consider only $T_x = 14.13 \text{ nm}$ and vary the island period along the track direction, T_y , as 31.2 nm, and 17.83 nm to obtain areal density D of 1.45 and 2.53 (Tera-bits/inch²) respectively. For these values of island periods and corresponding recording densities, the channel has a support of $L_x = 5$ and $L_y = 5$ at most. In PDFE and SFE, we use 2 iterations and we observed that using more iteration does not help to improve the performance. To keep the complexity of PDFE and SFE small, we only employ a 3x3 LMMSE equalizer.

During our simulations, we observe that PDFE and SFE converge using one iteration and two iterations for D= 1.45 and D=2.53 Tbits/ inch² respectively. For the target BER of 10^{-4} and D=1.45 both PDFE and SFE provide SNR gain of 1.25 dB over LMMSE. For this track density since the amount of 2D-ISI is relatively small and hence SFE didn't provide any SNR improvement over PDFE. For the same target BER and D=2.53, PDFE and SFE provide SNR gain of 4.5 dB and 8 dB over LMMSE respectively. For this density, the performance of SFE is superior and it provides

SNR gain of 3.5 dB compared to PDFE with two iterations. Hence, we conclude that under very high areal density and severe 2D-ISI, employing more iterations in SFE can result in higher SNR gains over both LMMSE and PDFE and therefore SFE has a high potential to be used in a ultra-high capacity PMS.

Signal Modeling for Ultra-high Density Bit Patterned Media and Performance Evaluation.

S. Zhang, Z. Qin, X. Zou

Data Storage Institute, Singapore, Singapore

1. INTRODUCTION

Bit-patterned-media (BPM) has been proposed as a candidate for next generation hard disk drives (HDD) [1]. However, manufacturing imperfections can cause these islands to vary in shape/size as well as their geometric locations. In this work, we look into the effects of such manufacturing defects on the signal characteristics and performance with a modeling technique based on our newly developed analytical 3D GMR sensor profile and the reciprocity principle [2].

2. SIGNAL AND CHANNEL MODELING

We simulated 2 heads of different geometric parameters listed in Table 1. On the media side, we target ultra-high density recording of 1 tera-bit per square inch (Tbpsi) and above, with a small bit-aspect-ratio (BAR) of 2 or 4 as the minimum lithographic imprinting feature size sets a lower limit on the island diameter. Based on the read head geometry, the ISI and ITI profile are summarized in Table 2.

Signal generation for BPM is based on the 3D read head profile derived in [2]. We compare the readback signal due to a single transition with those generated using mathematical models, such as error function, hyperbolic tangent function and other physics based model such as the Roger-Potter model [3]. From Fig. 1, we can see that error function and hyperbolic tangent function as well as R-P model matches well to our analytical model, but still not as accurate in modeling the tailing (under-shoot) part of the transition. Therefore we further improve these models by calculating two transitions matched to the media top readback and media bottom readback and combine them accordingly. These improved mathematical models match better to our analytical readback. Another example of this technique is given in Fig. 2 for readback pulse due to a single island in BPM. Also shown in this figure is the interference caused to the neighboring track after being normalized to the same amplitude of the on-track pulse to better illustrate the shape change.

3. PERFORMANCE OF A HIGH RATE LDPC CODES WITH BPM

With the accurate signal generation model for BPM developed, we then conduct channel performance with a 4096/4544 LDPC encoder, a minimum-mean-square-error (MMSE) equalizer, followed by an iterative detector/decoder which consists of a soft-input soft-output BCJR detector and an LDPC decoder. The SNR definition in our result plot is the ratio between the summation of channel coefficient (ISI coefficients) square and the noise power. Therefore longer ISI span means lower effective SNR for each bit.

Bit-error-rate (BER) curves and frame-error-rate (FER) curves are obtained for different head/ density/ BAR combinations in Fig. 3 and Fig. 4. From Table 2 we can see that ITI for smaller BAR can be quite severe at high recording density, resulting very poor performance.

In Fig. 5-6, we explore the effects of island position jitter levels as they could be quite severe in real product [4]. For example, 15% island position jitter roughly translates into 1.5dB SNR loss when comparing the error rate performance, for both read heads. However, the effect of island size fluctuation at different head/density can be quite different. In Fig. 7, 10% island size variation roughly translates into 0.5dB SNR loss for small head and low density, while it translates into about 2dB for larger head and double the density in Fig. 8. With read head B and density 2Tb/in², 15% island size variation equals nearly 7dB in SNR loss.

4.SUMMARY

In this work we developed a signal generation model for BPM recording system based on analytical 3D read head profile and reciprocity principle. We also proposed method to tune simple mathematical model with parameters extracted from analytical model for faster signal generation. Simulation of BPM recording system with advanced channel algorithm is conducted and effects of media noise on performance are discussed.

Patterned media recording, where bits are stored on predefined, signal domain magnetic islands, may provide an alternative to conventional recording on continuous media. In this paper, we present a very simple equalization procedure and compare several different detection methods for patterned media recording channels [1].

In the read channel model considered here, a track consists of three parallel sub-tracks, and the read head, when centered over the middle sub-track, spans a specified fraction of the outer sub-tracks. Electronics noise, modeled as AWGN with mean zero and variance σ^2 , is assumed to corrupt the output of the read head. For certain recording densities, the noiseless discrete-time readback model can be represented by a 3x3 channel response matrix H , shown in (1) of Fig. 1. Each cross-track triplet of islands represents one of 8 possible recorded symbols. The channel represented by H has memory equal to 2 symbols, so the trellis representing the noiseless channel output sequences has $8^2=64$ states, and from each state there are 8 outgoing branches. When the channel response matrix has cross-track symmetry, the number of states can be reduced to $6^2=36$ with 6 outgoing branches from each state. If, in addition, the corner entries are equal to zero, the number of states can be reduced to $2^2=4$ with 3 parallel branches between each pair of connected states [2]. In the reduced-state trellis structures, some output sequences may be generated by more than one input sequence. Therefore, when using these trellises as the basis for symbol detection, we may have to use a restricted input symbol alphabet [1]. Alternatively, we may use them for detection of the middle sub-track only.

We consider maximum-likelihood (ML) detection of symbol sequences or bit sequences, as well as maximum a-posteriori (MAP) detection of symbols or bits. The ML detector uses the Viterbi algorithm to find the ML symbol sequence, with a simple modification for ML bit sequence detection. The MAP symbol detector uses the Bahl-Cocke-Jelinek-Raviv (BCJR) algorithm, which we can modify slightly to obtain the a posteriori probability ratio (APPR) of the coded bits for MAP bit detection. Specifically, if $u_{i,0}$ represents a recorded bit on the middle sub-track at time index i and y represents the channel output samples, the modified BCJR algorithm outputs the APPR in (2) of Fig. 1, where S_i^{-1} and S_i^1 are, respectively, the set of trellis branches (s_{i-1}, s_i) corresponding to input bit -1 and 1.

We compare the performance of four different schemes using the channel response introduced by Nabavi et al [2], H_1 , shown in Fig. 2. The first scheme uses an ML bit sequence detector whereas the second scheme uses an MAP bit detector. Both detectors use a trellis with 36 states and 6 outgoing branches per state. In the third scheme, we use a one-dimensional MMSE equalizer with finite impulse response (FIR) designed using an adaptation of the method in [3] but with a 3x3 target response G having corner entries equal to zero and $g_{-1,0}=1$ [2]. The detector trellis has 4 states with 3 parallel branches between each connected pair of states. We use the Viterbi algorithm with squared-Euclidean metric to detect the middle sub-track bit sequence. (Since the equalizer colors the electronics noise, this detector is no longer ML.) The fourth scheme was introduced by Nabavi et al. [2] for the same channel model. Their detector also uses the Viterbi algorithm on a trellis with 4 states and with 3 parallel branches between each connected pair of states. The detector complexity of the first and second schemes is considerably greater than that of the third and the fourth schemes. For channel response matrix H_2 shown in Fig. 2, we simulate the first three schemes.

The simulation results are shown in Fig. 3 for H_1 and H_2 . The signal to noise ratio (SNR) is defined as $20\log_{10}(V_p/\sigma)$ where $V_p=1$. In all equalized systems, the FIR filters were limited to 11 taps. For channel H_1 , the first three schemes substantially outperform the fourth scheme where the results are taken from [2]. At a target bit error rate of 10^{-4} , the proposed schemes provide a gain of 1.5dB for channel H_1 . For channel H_2 , the first three schemes have approximately the same performance.

Understanding sources of errors in bit patterned media to improve read channel performance.

Y. Shi, P. W. Nutter, J. J. Miles

School of Computer Science, The University of Manchester, Manchester, United Kingdom

It is believed that the superparamagnetic limit will restrict the storage density of continuous magnetic media to approximately 1Tb/in^2 . Consequently, research has been directed into the development of new storage paradigms to overcome this limit, such as the use of bit patterned media [1]. However, there are considerable problems that need to be overcome in order to fabricate a patterned magnetic storage medium with densities in excess of 1Tbit/in^2 . The limitations of practical fabrication techniques result in a variation in the size and position of the fabricated islands that manifests itself as jitter in the replay signal; this inevitably has a detrimental effect on the bit-error-rate (BER) performance of the read channel [2]. Recent work investigating read channel designs for bit patterned media has shown that the application of low density parity-check (LDPC) codes offers improved BER performance in the presence of lithography jitter [2]. However the differing effects of size and position variation upon read errors has not been studied. In this paper, we separate island position and size variations and investigate their effects on the read channel performance. We then propose an extended trellis structure that can be shown to improve the BER performance with position jitter present, without the complexity of LDPC codes.

To predict the performance of the read channel in terms of BER performance against replay signal-to-noise ratio (SNR), a simulation of the data recovery process has been developed [2,3]. The simulation consists of a read channel model and a 3-D replay model which takes into account the geometrical aspects of both the patterned storage medium and the GMR sensor. The read channel model consists of an FIR to equalise recovered samples to a $[0.1, 1, 0.1]$ PR target, followed by a Viterbi decoder. In the following analysis a patterned medium comprising of a track of square islands with island length and period of 12.5nm and 25nm respectively has been adopted, corresponding to 1Tbit/in^2 ; the read sensor dimensions are given in [3]. The variation in island position and size are assumed to have a Gaussian distribution [2,3], with standard deviation, σ , specified in terms of a percentage of the island period. Figure 1a) illustrates BER v. SNR curves for four cases using a conventional trellis: no jitter (solid); 10% island position jitter (dashed); 10% island size jitter (dotted); and 10% island position and size jitter (dash-dot). The introduction of jitter, whatever its source, has a detrimental effect on the performance of the read channel, and the degradation in performance is dominated by variations in island size. In order to combat the effects of position jitter, an extended trellis has been introduced, to replace the standard trellis. In the extended trellis, the states are defined by both the state of the magnetised islands and the discrete values representing a position shift of each island due to jitter. The pulse amplitude with fixed jitter is determined to characterise the amplitude due to each magnetised island, and the ideal output value of the branches from one state to the next is calculated accordingly. In the extended trellis the state bits and the contributions of position jitter are considered when selecting the most likely input sequence. A similar approach has been used for transition jitter estimation in perpendicular storage media [4]. However, unlike transition jitter in perpendicular media, position jitter is signal-independent and uncorrelated and thus causes the state definitions and the transitions between states to differ from the solution described in [4]. Here we use a PR target of tap length 3 and choose 3 discrete jitter levels, $\{-2.5\text{nm}, 0, +2.5\text{nm}\}$ for $\sigma=10\%$, which results in 36 states in the extended trellis. The configuration of the extended trellis depends upon the known amount of jitter present. Figure 1b) demonstrates the improvement in BER performance that is observed when adopting the pro-

posed extended trellis in the presence of 10% position jitter (dotted line), compared with the use of the standard trellis (dashed line).

We have shown that read channel performance in bit patterned media is degraded by the presence of variations in island position and size and that variations in island size are a more significant source of error. We have investigated new trellis designs that can be shown to offer improved read channel performance, initially in the presence of island position variations in the media. This work will be extended by investigating optimal trellis designs and alternative extended trellis designs that offer improved performance in the presence of island size jitter and both island position and size jitter, as well investigating reduced complexity designs.

Global timing control for tape storage channels.

S. Ölçer¹, J. Jelitto¹, R. A. Hutchins²

1. IBM Zurich Research Laboratory, Rüschlikon, Switzerland; 2. IBM STG, Tucson, AZ

Efficient symbol timing recovery is a key issue in read channels for data storage systems. In particular, approaching the Shannon-limit performance requires highly robust solutions, capable of reliable operation under low signal-to-noise ratio (SNR) conditions. In tape-based data storage, timing recovery problems are exacerbated by disturbances such as dropout events, instantaneous speed variations, or nonlinear signal distortion, which erode the available SNR margins further. Degraded channel conditions typically lead to “cycle slip” or temporary “loss-of-lock” events. Although techniques for symbol synchronization in low SNR have been proposed, e.g., [1]-[5], complexity usually is an obstacle for practical applications.

Here, a new approach is introduced for robust timing recovery called global timing control (GTC). The proposed technique exploits the multi-channel nature of tape storage systems. The idea of GTC is to combine the timing information provided by a plurality of channels and generate “global” control signals that are used by all channels for their timing recovery functions. Channels subject to disturbance are aided with the timing information from channels operating under more reliable conditions.

The GTC scheme is derived by applying results from optimum filtering theory to the state-space model of the timing process in an N-channel system. The optimal solution obtained can be regarded as N second-order phase-locked loops (PLLs) coupled by a multi-input multi-output (MIMO) loop filter with time-varying coefficients. The paper describes how practical GTC schemes are obtained from the optimal solution. A particularly simple solution is shown in Fig. 1 for a 2-channel system. Here, $\gamma^{(1)}$ and $\gamma^{(2)}$ denote the loop coefficients for the proportional terms. The factors $w_k^{(1)}$ and $w_k^{(2)}$ weight, at time k, the contribution of each phase signal to the global frequency estimation; together with $\sqrt{\zeta}$ they form the loop coefficients for the integral terms. The coefficient values are derived from Kalman filtering theory. To simplify computations, the weights $w_k^{(i)}$, $i=1,\dots,N$, can be approximated, e.g., by using the SNRs at the read-channel detection points (SNRDs). The simplest implementation uses equal-weight combining with weights $1/N$ for all N channels.

The performance of the GTC scheme was analyzed using readback waveforms captured in a commercial tape drive. Three cases were considered, corresponding to waveforms with increasingly higher linear recording densities. Data were written onto 16 tracks in “sectors” of 8 Kbits separated by synchronization (Sync) patterns. The waveforms were captured from 16 parallel channels, with each waveform extending over 32 sectors. A 16-channel software read channel was used to process the waveforms. Timing recovery was performed either independently on each channel (local mode) or in GTC mode. Performance results showed that adaptive weighting usually achieves some improvement over equal gain weighting. The implementation loss introduced by the simplifications is very small. The results in Table I demonstrate the robustness of GTC and its resilience against loss-of-lock phenomena (“missed sectors” are due to missed Sync patterns and indicate loss-of-lock). Hence, a significant improvement is achieved over local timing control. The simplified GTC scheme using SNRD-based weighting incurs a fairly low implementation complexity. GTC can be applied to other storage technologies that use multi-track recording.

Multilayered thin film structure for negative permeability.

S. Cho¹, J. Kim¹, K. Kim²

Introduction

In recent, electromagnetic and communication devices are faced with the physical limitation of electromagnetic materials. This physical limitation is suggested to be overcome by the development of new artificial meta-materials, which have negative permittivity and permeability. Thus these meta-materials are generally known as LHM (Left-Handed Material) and NRM (Negative Refractive Index Material) suggested by Veselago in 1968 [1]. This negative value of permittivity and permeability of LHM is expected to show different electromagnetic response, which is not found in nature, such as negative refractive constant. Therefore, LHM can apply to various new electromagnetic and communication devices in frequency ranges from MHz to THz without less design space constraint.

Up to now, LHM are realized as a circuitry type by using a SRR (Split Ring Resonator) and thin wire structure [2, 3]. Because this circuitry type LHM requires large volume and complicate fabrication process, it is of prime interest to develop a non-circuitry type LHM with simple fabrication process and small volume. In this study, we suggest a new non-circuitry type LHM with a multilayered thin film structure. This new LHM is expected to bring a new design concept and paradigm of LHM.

Experimental Procedures

In this experiment, two kinds of multilayered thin film structures were designed and fabricated on corning glass: the one is a non-insulating type structure with Cu (20nm) / Ni80Fe20 (100nm) / Cu (20nm) and the other an insulating type structure with Cu (20nm) / SiO₂ (10nm) / Ni80Fe20 (100nm) / SiO₂ (10nm) / Cu (20nm). The metal thin film layers were grown by a RF magnetron sputtering method in Ar plasma atmosphere (working pressure: 2 mTorr, working power: 300 W) and the insulating layer (SiO₂), deposited by a chemical vapor deposition method (deposition temperature: 300°C, working pressure: 1000 mTorr, carrier gas: SiH₄, working power: 20 W). The permeability of the thin film structures was measured by a broadband CPW (Coplanar Waveguide, a dimension of 0.1 × 5.2 × 0.003mm) method which was discussed in other literature [4].

Results and Discussions

Fig. 1 shows the S-Parameter variations of CPW loaded with multilayered thin films versus the operation frequency. As shown in the figure, the values of S₁₁ and S₂₁ were changed by the loading of the thin films. In particular, the value of S₂₁ is larger than that of S₁₁ when a non-insulating type sample is loaded on the CPW. In order to extract the permeability of these multilayered samples, a broadband CPW method was used and the results are shown in Fig. 2. As shown in the Fig. 2 (a), the magnetic resonance of the non-insulating type sample is observed to occur at ~ 1.5 GHz. This magnetic resonance should be related to the resonance of the Ni80Fe20 layer. However, the real value of the permeability is shown to be decreased although the operation frequency is increased over the resonance frequency. This should indicate that this material have negative permeability over resonance frequency. Contrary to the non-insulating sample, there is no indication of magnetic resonance in the insulating sample. Moreover, the real part of permeability in the insulating type material shows a constant negative value of -40 up to ~15 GHz.

These experimental results show that meta-materials with negative permeability can be fabricated by a multi-layer structure. This finding suggested that LHM could be very innovative materials for EM and communication devices.

Interlayer exchange coupling in $\text{Co}_2\text{FeAl}_{0.5}\text{Si}_{0.5}/\text{Cr}/\text{Co}_2\text{FeAl}_{0.5}\text{Si}_{0.5}$ trilayers.

T. Furubayashi¹, K. Kodama², K. Inomata¹, K. Hono¹

1. Magnetic Materials Center, National Institute for Materials Science, Tsukuba, Japan; 2. Graduate School of Pure and Applied Sciences, University of Tsukuba, Tsukuba, Japan

Much attention has been paid to the problem of interlayer exchange coupling in multilayered films consisting of half metallic full-Heusler alloys. Ambrose et al. [1] reported that, in $\text{Co}_2\text{MnGe}(\text{CMG})/\text{V}/\text{CMG}$ and $\text{CMG}/\text{Mn}/\text{CMG}$ trilayers, the magnetizations of two CMG layers couples with 90 degrees to each other, while the $\text{CMG}/\text{Cr}/\text{CMG}$ films exhibited no significant coupling. Recently, Wang et al. [2] showed that (001) epitaxial $\text{Co}_2\text{MnSi}(\text{CMS})/\text{Cr}/\text{CMS}$ films show very strong 90-degree interlayer exchange coupling. In this system, the biquadratic coupling is dominant while the bilinear component, which gives parallel or antiparallel couplings, is negligibly small. The mechanism of such strong 90 degree coupling is still unclear. It is of much interest to see if such a property is observed commonly in Heusler alloys or half metals. For obtaining further insights in this problem, we have examined trilayers consisting of a Heusler alloy $\text{Co}_2\text{FeAl}_{0.5}\text{Si}_{0.5}$ (CFAS). Tezuka et al. [3] reported that magnetic tunnel junctions with the structure $\text{CFAS}/\text{MgO}/\text{CFAS}$ show high MR ratio reaching 220 % at room temperature. CFAS is expected to have a high spin polarization, so is promising for various spintronic applications. In this work, magnetic properties were examined for both (001) epitaxial and polycrystalline films with the trilayer structure of $\text{CFAS}/\text{Cr}/\text{CFAS}$. Such trilayers are of much interest in view of potential applications to GMR devices not only from physical viewpoints.

Layered structures with CFAS Heusler ally were grown by dc magnetron sputtering in an ultra-high vacuum system with the base pressure lower than 5×10^{-7} Pa. The films were deposited upon MgO (001) single crystalline substrates and thermally oxidized Si substrates at room temperature (RT) with the layer structure of $\text{Cr}(30)/\text{CFAS}(20)/\text{Cr}(t)/\text{CFAS}(5)/\text{Ta}(5)$ in nm from the bottom. After depositing the bottom CFAS(20) layer, the films were annealed at 400 °C in situ for improving the structure order and then cooled to RT. Layers of Cr and CFAS deposited on MgO (001) single crystals were found to show epitaxial (001) growth. The CFAS was in the B2 structure. In contrast, the films deposited on SiO_2 were polycrystalline with no significant texture, in which the CFAS was in the A2 disordered structure.

Magnetization curves were recorded at RT using VSM with a magnetic field applied in the film plane. For epitaxial films prepared on MgO (001), a magnetic field was in the direction parallel to the [110] axis of CFAS, the easy direction.

The magnetization curves, as shown in Fig. 1, exhibit different behaviors for two samples with different Cr interlayer thicknesses of (a) 2.5 nm and (b) 1.5 nm. The results obviously indicate non-ferromagnetic coupling between two CFAS layers through the 1.5 nm thick Cr layer. In the sample deposited on MgO (001), we obtain $M_R/M_S = 0.82$, where M_R is the remanent magnetization and M_S is the saturation magnetization. This value is near 0.8 expected for the case that the two CFAS layers with the different layer thicknesses have 90 degree coupling. Thus, in the $\text{CFAS}/\text{Cr}/\text{CFAS}$ film grown epitaxially on MgO (001), biquadratic coupling is dominant, as observed in the $\text{CMS}/\text{Cr}/\text{CMS}$ (001) system [2]. Note that the polycrystalline film deposited on SiO_2 shows smaller M_R/M_S of 0.65, which is near the value 0.6 expected for an antiferromagnetic coupling. This result indicates that, in the polycrystalline $\text{CFAS}/\text{Cr}/\text{CFAS}$ film, the bilinear coupling exists in addition to the biquadratic coupling. In other words, the amplitude of the bilinear coupling strongly depends on the crystal orientation. It is negligibly small compared with the biquadratic one when

stacked in the (001) direction. Thus the interlayer couplings would depend on the band structure of Cr and CFAS for different direction of the electron propagation.

In summary, interlayer couplings were examined for both (001) epitaxial and polycrystalline $\text{CFAS}/\text{Cr}/\text{CFAS}$ layered films. Strong couplings were observed for the films with the 1.5 nm thick Cr interlayer. A 90-degree coupling is dominant in the (001) epitaxial film, similarly with the $\text{CMS}/\text{Cr}/\text{CMS}$ system. In contrast, an antiparallel coupling also exists in the polycrystalline one. Thus, the interlayer couplings in this system strongly depends on the crystal orientation of the layers. The mechanism of the interlayer couplings is expected to be clarified theoretically by accounting for the electronic structure of both Cr and CFAS.

Thickness and Temperature Dependence of Extraordinary Hall Effect in Interlayer Coupled [Pt/Co]₅/Ru/[Co/Pt]₅ Multilayers with Perpendicular Anisotropy.

J. Zhao¹, Y. Wang¹, S. Zhang², X. Han¹

1. State Key Laboratory of Magnetism, Institute of Physics, Chinese Academy of Science, Beijing, China; 2. Department of Physics and Astronomy, University of Missouri–Columbia, Columbia, MO

Due to spin-orbit interaction and the strong hybridization between Pt-5d and Co-3d at the Pt/Co interface in Co/Pt multilayers (MLs), its extraordinary Hall effect (EHE) is substantially larger. It may serve as a good electric transporter for the measurement of hysteresis loop because the Hall resistivity is proportional to the perpendicular component of magnetization[1].

Because the dependence of the interlayer coupling oscillatory behavior and extraordinary Hall effect on the thickness of the nonmagnetic (NM) Pt and the ferromagnetic (FM) Co have been reported previously [2,3], our this work is focused on the temperature dependence of EHE in the interlayer coupled Co/Pt MLs, in which the spacer layer is Ru between (Pt/Co)_n and (Co/Pt)_n.

The Hall effect was measured for some selected interlayer antiferromagnetic (AF) coupling samples by four probe method from 300K to 4.2K, as shown in Fig. 3. Only the extraordinary term contributes to the Hall resistivity, i.e. it is only proportional to the magnetization. The saturation field H_s and interlayer AF coupling field H_{ex} decay linearly with the increase of T , while EHE enhances with the increase of T . An inflexion point appears at the temperature of about 125K, where the alignment of the magnetization vectors of the top and bottom Co/Pt MLs begins to deviate from the previous complete antiparallel state. Such behavior can be explained by the competition between magnetic anisotropy energy and interlayer AF coupling energy. As the perpendicular anisotropy field is stronger increased than that of the interlayer coupling field H_{ex} during decreasing temperature, it become difficult to turn the magnetic vector in one layer to the opposite direction on the reversal process. It is known that skew scattering and side jump contribute to Hall resistivity near RT[4], however, the skew scattering dominates at low temperature according to our results.

We have measured low field domain wall motion in a weakly disordered ultrathin Co film coupled (through a Pt spacer) to a second, magnetically harder Co layer. We examine how the effective coupling field created by the antiferromagnetic coupling to the harder layer results in asymmetric domain wall creep motion. The coupling field is determined from the wall velocity measurements by way of a modified creep expression which takes the effective coupling field into account. The sample was sputter deposited at ambient temperature onto an etched Si substrate and has the following structure: Pt(4.5 nm) / Co(0.5 nm) / Pt(4 nm) / Co(0.8 nm) / Pt(3.5 nm). Both Co layers exhibit perpendicular anisotropy with the thinner Co layer being the magnetically softer one (Fig 1). Interlayer coupling in such films is thought to result from a combination of RKKY and orange-peel coupling [1]. The antiferromagnetic interlayer coupling in this particular film can be first evidenced from the leftward shift of the minor hysteresis loop of the soft layer (inset of Fig 1), obtained while keeping the harder Co layer negatively saturated. The observed shift can be interpreted in terms of an effective coupling field, $H_j = 5.2 \pm 2.0$ Oe, which acts on the soft layer during reversal [2]. While this is a common method of determining H_j , ambiguities can exist due to the multiple reversal processes (domain nucleation and wall propagation) occurring during reversal [3]. A more relevant and easily interpreted measurement is to determine the effect of the coupling field on individual reversal processes [4].

We have measured the velocity of domain walls in the soft layer under both positive and negative applied fields, H , while keeping the hard layer (to which the soft layer is coupled) negatively saturated. This was done using a quasi-static PMOKE microscopy technique [5]. An asymmetry was found for velocities measured for $H > 0$ and $H < 0$ (Fig 2) which resulted from the different relative directions of the applied field and coupling field (which was always positive) in the two cases. For $H > 0$, H_j reinforced the applied field whereas for $H < 0$, H_j worked against the applied field, resulting in a lower wall velocity.

In single layer ultrathin Pt/Co/Pt films, low field domain wall motion can be understood [5,6] in terms of interface creep theory [7] for which we expect $v \propto \exp[-(E_B/k_B T)H^{-1/4}]$. E_B characterizes the pinning potential induced by the structural disorder in the film and μ is a universal exponent equal to 1/4 for a 1D interface (domain wall) in a 2D weakly disordered medium. This expression however cannot be used to describe our data since it does not take the effective coupling field into account. We therefore modified the standard expression, including the effective coupling field resulting from the interlayer coupling as a component of the total effective field acting on the wall (as done for viscous wall motion [4]). This yields $|v| \propto \exp[-(E_B/k_B T)|H+H_j|^{-1/4}]$. We then tested if this approach could reconcile the $H > 0$ and $H < 0$ data sets, treating H_j as a fitting parameter and searching for the value which overlapped the two data sets. The two data sets could indeed be reconciled with $H_j = 4.9 \pm 0.2$ Oe, consistent with the value determined from the loop shift. The $\ln(v)$ data (inset of Fig 2) is linear in the corrected total scaled field $|H+H_j|^{-1/4}$ up to about 300 Oe confirming the validity of the universal creep exponent $\mu = 1/4$ for describing the low field wall motion once H_j is taken into account. As expected, E_B (which describes the film's intrinsic disorder) does not show any appreciable dependence upon the relative directions of H and H_j .

Magnetic properties of low dimensional objects (layers and particles) depend on their size. In some cases the size dependence of magnetic ordering temperature T_{ord} for rare-earths (RE) layers, e.g. for $[\text{Gd}/\text{X}]_n$ and $[\text{Tb}/\text{X}]_n$ multilayers, where X is a nonmagnetic spacer, can be described satisfactorily by a finite size scaling theory [1-4]. However, when the thickness of the RE layers decreases down to a few nanometers, deviations from this law appear [2,4]. The objective of this work is the study of the structure and magnetic properties of Tb/Si and Tb/Ti nanoscale multilayers aiming to understand the cause of the observed size dependence.

The multilayers were prepared by alternative deposition of Tb layers and nonmagnetic spacers onto glass substrates by rf-sputtering. The thickness of Tb layers (L_{Tb}) varied from 1.5 nm to 12 nm and total thickness of magnetic component in the multilayers was 90 or 120 nm. The spacer thickness was 2 nm. Magnetic properties were measured using a SQUID magnetometer. The microstructure was examined by X-ray diffraction and transmission electron microscopy. Small angle X-ray diffraction was used to determine the quality of the layers in multilayered structures.

Zero Field Cooling (ZFC) and Field Cooling (FC) dc susceptibility χ_{dc} was measured in 120 Oe. For all samples ZFC curves had a maximum at certain temperature T_m . Below T_m a clear difference between the FC and ZFC curves was observed. Such a behavior of the magnetization is typical both for spin glass [6], and for superparamagnetic objects [5]. However this feature may also be a consequence of the high crystalline magnetic anisotropy of terbium at low temperatures. It was observed that T_{ord} and T_m depend on the type of the material of the nonmagnetic spacer at $L_{\text{Tb}} < 10$ nm, e.g. for $[\text{Tb}(1.5\text{nm})/\text{Ti}]_{60}$ and $[\text{Tb}(1.5\text{nm})/\text{Si}]_{60}$ multilayers T_m is 80 K and 9 K, respectively (Fig. 1). For $[\text{Tb}(1.5\text{nm})/\text{Si}]_{60}$ multilayers ac susceptibility χ_{ac} was measured also for different frequencies (10-700 Hz) and 4 Oe ac magnetic field. The susceptibility peak shows an increase in intensity and a shift to lower temperatures with decreasing frequency, consistent with the classic spin glass behavior. The value of the effective moment μ calculated according to Curie-Weiss law for $[\text{Tb}(1.5\text{nm})/\text{Si}]_{60}$ multilayers is within 10% of the expected value for trivalent Tb ($9.72 \mu_B$).

Fig. 2 shows the hysteresis loops of the $[\text{Tb}(1.5\text{nm})/\text{Si}]_{60}$ multilayer measured below and above T_m . The shape of the $M(H)$ curves is reminiscent of that of the superparamagnetic particles with blocking temperature $T_b = T_m$. The superparamagnetic behavior can be also confirmed by the usual superposition of the magnetization vs H/T curves above 10 K (Fig.2, inset). If one consider the value of the anisotropy constant of the bulk Tb ($5.5 \times 10^8 \text{ erg/cm}^3$) in case of $[\text{Tb}(1.5\text{nm})/\text{Si}]_{60}$ multilayer, the size of the superparamagnetic particles can be estimated as 1.5 nm. The hysteresis loops of the $[\text{Tb}(1.5\text{nm})/\text{Ti}]_{60}$ multilayer measured at the same temperatures have different shapes (Fig. 3). It was found that the coercivity H_c at 80 K (Fig. 3, inset) is comparable to the applied field of 120 Oe for which the ZFC curve has a maximum at $T_m = 80$ K.

In summary, the size dependence of T_{ord} for Tb/Ti multilayers can be satisfactorily described by a finite size theory up to $L_{\text{Tb}} = 1.5$ nm and the observed spin-glass like behaviour is caused by the

high crystalline magnetic anisotropy of terbium. For Tb/Si multilayers with $L_{\text{Tb}} \leq 3$ nm the spin-glass like behaviour can be due to the formation of superparamagnetic particles of Tb and/or Tb-Si spin-glass alloys.

Multilayered films appear to be a good solution to relief the stress stored during the sputtering deposition of thick the ferromagnetic layers for magnetoimpedance sensors, as well as to tailor the DC impedance of a given device. The accumulated stresses contribute to an increase in the dispersion and strength of the effective anisotropy which, in turn, decreases the permeability and magnetoimpedance (MI) in these materials.

In particular, permalloy-based multilayered films are used in much read/write magnetic devices due to the excellent soft magnetic properties and signal/noise ratios obtained in such devices. MI sensors based in permalloy and permalloy-based multilayers become attractive as they can be integrated with the electronics or pre-existing read/write devices without extra processing steps.

In this work, we report a comparative study of the MI is investigated in both, Py/Ag and Py/Cu multilayers, produced by magnetron sputtering over glass substrates. The samples were produced with the number of bilayers 15, 30, 50, 70 and 100. The MI measurements were performed in the samples with $t_{\text{Py}}/t_{\text{Ag}}$ and $t_{\text{Py}}/t_{\text{Cu}}$ ratio thickness of 10/0.7, 10/2.5 and 10/10. The thickness of the permalloy layer was fixed as 10nm. The impedance spectra $Z(f,H) = R(f,H) + jX(f,H)$ was measured with an impedance analyzer HP4396B at frequencies in the range 100kHz - 1.8GHz with a strip line microwave sample holder under a slowly varying magnetic field. The samples were cut in two different directions: longitudinal and transverse (relative to motion of the substrates during the deposition process) as a transverse anisotropy appeared in some of the samples. The magnetoimpedance measurements were performed with the probe current flowing in these two directions.

For the Py/Cu multilayers, we observed single peak structures in both directions up to the highest frequency, which is consistent with in-plane isotropic magnetic properties. Some magnetoimpedance vs. field curves for the $[\text{Py}(100\text{\AA})/\text{Cu}(25\text{\AA})] \times n$ sample with $n = 15$ and 100, are shown in figure 1 below.

For the Py/Ag samples, however, a characteristic single peak at longitudinal direction and double peak at transverse one were observed, as shown in figure 2.a. This behavior is in accordance with the predominantly uniaxial properties observed in these samples. The highest MI ratios were observed for samples with 100 bilayers. Interestingly, both materials (Py/Ag and Py/Cu) present almost the same maximum MI ratio: 250% for 2.5nm of Cu or Ag and 10nm of Permalloy, both with 100 bilayers.

Moreover, for some Py/Ag samples with small number of bilayers, the frequency and field dependent impedance curves show multiple-peak structures (see figure 2.a), characteristic of multiple FMR lines. This effect was stronger for samples with thickness ratio $t_{\text{Py}}/t_{\text{Ag}} = 4$. These features are the fingerprint of a complex dynamics, possibly associated with the magnetic coupling between individual layers.

Structural Characterization of Ferromagnetic Mn/ZnO Multilayers.

E. Céspedes, A. Espinosa, M. García-Hernández, A. de Andrés, C. Prieto
Instituto de Ciencia de Materiales de Madrid, Consejo Superior de Investigaciones Científicas (CSIC), Madrid, Spain

Mn-Zn-O system has attracted great theoretical and experimental attention in the last years due to its potential functionalities in spintronics as a wide band gap diluted magnetic semiconductor (DMS). Since Dietl et al.¹ predicted the possibility of room-temperature ferromagnetism (RTFM) in p-type $\text{Zn}_{1-x}\text{Mn}_x\text{O}$, ferromagnetism with transition temperatures above RT has been experimentally obtained in Mn-Zn-O films prepared by different methods. However, experimental results obtained up to date have been very controversial and the origin of RTFM has been attributed either to an intrinsic or extrinsic property.² The role of Mn-ZnO interfaces, a quite unexplored field, has been claimed to be of great importance in the FM behaviour of these materials.^{3,4}

In this work, in order to study interfaces in the Mn-Zn-O system, a series of $(\text{ZnO}_{3\text{nm}}/\text{Mn})_n$ multilayers was prepared by magnetron sputtering on Si(100) substrates at room temperature (RT). The nominal Mn layer thickness, t , was varied from 6 to 0.1 nm while the number of bilayers, n , was increased from 5 to 75 to keep the total amount of Mn constant.

Structural information, as bilayer thickness and roughness, was obtained from X-ray reflectivity (XRR) measurements, carried out on a Bruker D8 X-ray diffractometer.

Magnetic properties were measured with a “Quantum Design” Superconducting Quantum Interference Device system up to 5 T. The magnetic behaviour of these samples varies within the series and ferromagnetic order gets favoured by increasing the Mn layer thickness (t). The transition temperature, T_C , is always above 400 K for these ferromagnetic samples.

X-ray absorption spectroscopy (XAS) measurements at the Mn K-edge were made at SpLine and Dubble beamlines (ESRF) in fluorescence detection mode. X-ray absorption near-edge structure (XANES) results indicate a variation of the Mn oxidation state with t . Mn valence states close to +2 are found for samples that exhibit ferromagnetic order while higher Mn oxidation states are obtained as t is reduced. The presence of pure metallic Mn is discarded in every sample. Further XANES analysis points towards the existence of two different Mn environments in samples with high t values. By comparison with reference XANES spectra, not only the existence of Mn in ZnO wurtzite structure, but also Mn in rocksalt lattice is revealed.

X-ray diffraction experiments were performed at SpLine (ESRF) at 14 KeV ($\lambda = 0.8857 \text{ \AA}$). Θ - 2Θ and grazing incidence high-angle X-ray diffraction spectra revealed that all multilayers contain ZnO wurtzite nanocrystals. Samples show texture in the (002) crystallographic direction. The size of these nanocrystals is of the ZnO layer thickness order (3 nm) in samples with t sufficiently high. In the case of samples with very thin Mn layers, though, crystalline grains above 7 nm are found, evidencing no restriction to the ZnO grain size in the out-of-plane direction; showing that for these small t , Mn deposition does not hamper ZnO growth. MnO nanocrystals are also identified, but just in samples with high values of t , in agreement with XAS results, where coexistence of wurtzite and rocksalt is identified. No traces of metallic Mn or other Mn-Zn-O phases are found from diffraction measurements.

According to the growth conditions, a model is proposed to explain all the obtained results. For all the samples, the oxygen excess at the surface of the lately deposited ZnO layer can provide a highly oxidized state to the very close Mn atoms and therefore, a small Mn^{4+} fraction should be expected at the first growth stage of the Mn layers. For samples with very thin Mn layers, no appreciable differences are expected between top or bottom of the Mn layer, leading to the formation of MnO_2

in the entire Mn layer. Due to big differences in the ionic radii, neither Mn^{4+} diffusion into ZnO nor Zn^{2+} diffusion in MnO_2 are expected. For samples with high t values, though, high reactivity of freshly deposited Mn along with competition between Mn and Zn to share oxygen explains interdiffusion and the formation of mixed $\text{Zn}_{1-x}\text{Mn}_x\text{O}$, with rocksalt and wurtzite phases coexisting. Further analysis of magnetic and XAS results indicates a relation between the Mn amount into ZnO lattice and the obtained saturation magnetization values, what points towards Mn diluted into ZnO as the origin of the obtained ferromagnetism.

Structural control of magnetic properties in Co/Pd multilayer for heat assisted perpendicular MRAM application.

B. Purnama, K. Waseda, S. Yoshimura, Y. Nozaki, K. Matsuyama

Electronics, Kyushu University, Fukuoka, Japan

Thermally assisted magnetization reversal is a promising scheme to utilize a superior data storage performance of recently developed ultra-high perpendicular anisotropy materials in MRAM technology[1]. A moderate value of magnetization switching field and sensitive temperature dependence are required for MRAM memory cell, where a fast memory operation should be performed with a tolerable amplitude of conductor current at an elevated temperature. In order to satisfy the above technological demands, structural control of coercive field H_c and whose temperature dependence have been systematically studied for Co/Pd multilayer. Samples were deposited on glass substrates by a tandem type DC magnetron sputtering with a multi-cathode system (Anelva SPC-350). Magnetic and structural properties in as-grown films were characterized with VSM and XRD measurements, respectively. The extraordinary Hall resistance R_H was measured for the microstructured samples with overlaid 4-terminal Ti/Au electrodes, fabricated with photolithography and following lift-off process.

Fig. 1(a) shows R_H hysteresis curves measured at various temperatures, ranged from 23°C to 150°C. The square hysteresis is observed up to 100°C, suggesting a nucleation type magnetization reversal at high temperatures. The value of H_c linearly decreases with the increase of temperature and is extrapolate to zero value at 150°C, defined as a threshold temperature T_{th} , as shown in Fig. 1(b). The sensitive temperature dependence of the coercivity can be associated with a thermally activated magnetization process, since the perpendicular anisotropy is still remained at T_{th} , as shown in Fig. 1(a). The H_c decreases with the increase of Co layer thickness t_{Co} , except a very thin thickness of 1 Å, suggesting an aspect of interface anisotropy[2]. While, the T_{th} linearly increases with the increase of t_{Co} . Resultantly, complementary properties for H_c and T_{th} are realized by adjusting the t_{Co} , which can be utilized for an exchange coupled bi-layer in a heat assisted MRAM architecture[3]. Practical data stability was confirmed by a sufficient value of the activation energy E_a for magnetization reversal, estimated from a field sweep rate dependence of coercive fields. A typical value of E_a obtained by fitting the experimental results to the Sharrock formula[4] was 100 for a sample of $[Co(1.7 \text{ Å})/Pd(8.0 \text{ Å})]_{10}$. The magnetic properties can be also controlled with the repetition number N of Co/Pd bi-layer, as shown in Fig. 2(b). The monotonous increase of H_c and T_{th} can be associated with the crystalline structural change due to the increase of film thickness. Drastic enhancement of coercivity was also attained by adding a Pd under layer of 10 nm, while keeping a low T_{th} , that is $H_c = 2.1 \text{ kOe}$ (@ 23°C) and $T_{th} = 200^\circ\text{C}$.

Antiferromagnetic Exchange Coupling at Interface between Fe₃O₄(001) and Fe(001) Epitaxial Films.

H. Yanagihara, A. Ohnishi, J. Hagiwara, Y. Toyada, E. Kita
Applied Physics, Univ. Tsukuba, Tsukuba, Japan

Interlayer exchange coupling (IEC) between two ferromagnetic layers is important phenomenon for magnetic recording technologies. Most of the reported IEC systems consist of two ferromagnetic metal (FMM) layers separated by a non-magnetic metal (NMM) spacer. Depending on the NMM layer thickness and the material, the IEC changes its sign as well as the coupling energy, explained by the picture of RKKY interaction or spin-dependent quantum well state. In contrast, the hybrid structure of two ferromagnetic layers without the spacer mostly gives ferromagnetic coupling or no magnetic coupling, and the direct exchange type of antiferromagnetic coupling is hardly observed at the interface between two ferromagnetic layers. In this presentation we report the strong antiferromagnetic exchange coupling in Fe₃O₄/Fe(001) epitaxial layers.

All samples were grown by using a molecular beam epitaxy (MBE)[1]. Base pressure was better than 1×10^{-8} Torr. We used cleaved MgO(001) as substrates. Prior to the film growth, the substrates were annealed at 700 °C to remove surface contaminations. After decreasing the temperature to 280 °C, Fe₃O₄ layers were grown by reactive MBE technique with oxygen gas. During the Fe₃O₄ growth, the chamber pressure was kept as 4×10^{-6} Torr. The Fe layers were grown at room temperature and at the pressure of $\sim 10^{-8}$ Torr. We finally deposited 2 nm of Au thin films as a protection layer. The typical sample structure was MgO(001) substrate/ Fe₃O₄(13 nm)/ Fe (3 nm)/ Au(2 nm). In some samples we also inserted thin MgO(001) spacers to investigate a role of the interface on the coupling between Fe₃O₄ and Fe(001). We monitored the growth process with a reflection high energy electron diffraction (RHEED) technique. In order to estimate the interface exchange constant for the antiferromagnetically coupled layers, the magnetic moments of both Fe₃O₄ and Fe layers were designed to be the same. Magnetization measurements were carried out by using a commercial SQUID magnetometer and a magneto-optical Kerr effect (MOKE) at room temperature. A RHEED image during the Fe₃O₄ growth is shown in Fig.1. Up to the 13 nm thick of Fe₃O₄, the intensity of the specular reflection spot oscillates as a function of the growth time. The oscillation period corresponds to the thickness of 0.21 nm which is equal to a quarter of the unit cell of Fe₃O₄ ($a = 0.84$ nm). Therefore the interface of Fe₃O₄/Fe is expected to be quite sharp. The RHEED pattern of the Fe (001) is a little spotty but still suggesting a high crystalline quality.

Magnetization curve measured at room temperature is shown in Fig. 2. At the remanence state, the magnetic moment is nearly canceled out and the saturation field is larger than $H = 10$ kOe which is much higher than both of the Fe and Fe₃O₄ films. In addition, the saturated value of the magnetic moment corresponds to the sum of the two layers, indicating the existence of strong antiferromagnetic coupling between Fe₃O₄ and Fe at the interface. The estimated value of the coupling constant from the *MH* curve is $J \sim -2$ erg/cm². A thin MgO(001) spacer inserted between two ferromagnetic layers, reduced the coupling constants, in contrast to the case of γ -Fe₂O₃ / MgO/Fe(001) in which the strong antiferromagnetic coupling appeared with 0.6 nm of MgO and the direct exchange is ferromagnetic between γ -Fe₂O₃ and Fe(001) layers[2].

Although the mechanism of this direct-exchange type strong antiferromagnetic coupling is unknown at this point, the unique electronic structure of the Fe₃O₄ is crucial to reveal such a strong exchange coupling with a negative constant. According to a band calculation for Fe₃O₄, the DOS of conductive (or high temperature) state is half-metallic [3]. The minority state of the Fe₃O₄ has a Fermi surface and the majority one has a band-gap, suggesting that only the minority spin-state can

be mixed with the electronic state in Fe. The observed strong antiferromagnetic coupling might be understood along with this framework.

Preparation of Longitudinally Oriented CoCrPt Thin Film in GMR Head at Room Temperature.

X. Liu¹, Z. Li¹, S. Li¹, W. Shi¹, F. Wei¹, D. Wei², J. Cao³

1. Lanzhou University, Research Institute of Magnetic Materials, Lanzhou, China; 2. Tsinghua University, Key Laboratory of Advanced Materials Department and Engineering, Beijing, China; 3. Lanzhou University, Research Institute of Magnetic Materials(Now woking in INESC-Microsystems and Nanotechnologies (INESC-MN), R.Alves Redol 9-1, 1000-29 Lisbon, Portugal), Lanzhou, China

The CoCrPt thin films can be used as longitudinal magnetic recording media or bias layers which provides longitudinal field in spin valve GMR read heads. For its application in GMR heads, not only the crystallographic c-axis should lie in the film plane^[1], but also the room-temperature preparation of the thin film is required to match with the micro-electronic device processing procedure.

In this work, the CoCrPt film, CoCr interlayer and CrW underlayer were prepared by DC and RF co-sputtering method using the CM-18 magnetron sputtering system. It is difficult to obtain Cr (200) texture on amorphous SiO₂ substrate.

We find that the doping of W element is helpful to improve the film texture, and the CrW alloy film has (200) preferential orientation with tungsten's atomic percentage from 5 to 22%^[2]. The CoCrPt films deposited on the CrW underlayer with (200) texture show a (10-11) orientation texture, but not the expected (11-20) texture; and the angle between the [10-11] and [0001] crystal orientation is about 28°. A 5nm CoCr intermediate layer is helpful to achieve a good (11-20) orientation of CoCrPt films, just shown in Fig1. This may be interpreted that the additions of W enhance an expansion of Cr lattice, and it is not favorable for formation of CoCrPt (11-20) texture. The CoCr intermediate layer plays a role to modulate the misfits between both.

The relationships between with Pt atomic contents and magnetic properties are also studied, as shown in Fig 2. When the Pt content rises from 8.5% to 25%, the lattice constant a increases from 2.537Å to 2.617Å, and the in-plane coercivity H_c is enhanced from 950 Oe to 3200 Oe, which suggests that the in-plane magnetostriction with a residual compressive stress would enlarge the longitudinal coercivity.

It is well known that the coercivity is controlled by the magnetic anisotropy of materials, mostly the magnetocrystalline anisotropy, but sometimes the magnetostriction or magneto-elastic anisotropy is also important. The magneto-elastic anisotropy is a result of the residual stress in the material. For the CoCrPt multilayer, the stress may arise from internal and external mechanical stress: a thermal component owing to the difference in the thermal expansion coefficients of the CoCrPt thin film and CrW underlayer, and an intrinsic one resulting from the structure of the film, such as the lattice deformation.

In the simulation part of M-H loops, the magnetocrystalline anisotropy is determined by the law of approach to saturation; and the magneto-elastic anisotropy is analyzed by using micromagnetic model^[3]. For the film with 0.85 at% Pt, the simulated results are shown in Fig 3. It is found that the in-plane magneto-elastic effect with a residual compressive stress on the order of 1.14GPa tends to enlarge the longitudinal coercivity, squareness, and enduce the open-up between the tails of the longitudinal and perpendicular loops. The simulated in-plane M-H loop agrees well with the experimental results, the deviation of the perpendicular loop maybe due to other anisotropy contributions, such as shape and interface anisotropies^[4], which will be discussed in this work.

Molecular dynamics investigation on interfacial mixing behavior in transition metals (Fe, Co, Ni)- Al multilayer system.

S. Lee, H. Park, Y. Chung

Department of Materials Science & Engineering, Hanyang University, Seoul, South Korea

1. Introduction

It has been generally known that the interface between metals or metal and insulator had a critical role in the spin polarization of the junction, and the spin polarization for the tunneling characteristics is strongly dependent on the structural quality of the tunnel junction [1]. For MRAM application, ordered and uniform thin films less than 1-2 nm are essentially required for the coherency of the device. Accordingly, a considerable amount of interest has been focused on the chemically affinitive interface between transition metal and Al. In this work, the intermixing characteristic of the Co, Fe, and Ni on Al(001) substrate surface was quantitatively investigated by molecular dynamics simulation.

2. Calculation Methods

The position of the bottommost two layers for Al(001) substrate were fixed at 0 K. The temperature of other layers was set to 300 K. The incident energy of adatoms was set to 0.1 eV. The adatom was added at a distance of 20 Å from the substrate surface. The positions of the adatoms were randomly selected in the x, y-plane and the incident angles were set to be normal to the substrate. The MD time step was set to 1 femto-second(fs) and the system was fully relaxed for each additional adatom in the limit of 5 pico-second(ps).

3. Results and Discussion

The arriving Co, Fe, and Ni adatom was initially absorbed into a hollow site of the substrate surface layer (Fig. 1(a)). The Co, Fe, and Ni adatom then interchanged with the substrate Al atom below the surface, and the exchanged Al atom finally comes to reside in the hollow site on the Al surface (Fig. 1(b)). A time of only 1 ps was sufficient for the adatom to mix with the Al(001) surface at room temperature. Active surface alloying can be explained by the corresponding surface energy. Because the surface energy of Al(001) is much lower than that of Co, Fe, and Ni(001), the adsorbate films could be incorporated into the Al substrate. Moreover, the maximum local acceleration coming from the strong affinity between Al adatom and surface Co, Fe, and Ni atom was in the range of 2~4 eV. It can be reasonably expected that the adatoms could be considered as being mixed with the Al substrate in spite of the low adatom incident energy of 0.1 eV at room temperature. The mixing length and ratio for Fe was found to be the lowest value among these systems and the degree of mixing at the interface could be dependent on locally accelerated energy of each adatom near the Al substrate surface (Table 1). These results showed a similar tendency with that of an experimental report [2]. When Co, Fe, and Ni atoms are deposited on Al substrate up to 10 monolayers (Fig. 2), Fe atoms were incorporated into the substrate less than Co and Ni atoms. The origin of these phenomena can be found in the difference in cohesive energy. Moreover, it can be inferred that interfacial structure for Co/Al(001) was apparently revealed to be the most forming B2 structure (Fig. 2(a)), since perfect B2 structure indicates the structure in which the first atomic layer has 100 at% substrate atom - 0 at% adsorbate atom and the second atomic layer has 0 at% substrate atom - 100 at% adsorbate atom (mixing layers) repeatedly. Additionally, the interfacial structure for Co, Fe, Ni on Al substrate surface was quantitatively analyzed by pair correlation function (PCF).

1. Center for Condensed Matter Sciences, National Taiwan University, Taipei, Taiwan; 2. Department of Physics, National Taiwan University, Taipei, Taiwan; 3. Center for Nanostorage research, National Taiwan University, Taipei, Taiwan

I. INTRODUCTION

The antiferromagnetic interlayer coupling in layered magnetic system was observed in 1986 and suggested to be Heisenberg type. However, the observation of one-half of the saturation magnetization in Fe/Cr/Fe prevailed that another type of magnetic interlayer coupling might occur, which was named as biquadratic interlayer coupling. Generally speaking, the understanding of the nature of magnetic interlayer coupling between magnetic layers is important from both scientific and industrial application points of view. In this work, the coupling between two Co thin layers separated by a TiO₂ (X nm) layer with various thickness X is investigated. We observe an intermediate zero-magnetization state at some finite interval of applied field for the sample of X = 8. The nature of this intermedium state is proposed to be either the meta-stable state at which the direction of total moment is perpendicular to the applied field or an antiferromagnetic state with a pinned Co-layer by interface roughness.

II. EXPERIMENT

A series of Co/TiO₂(X nm)/Co trilayers with the thickness of amorphous TiO₂ spacer X varying from 2 to 10 nm are synthesized on TiO₂/Si(100) at room temperature. The thickness of the Co ferromagnetic layers was fixed to be 20 nm in all samples. For comparison, a sample with pure Co layer of 40 nm (X = 0) is also prepared. The field dependent in-plane magnetization (M-H) was measured at 300, 80 and 10 K with a physical-property-measurement system (PPMS, Quantum Design model 6000). Scanning electron microscopy (SEM, JEOL 6700) was used to determine the thickness of each layer. Atomic force microscopy (AFM) was utilized for the morphology of TiO₂(X)/Co(20nm)/TiO₂(10nm) layers. X-ray diffraction patterns of the samples were taken with PANalytical X'Pert PRO system.

III. RESULTS AND DISCUSSION

Figure 1 is the plot of M-H at 10 K for the samples with X = 0 to 10. It indicates that the value of the H_c for all samples get much larger than those measured at room temperature. Moreover, the sample of X = 8 show a very unusual behavior with two steps of zero magnetization at -10 Oe < H < -50 Oe and 30 Oe < H < 80 Oe. This two-step feature of X = 8 also occurs at 80 K within two narrower intervals of (-10 Oe, -40 Oe) and (30 Oe, 60 Oe). Figure 2 shows the plot of M-H for X = 8 at 80 K and 10 K with respect to the symbols of open and close squares. The occurrence of zero magnetization at a finite interval of field implies a meta-stable state between two field-parallel ferromagnetic states. Comparing our M-H results with that in NiFe/SiO₂/CoFe [8], the observed zero magnetization in our sample of X = 8 seems resemble to the AFM state under a single domain model. However, the major difference between our sample and NiFe/SiO₂/CoFe is that our two Co-layers are identical, meaning the same switching field for these two Co-layers; while NiFe and CoFe have very different coercivities of 25 Oe and 130 Oe respectively. Therefore, it is hard to explain why two Co-layers can form an AFM state without an additional pinned layer, unless the interface roughness provides a directional pinning mechanism. The other possibility is that when two coupled Co-layers rotate together, they are temporarily pinned at the direction perpendicular to the field, under the circumstance that the domain structure prefers a directional pinning force.

IV. CONCLUSION

A series of Co/TiO₂(X)/Co trilayers with X = 0 to 10 nm are synthesized. In the M-H curves at 10 and 80 K, the samples with X = 2 and 4 nm exhibit weakly coupled FM behaviors. As increasing the spacer layer thickness up to 6 nm, the percolation/pinhole effect disappears, and the interlayer coupling becomes dominating. Our salient finding is the observation of an intermedium zero-magnetization state for X = 8, which maybe associated with a meta-stable FM state with the direction of magnetic moment perpendicular to the applied field or an AFM state with one of Co-layers pinned by surface roughness.

Magnetite (Fe₃O₄) is a half-metallic ferromagnet with a high Curie temperature (860 K) that is expected to exhibit suitable properties for its implementation in spintronic devices [1-3]. In addition, the interest in spintronic structures based on magnetic oxides has increased recently [4]. MgO is a serious candidate as tunnel barrier because of the small lattice mismatch with the Fe₃O₄ (0.3%) electrode [5-7]. Nevertheless, the performance of Fe₃O₄-based magnetic tunnel junctions (MTJs) has been limited with scattered values and a maximum of ~14% at room temperature [8, 9]. Other tunnel barriers were not significantly better [10-12]. We believe that prior to application in real devices, the epitaxial growth of heterostructures with Fe₃O₄ and MgO should be further optimized. In this work we report the growth of epitaxial Fe₃O₄/MgO/Fe heterostructures on MgO (001) substrates by means of pulsed laser deposition (PLD) and their structural and magnetic properties.

We have grown epitaxial Fe₃O₄ and Fe thin films on single-crystal MgO (001) substrates by PLD using a KrF laser (248 nm). Stoichiometric polycrystalline Fe₃O₄ and MgO, and pure (99.99%) Fe targets have been used. All layers have been deposited in ultra-high vacuum (base pressure < 5×10⁻⁹ Torr) at substrate temperatures of 400 °C for Fe₃O₄ and between room-temperature (RT) and 400 °C for Fe and MgO layers. Individual thin films and Fe₃O₄/MgO/Fe heterostructures on MgO (001) have been characterized by X-ray diffraction (θ-2θ, ω scans, Φ scans, and reciprocal space maps) and X-ray reflectivity (XRR), high-resolution transmission electron microscopy (HRTEM) and VSM and SQUID magnetometry. Previous magnetoresistance and anomalous Hall effect measurements in our epitaxial Fe₃O₄ thin films have been published elsewhere [13, 14].

After optimizing the growth conditions and fully characterizing the single Fe₃O₄ and Fe layers onto MgO (001), we undertook the growth of the full Fe₃O₄/MgO/Fe heterostructures by PLD. HRTEM data (not shown here) demonstrate a high crystallinity of the MgO (001) tunnel barrier and sharp interfaces. XRR in a selected heterostructure where both MgO barrier and Fe counterelectrode have been deposited at RT are shown in Fig. 1. As can be seen from the fit the rms roughnesses are relatively low, ~0.2 nm, this being indispensable for future MTJs. The RT hysteresis loop in a sample grown in similar conditions, Fig. 2a, reveals an independent switching of both Fe₃O₄ and Fe electrodes, this also being required for tunnel magnetoresistance. The low field (500 Oe) temperature dependence of the magnetization of the same sample as seen in Fig. 2b displays a clear and sharp drop at the Verwey transition, T_V=115 K, demonstrating the high quality of the Fe₃O₄ layer.

We have produced high quality epitaxial Fe₃O₄/MgO/Fe heterostructures by PLD. To our knowledge, this type of heterostructure has not been grown before by PLD. Microfabrication of MTJs from these is in progress.

Introduction:

Recently, MgO-based MTJs have attracted much attention due to ultra high MR ratio and low RA products [1], which may make MRAM compatible in commercial applications. The synthetic antiferromagnetic (SAF) structure is extensively used in the fabrication of MTJs not only to get better thermal stability but also to avoid biasing effect on the free layer due to the stray field, especially when the pattern size is small [2],[3]. In this work, we investigated the thermal stability of the SAF structure, FM/Ru/Co₅₀Fe₅₀ in the top-type MgO-based MTJs, where Co₅₀Fe₅₀, Co₄₀Fe₄₀B₂₀, Co₄₀Fe₄₀B₂₀/Co₅₀Fe₅₀, and Co₅₀Fe₅₀/Co₄₀Fe₄₀B₂₀ were used as the FM layer. We found that orientations of FM and Ru influenced the thermal stability of the SAF structure.

Experiment results & discussion:

We prepared the full stack structure, consisting of substrate/Ta(20)/Co₄₀Fe₄₀B₂₀(3)/MgO(2)/FM(3)/Ru(0.9)/Co₅₀Fe₅₀(3)/IrMn(10)/Ta(40) (unit: nm), where (002) Co₅₀Fe₅₀(3 nm), amorphous Co₄₀Fe₄₀B₂₀(3 nm), amorphous Co₄₀Fe₄₀B₂₀(1.5 nm)/(110) Co₅₀Fe₅₀(1.5 nm), and (002) Co₅₀Fe₅₀(1.5 nm)/ amorphous Co₄₀Fe₄₀B₂₀(1.5 nm) were used as the FM layer. All films were deposited by using a magnetron sputtering system with a base pressure less than 5x10⁻⁸ Torr and an in-plane magnetic field of 80 Oe was applied during deposition to define the anisotropic direction. In our layer structure, the orientation of the FM layer can be tuned to amorphous, (002), or (110) direction while the MgO barrier remains (001)-orientated. The MTJ films were annealed for 1hr at various temperatures in a vacuum of 2 x 10⁻⁵ Torr under a magnetic field of 7 kOe. The magnetic and structural properties were measured by a vibrating sample magnetometer (VSM) and an X-ray diffractometer (XRD) using Cu K α radiation, respectively.

The strength of the RKKY coupling was correlated to FM/Ru interface, shown in Fig. 1, where CoFe/Ru showed larger coupling strength than CoFeB/Ru in the as-deposited state no matter which orientation CoFe was. However, after annealing at high temperatures, a remarkable drop of RKKY coupling was observed in (002) CoFe/Ru/CoFe interface with an antiferromagnetic layer, IrMn. The RKKY antiparallel coupling between adjacent CoFe layers was completely destroyed after 275 °C annealing, leading to a single biased pinned loop. For comparison, we prepared the similar structure without the IrMn layer, Ta(20)/CoFeB(3)/MgO(2)/CoFe(3)/Ru(0.9)/CoFe(3)/Ta(2) to examine how the annealing process affected the RKKY coupling. The strength of RKKY coupling with (002) CoFe as the FM layer is about the same even after thermal treatment, which strongly indicated that Mn diffusion was the main reason to deteriorate the antiferromagnetic coupling of CoFe/Ru/CoFe. The Ru spacer has been known as an effective diffusion barrier for Mn in the bottom-type SAF, in which CoFe is (110). To clarify if the orientations of FM and Ru affected the roles of the diffusion barrier, Ru, we prepared samples consisting of substrate/MgO(2)/FM(3)/Ru(15)/Ta(2). XRD results revealed that all samples showed strong (002) Ru intensity except for (002) CoFe as the FM layer in the as-deposited and annealed states. From TEM cross-sectional images, (002) CoFe/Ru/CoFe showed serious diffusion while other samples still kept sharp interfaces after 275 °C annealing. These results implied that Ru is no longer an

effective diffusion barrier for Mn with (002) CoFe and the thermal stability of SAF is strongly correlated to the orientations of FM and Ru.

Numerical Analysis of Heat Transfer Mechanisms Induced by Laser Heating in Far- and Near- Field HAMR Systems.

Heat-assisted magnetic recording (HAMR) systems utilize the phenomenon during which the magnetic properties of the recording media could be locally modified via heating (optionally, by an optical source in the near field) to temperature in the vicinity of the Curie value of the media material [1]. As a result, heat induced by the optical source can temporarily reduce the magnetic coercivity of high anisotropy material to a level attainable by the magnetic writing head, thus making it feasible to record on relatively small ultra-high anisotropy (and thermally stable) grains, consequently dramatically enhancing the areal density. In other words, in a HAMR system, certain transfer of heat at nanoscale is initiated by a source. This energy transport affects the physical properties of the recording media as well as the stability of the system. This paper will present of a numerical analysis of heat transfer mechanisms induced by laser heating in far- and near-field HAMR systems.

The absorption of electromagnetic waves by the recording media will induce heat due to the electron-phonon interplay. Thus, the thermal behavior of energy carriers, particularly, electrons and phonons should be considered during the numerical analysis for predicting the transient thermal transport in the magnetic media. The absorption process can be considered as a secondary source of energy inside the material. It is the secondary source, rather than the beam generated by the laser device, that will determine the dynamics of the irradiated material. A laser beam will be used to locally heat a magnetic thin film deposited on glass substrates spinning at 5400-7200 rpm with respect to the stationary light source. The beam penetration depth, which can be described with an absorption coefficient, depends on the ambient temperature. Therefore, the model will examine the penetration depth and the influence of the disk rotation on the transient temperature distribution and cooling effects. Figure 1 shows calculated temperature rise induced by different power levels. Figure 2 shows the effect of spinning frequency on convective cooling as compared to no cooling effects. The simulation model considers the laser beam to have an infinitesimal width that will vary from diffraction limited spot sizes ($\sim \lambda/2$) to 50-nm spot sizes in the near-field regime of the emitting source to address the heating issues associated with both HAMR setups: far- and near-field. The transient energy-balance equation solved is given by Expression 1, where the boundary condition on the heated boundary of the disk was assigned to assess cooling effects resulted by air-convective cooling and surface radiation, as given by Expression 2.

Micromagnetic studies of probe recording on magnetic nanocaps.

Recently fabricated Co/Pd nanocap arrays have been shown to be a promising candidate for the magnetic recording with densities above 1 Tbit/inch² [1]. We present results on micromagnetic studies of possibilities of the MFM tip recording on these nanostructures. For these studies a nanocap with 20 nm diameter and Co coated tips were used. First, we investigated the impact of different tip geometries and coatings onto the tip apex field. Further, the results of integrated recording simulations and the impact of the bias field on the stability of the magnetization direction in the nanocaps is discussed.

In order to estimate an impact of the material properties and a geometry of the magnetic coating on the stray field, produced by an MFM tip, full micromagnetic studies have been performed. Three ferromagnetic parameters (M_s , K , and A) of the layer and its shape were varied. The three different MFM tip coatings, corresponding to conical and pyramidal shaped tips were modelled. The results are grouped into parts describing the dependence of the stray field on the following parameters: film thickness, saturation magnetization, magnetocrystalline anisotropy, exchange constant. As a starting point, values from bulk hcp cobalt for the anisotropy ($K_1 = 4.5 \times 10^5 \text{ J/m}^3$, $K_2 = 1.5 \times 10^5 \text{ J/m}^3$), exchange ($A = 1.3 \times 10^{-11} \text{ J/m}$) and saturation magnetization ($M_s = 1.76 \text{ T} / \mu_0$) were taken. Our results show, that significant decrease in the anisotropy of the magnetic material does not influence the stray field of the tip, as the magnetization configuration is governed by the shape anisotropy of the high aspect ratio tips. In addition, Our data suggests that the exchange constant does not affect the stray field significantly within a realistic range of values. High values of the magnetization polarization can help to increase the stray field, but also introduce higher demagnetizing field, which degrades the performance of the tip. The impact of the film thickness on the stray field is an important parameter as it is the only feasible parameter that can be varied in the coating of the MFM tips if the magnetic material is not changed. It has a significant influence on the stray field generation. The strength of the field can be increased by the factor of two by changing the coating thickness from 4 nm to 7 nm. This dependence has been simulated for two tip shapes, the conical and the pyramidal shape with one covered facet.

Recording simulations for writing bits using an MFM tip were performed at 0 K using tip with a conical shape, with a bottom diameter of 10 nm and the coating thickness of 5 nm. A sphere size of 20 nm was chosen for these simulations, covered with a magnetic nanocap of 3.5 nm film thickness on top. For the cap to be thermally stable a magnetocrystalline anisotropy constant of $4.77 \times 10^5 \text{ J/m}^3$ was taken. This value corresponds to an effective energy barrier of 50 $k_B T$, which is required for magnetic storage application. The exchange constant and M_s were set to $1.0 \times 10^{-11} \text{ J/m}$ and 0.6 T, respectively. It was shown that a successful writing is only possible if unrealistically low anisotropy values for the cap material are assumed ($K < 10^4 \text{ J/m}^3$). This leads to thermally unstable media and thus is not suited for a practical storage application. Further simulations were made at 300 K that included thermal activation during the recording process. Thermal fluctuations assist in the recording process, but their effect was found to be too small to sufficiently lower the switching field of the nanocaps in order to be writable with a MFM tip. When writing on nanocaps using a locally applied magnetic bias field, it is possible to achieve selective switching of single nanocaps. The sum of the bias field and the field from the MFM tip exceeds the coercive field of the cap and

switching is possible. The optimal bias field for 20 nm caps at 300 K was found to have a magnitude of at least 0.22 T at an angle of 20 degrees with the film normal. The bias field has to reduce the energy barrier to 16 $k_B T$. Together with the reduction of the 10 $k_B T$ by the field of the tip this will lead to 6 $k_B T$. The target cap can be switched with the field from the tip within 1 ns by the help of thermal fluctuations. However, all caps in the array that are subject to the bias field have a relaxation time of about 10 microseconds. For 10^4 write cycles, the accumulated field exposure time, will be 10 microseconds which can give rise to adjacent track erasure. The way to overcome this problem is to increase the stray field strength of the tips by using thicker coatings or harder magnetic materials or employ local anisotropy reduction in the caps such as heat assisted magnetic recording.

Compositional dependence of g-factor and damping constant of GdFeCo amorphous alloy films.

T. Kato¹, K. Nakazawa², R. Komiya², N. Nishizawa³, S. Tsunashima², S. Iwata¹

1. Department of Quantum Engineering, Nagoya University, Nagoya, Japan; 2. Department of Electrical Engineering and Computer Science, Nagoya University, Nagoya, Japan; 3. Osaka University, Suita, Japan

Understanding of the magnetization dynamics in magnetic thin films is one of the recent critical issues to develop ultra-high speed magnetic sensors and memories. Ferrimagnetic rare-earth (RE) transition metal (TM) systems are known to be possible to compensate their angular momentums even at the RE-TM composition having a small saturation magnetization due to the difference of the g-factors between RE and TM sublattice magnetic moments. Thus, in such systems, divergence of the effective g factor at the angular momentum compensation point is expected, which is considered to contribute to the fast magnetization reversal. Recently, spin dynamics of GdFeCo [1] and GdCo [2] alloys were measured by pump-probe setup using a Ti sapphire fs laser, and the temperature dependence of the precessional frequency and effective damping factor has been reported. Here we report the magnetization dynamics of GdFeCo with various compositions measured by pump-probe method using an ultra short pulse fiber laser, which has characteristics of high power and excellent stability and is available recently. The compositional dependence of g-factor and damping constant of GdFeCo films has been evaluated and discusses together with the data taken by ferromagnetic resonance (FMR).

SiN (140 nm) / GdFeCo (30 nm) / AlCu (100 nm) / SiN (10 nm) / oxidized Si substrate was prepared by a magnetron sputtering method. Hysteresis loops were measured by an alternating gradient field magnetometer (AGM), and Kerr loops were checked by a polarized angle modulation method. Time-domain magnetization dynamics of GdFeCo was measured by pump-probe method using high-power fiber laser with a wavelength of 1560 nm, a pulse width of 1 psec, a maximum energy of 2 μ J/pulse, and a repetition frequency of 200 kHz. The pump and probe beams were focused onto GdFeCo films with a diameter of 60 μ m and 15 μ m, respectively. The probe beam was incident normal to the film surface and the polarization of the reflected probe beam was analyzed to monitor the perpendicular component of the magnetization, M_z , after the illumination of the pump beam. During the measurements, an external field of 2 kOe was applied 45 deg from the film normal direction. Ferromagnetic resonance (FMR) spectra at room temperature were obtained by an X-band spectrometer ($f \sim 9.15$ GHz) applying an external field parallel or perpendicular to the film plane.

Just as in the reported papers [1, 2], the time-domain magnetization dynamics of the GdFeCo film showed a sudden drop of the M_z component at delay time of $\Delta t \approx 0$, due to the laser induced demagnetization and a clear oscillation during the recovery of M_z , which allow to estimate effective g-factor g_{eff} and effective damping constant α_{eff} using a numerical calculation of Landau-Lifshitz-Gilbert equation [3]. Figure 1 shows the compositional dependences of precessional frequency f , g_{eff} and α_{eff} of the GdFeCo films obtained from the pump-probe data (closed circles). The precessional frequency took a maximum near the magnetization compensation point C_M , while the g_{eff} increases around the angular momentum compensation point C_A . This means that the increase of the precessional frequency f near C_M is due to the increase of the anisotropy field near C_M as well as the increase of g_{eff} near C_A . The compositional dependences of g_{eff} and α_{eff} are roughly described by a mean-field model [4]. The g_{eff} calculated by the mean-field model assuming the g-factors of Gd and FeCo to be 2.0 and 2.2, respectively, are drawn as a solid line in the figure. The calculated

g_{eff} shows a divergence at C_A , which is qualitatively consistent with the experiment. The g_{eff} and α_{eff} are also estimated from the FMR spectra, which are plotted in Fig. 1 as a comparison (open circles). The data from the FMR spectra agree well with those from the pump-probe measurement except for near C_M and C_A . The FMR method cannot excite the magnetization near the magnetization compensation point C_M because of the small magnetization. However the pump-probe measurement utilize the laser pulse to excite the spin system, so that it is possible to observe the oscillation of the magnetization and possible to estimate g_{eff} and α_{eff} .

Magneto-optical properties of nanometer crystal giant magneto-optical BiAlDyIG thin film materials post-treated by rapid recurrent thermal annealing (RRTA) method.

Q. Yang, H. Zhang, Q. Wen, Y. Liu

University of Electronic Science and Technology of China, Chengdu, China

BiAlDyIG film is an outstanding candidate for next generation magneto-optical (M-O) recording for its intense magneto-optical effect in shortwave length and proper uniaxial anisotropy property. However, the BiAlDyIG films prepared by sputtering or sol-gel method, after treating by common thermal annealing (CTA), have big crystal grains which are much larger than the size of magnetic domain, leading to a deformation of domains and decrease of signal-noise-ratio. Different methods have been applied to solve this problem, such as ions doping, annealing process optimizing, but the effect is very limited. Suzuki developed a rapid thermal annealing (RTA) method to treat the Bi-YIG films [1]. On this basis, a recurrent rapid thermal annealing (RRTA) method was developed by Dr. Zhang [2, 3]; it provides more conditions to optimize annealing technology comparing to RTA method; so the RRTA technology is a better choose based on the magnetic properties of the film, and ultra-fine crystal grains and small surface roughness can be obtained. Since the sol-gel method was successfully applied to prepare the bismuth substituted YIG film [4], the main difficulty now is how to fine the crystal grains and increase the signal-noise-ratio of the magneto-optical disk.

In this paper, the formula of BiAlDyIG film with giant magneto-optical effect within blue and violet light ranges is obtained. Based on the electric dipole transition model of four energy levels, the frequency spectrum of Faraday angle in blue and violet light ranges has been analyzed. According to theoretical results, the optimized stoichiometric compositions is $\text{Bi}_y\text{Dy}_3\text{-yFe}_5\text{-xAl}_x\text{O}_{12}$ with $x=0.8 \sim 1.2$ and $y=1.0 \sim 1.96$, and then high quality BiAlDyIG thin films have been prepared by a sol-gel method and post-treated by RRTA method. The effects of RRTA on Faraday angle of the films have been studied in detailed, a maximum Faraday angle of 4.9degree in the 450nm thickness film ($\text{Bi}_{1.96}\text{Dy}_{1.04}\text{Fe}_4\text{AlO}_{12}$) was obtained, which is about 2.0degree larger than that of the common thermal annealed (CTA) samples. These results are potentially helpful to improve the recording density and signal-noise-ratio of magneto-optical disk.

A magneto-optical (MO) recording material is candidate for high-density optically recording. Controlling the microstructure of the sputtering process and layer structure was found to be an effective way of managing the magnetic properties of the amorphous Rare earth-Transition metal film for memory devices. [1] The relationship between $M_s H_c$ and microstructure in recording layer is discussed, and it is found that the columnar structure is effective for tiny mark recording.

Coecivity of conventional magnetic recording material necessarily enhanced to solve the thermal stability for tiny mark recording. There are some solutions in recording materials but it is quite difficult to apply a huge magnetic field. Under these backgrounds, optically assisted magnetic recording, which is similar approach to MO high-density magnetic recording. This paper describes the prospect for a tiny domain stability using MO recording materials. Our approaches and results for ultra-high density recording are also discussed.

Feasibility of Perpendicular Magnetic Printing at 1 Tbit/inch²

T. Komine, T. Murata, Y. Sakaguchi, Y. Hosoya, N. Suhaimi, R. Sugita

Department of Media and Telecommunications Engineering, Ibaraki University, Hitachi, Japan

1. Introduction

As the high density hard disks (HDs) are in high demand, a method to realize the 1 Tbit/inch² HD with perpendicular magnetic recording has been investigated. A perpendicular magnetic printing, which can write servo signals with high speed, high accuracy and low cost, has been studied [1]. However, feasibility of the perpendicular magnetic printing for ultra-high density HDs has not been discussed yet. In this study, the feasibility is investigated by using the micromagnetic simulation.

2. Simulation method

Fig. 1 shows the simulation model used in this study. Table 1 shows the parameters of master and slave media for recording density of 0.25, 0.5 and 1 Tbit/inch². First, magnetic field distribution near the master media was calculated by using the three-dimensional finite element method (3D-FEM) when the printing field was applied in the perpendicular direction to the recording layer. Next, the magnetization distribution of the recording layer of the slave media was computed by the LLG equation with the magnetic field distribution calculated by the 3D-FEM [1]. It was assumed that the averaged anisotropy field H_k increased and the spacing between master and slave media became smaller as the recording density increased. The recording layer was composed of rectangular parallelepiped single domain particles whose size was $5 \times 5 \times 20$ nm³. The z-component calculated magnetization was compared with the z-component of ideal printed magnetization, and printing performance was estimated for each recording density. The printing performance is 100 % when printed pattern equals master pattern.

3. Results and discussion

Fig. 2 shows the magnetization distribution of the recording layer printed at the recording density of 0.25 and 1 Tbit/inch². The exchange constant was set to 1.5×10^{-7} erg/cm. The printing field was the same value as the coercivity H_c of the recording layer. It was reported in the previous study that in order to obtain the best printing characteristics, the printing field should be applied at much the same value as H_c . In Fig. 2, white and black areas represent $M_z/M_s = -1$ and 1, respectively. For 0.25 Tbit/inch², the magnetization was reversed at the contact area of slave and master media, and the initial magnetization was preserved at the non-contact area. The magnetization was not reversed at the center of the contact area, because the magnetic field at the center of the magnetic pattern of master has no in-plane component. For 1 Tbit/inch², the magnetization at the contact area was reversed all over, but the reverse region was enlarged owing to increase of the reversed particle by the exchange interaction. Fig. 3 shows the recording density dependence of maximum value of printing performance in each recording density. Although the printing performance slightly deteriorated at 1 Tbit/inch², the printing performance maintained 70%. This result shows that perpendicular magnetic printing at 1 Tbit/inch² is feasible.

4. Conclusion

The feasibility of perpendicular magnetic printing for ultra-high density HDs was investigated. As results, it was clarified that the printing performance does not deteriorate much and the perpendicular magnetic printing is feasible even at ultra-high density.

Off-Track Performance and Track-Edge Structure in Narrow Track Perpendicular Magnetic Recording.

K. Miura, T. Ogawa, H. Muraoka, H. Aoi, Y. Nakamura
RIEC, Tohoku University, Sendai, Japan

For the steady growth of track density, writing field fringing and fluctuated track edge structure have to be urgently improved. Particularly erase-band (EB) and/or track edge noise is becoming the most significant issue to narrower the track pitch. For this aim, recorded magnetization distribution at track-edges should be clarified and recording parameter must be optimized. We proposed accurate estimation of erase band width (EBW) [1]. From this measurement, accurate track edge position and EBW in off-track noise profile can be known. In this study, the location of track-edge noise was specified using the accurate EBW and magnetic write width (MWW). Influence of the EB on the off-track capability (OTC) versus track pitch, or the '747' performance, that governs attainable track density is also investigated.

A spindrive was used for the measurements of read/write properties with a hardware error rate tester (BES #M6) for the measurement of the 747 curves. A trailing-shield single-pole writer with a GMR reader was employed. The write and read width T_{ww} and T_{wr} were 160 nm and 100 nm, respectively. Coupled granular and continuous (CGC) perpendicular media [2] were tested, in which the continuous layer thickness was varied to control in-plane exchange coupling of the recording layer. Our precise measurement for track width and EB [4] was employed.

Measured off-track profile of media noise is shown in Fig. 1, in which the noise power was reduced to that for track width of 10 nm. First wide area was dc-erased, then one track erasure with opposite polarity dc current was carried out. In the figure, written track position and EB measured for 300 kfc/track is also depicted. The noise power from the EB was relatively large as the peak around the EB was observed. Since large medium noise emanated from the EB, the error rate performance at track-edge EB will be influenced by this EB noise.

Past analyses for the 747 curve presumed that the EB exhibited noise minimal [5], however above experiment rather large medium noise was observed. The 747 curves modeled according to the noise amplitude at EB using the calculation in which signal and noise are proportional to corresponding on-track width [5]. Fig. 2 schematically shows three assumptions. In the case of model #1 old data is noisy but EB shows no noise or quiet, in model #2 both EB and old data are noisy, and in model #3 the EB is noisy but no old data. The signal in the adjacent track always acts as cross-talk noise. Fig. 3 shows the 747 curves of the three models with experimental data. Because the measurement of 747 curve carried out under the condition of DC erase background, model #3 seemed to be the most suitable for the condition. The bump of 747 curve was notably seen only in the model #1, which indicates that the bump is observed in the case of the quiet EB. No bump appeared when EB generates noise.

Normalized 747 curves for three CGC media samples with various in-plane exchange couplings are shown in Fig. 4. The sample #1 had the thickest continuous layer, which has larger strong in-plane coupling, and its EB noise was large. While, in the case of medium #4 an obvious bump appeared, in which the continuous layer thickness is the thinnest among these samples. The noise of the EB suppresses the bump that improves OTC. Therefore, a large medium noise from the EB deteriorates attainable track density in the 747 performance. In this experiment it is revealed that the reduction of EB noise due to the optimization of in-plane exchange coupling in perpendicular magnetic recording is crucial for high track density recording.

Microwave assisted magnetization reversal and its thermal activation.

S. Okamoto, N. Kikuchi, O. Kitakami
IMRAM, Tohoku University, Sendai, Japan

Magnetic recording has been a fundamental technology in the present high density storage system. However, further increase of the recording density strongly requires a new advanced recording technique. Very recently, the microwave assisted magnetic recording (MAMR) has been explored both experimentally and theoretically [1-3]. In this study, we discuss the effectiveness of MAMR on the perpendicular magnetic recording and its thermal activation.

Dynamical magnetization motion and the switching field H_{sw} are calculated by using the Landau-Lifshitz-Gilbert (LLG) equation of motion without thermal fluctuation. The external reverse dc field H_{dc} is applied along the easy magnetization axis, and the sinusoidal ac field h_{ac} is applied perpendicular to H_{dc} . Taking into account the recording conditions of the present perpendicular recording, H_{dc} is applied in the form of a rectangular pulse with the rise time of 0.1 nsec and width of 1 nsec. A single spin nanoparticle with the anisotropy field H_k of 20 kOe is treated in this calculation. Fig. 1 shows the 2D mapping of magnetization switching under the conditions of $h_{ac} = 1$ kOe and the Gilbert damping $\alpha = 0.06$ as functions of $H_{dc}/H_{sw}(0)$ and the ac frequency f_{ac} , where $H_{sw}(0)$ is the static switching field for $h_{ac} = 0$. Note that the switching field H_{sw} significantly reduces along the condition of ferromagnetic resonance (FMR) indicated by the thick line in Fig. 1, suggesting that the magnetization switching is brought about by the absorption of microwave energy. The effective absorption of microwave energy excites precessional motion of magnetization, resulting in the magnetization switching when the precessing spin crosses over the energy barrier into the energy minimum. This mechanism is very similar to that for spin transfer switching (STS). It is easily understood that the MAMR strongly depends on α and h_{ac} . Figs. 2(a) and (c) show the minimum H_{sw} obtained at each condition as functions of α and h_{ac} , respectively, and Figs. 2(b) and (d) show the f_{ac} which gives the minimum H_{sw} shown in Figs. 2(a) and (c). It is clearly noticed that the smaller α effectively reduces the H_{sw} , and H_{sw} is almost saturated when the α is smaller than 0.02. On the other hand, the H_{sw} linearly decreases with increasing h_{ac} . Thus, it is concluded that MAMR is very effective to reduce the magnetic field necessary for saturation recording.

Since magnetic recording systems operate at the ambient temperature, thermal activation in the MAMR process should be taken into account as well as the conventional magnetic recording. For this purpose, we adopt almost the same idea developed for STS [4]. The effective Gilbert damping α_{eff} can be derived from the LLG equation under the FMR condition, and it can be described as $\alpha_{eff} = \alpha - (h_{ac}/H_{eff}) \times (1/\sin\theta_0)$, where $H_{eff} = H_{dc} + H_k$, θ_0 is the angle of the precessional motion of magnetization with respect to the easy axis under the assumption of the steady state. Finally, by using the relation of $\alpha T = \alpha_{eff} T_{eff}$ based on the fluctuation-dissipation theorem, the fictitious temperature T_{eff} is obtained. Thus, the widely used analytical expressions for thermal activation events, such as Sharrock formula, with T_{eff} instead of the actual temperature T can be applied to MAMR.

Prediction on the recording performance of exchange coupled composite media and discrete track media.

Y. Tahk, J. Lee, S. Lee

Storage System Division, Samsung Electronics, Suwon, South Korea

Recently, PMR media with dual or triple magnetic layer show feasibility of high areal density more than 250 Gbpsi. However, the conventional PMR head media system will be under lack of head field and difficulty in the control of grain size and coercivity of media. To satisfy these needs of head/media industry, ECC (Exchange Coupled Composite) media [1] and DTR (Discrete Track Recording) media have been proposed and studied. The basic idea of the exchange coupled composite media (ECC media or semi-ECC media) is to overcome the write head field deficiency by utilizing magnetostatic and exchange coupling field from semi-hard layer (semi-ECC case) or soft layer (ECC case) which switches at lower field. Discrete track media has grooves which separate tracks physically and magnetically. In this paper, comparison results of magnetic recording performance of both types of media through micromagnetic modeling will be shown and the synergy of two kinds of media concept.

In the present work, full 3D-micromagnetic simulations of the exchange-coupled composite media were performed to understand the read/write properties by changing interlayer exchange coupling strengths (Jex) between top magnetic layer and bottom magnetic layer, each layer's thickness, crystalline magneto anisotropy constant (Ku), and intergranular exchange coupling constant (A*) within each magnetic layer.

SNR result shows the semi-ECC media with weak exchange coupling is not desirable. To understand why the media with insufficient Jex do not have good read/write performance, dynamic M-H loop of each layer in the ECC media was compared. To configure out the switching mode of top and bottom layer, the magnetization of each layer was obtained separately. Obviously, top magnetic layer which has lower Hc is switched first and it makes magneto static field to help switch the higher coercive bottom layer. It should be noted that not sufficient exchange coupling gives kink in the hysteresis loop. Intuitively, these characteristics seem to be unique in ECC media.

However, in view of dynamic writing, this kind of big difference in Hc will result the transition time shift between top and bottom layer. For better understanding writing process of ECC type media, it will be helpful to check magnetic dynamics of each magnetic layer when writing current is changed from positive to negative. As shown in Fig. 1, ECC media with insufficient Jex have unclear transition shape and blurred write bubble. This kind of irregular transition shape is from the mismatch in transition timing. When the difference in the dynamic coercivity (Hc) of top and bottom magnetic layers is big, ECC media with weak interlayer exchange coupling strength do not give desirable SNR and need more exchange coupling strength.

ECC media and Semi-ECC media show maximum on-track SNR (single track). However, more likely ECC media is a little bit easier to squeeze compared with Semi-ECC media with higher Hc of top mag-layers. DTR was implanted to ECC media to get higher TPI performance. DTR (75 % Land : 25% Groove) with ECC media gives extra 2dB SNR gain at squeezed condition with side writing. When the groove portion is increased to 33 % or higher, SNR gain is less than 1 dB.

As shown in Fig.2, optimized triple magnetic layered semi-ECC media with Jex of about 0.6 erg/cm² shows higher SNR than the very strongly exchange coupled composite media like conventional media. Expected SNR gain from optimized ECC design compared with conventional dual-magnetic layer media can be higher than about 3 dB. However, the magnetic distribution such as Hk distribution and Jex distribution should be well evenly controlled. More enhanced semi-ECC

media will be possible breakthrough for the near future and the ultra high density recording above 600 Gbpsi can be realized by DTR combined with ECC media.

Attempt Frequency with Respect to Field Dependence and Modified Sharrock's Formula for Perpendicular Recording Media.

M. Igarashi¹, Y. Sugita²

1. Hitachi, Ltd., Kokubunji, Japan; 2. Tohoku Institute of Technology, Sendai, Japan

In the previous work using micromagnetic simulation, we have found that time-dependent remanent coercivities $H_{cr}(t)$ for perpendicular recording media (PRM) are well expressed by Sharrock's formula[1, 2] with assuming a constant value of the attempt frequency f_o as written by Eq. (1).

Here H_{cro} and t are the switching field of recording medium and the elapse time, respectively. The thermal stability factor K_β is defined by $K_u V/kT$, where K_u , V , and kT are the uniaxial anisotropy energy, the switching volume, and the thermal energy, respectively. However, f_o is theoretically written by Brown for a single magnetic particle as a function of the external field H as written by Eqs. (2, 3)[3].

Here $h(=H/H_{cro})$, γ , H_k , and α are the normalized field, the gyro-magnetic ratio, the magnetic anisotropy field, and the Gilbert damping constant, respectively.

In this study, f_o as a function of the external field and a modified Sharrock's formula for PRM are discussed.

A 64x64 array of uniform hexagonal prism grains with a diameter D of 8.5 nm and a height t_{mag} of 12.0 nm was used to simulate a medium. The separation between grains d was 0.5-10 nm. In each grain, the magnetization rotates coherently and interacts with the neighbors by a weak exchange coupling. The easy axis of each grain was perpendicular to the film plane with a distribution of 3 degrees. The value of the uniaxial perpendicular anisotropy energy K_u was 4.0 Merg/cm³ with a normal dispersion of $\pm 10\%$. A constant value of the attempt frequency f_o^* , K_β , and H_{cro} were determined in order that 12 points of calculated H_{cr} vs. t satisfy Eq.(1) simultaneously[2]. Also f_{oo} was determined from the 12 points of calculated H_{cr} vs. t using modified Sharrock's formula in which f_o is replaced by $f_o(h)$ in Eq.(1).

Figure 1 shows f_{oo} along with f_o^* as a function of the inter-grain exchange surface energy density w . Both f_{oo} and f_o^* decrease with increasing w initially below a critical value w_c , and increases above w_c . The reason for the initial decrease of f_o with w below w_c is that the increment of f_o by the magnetostatic coupling is being lowered by the exchange coupling with increasing w [4]. It should be noted that f_{oo} is clearly larger than f_o^* for each w . Table 1 shows the ratio of f_o^* to f_{oo}^* . Here f_{oo}^* is obtained from Eq.(2) using f_{oo} and the average field of 12 points of H_{cr} calculated. The ratios are roughly equal to 1.0. This means that the field dependence of the Brown's attempt frequency is valid for PRM and the modified Sharrock's formula should be used in strict discussions.

You should note that the values of f_{oo} discussed here for PMR are much larger than that for a single particle in Eq.(3). Inter grain exchange and magneto static couplings increase f_{oo} . This large f_{oo} is also consistent with the results of f_o in exchange coupled nano-chains [5] and graded media [6].

Introduction

After the technology transition from longitudinal to perpendicular magnetic recording (PMR) in hard disk drives, some classic recording methods attract lots of attention as a way to realize areal density of tera-bits per square inch. Patterned media, including discrete track media (DTM) [1], [2] and bit patterned media, is one of those methods. DTM, shown in Figure 1, consists of pre-patterned data tracks, or lands, separated by non-magnetic bands. DTM recording is considered the first comer among the novel recording schemes because it has higher affinity for conventional PMR than others. It has been recently reported that DTM realizes higher tracks-per-inch (TPI) than PMR [3].

Demagnetizing field distribution in recording layer

Figure 2 shows calculated demagnetization (demag)-field distribution along the cross-track direction. A 2-dimensional surface charge model was used, so the bit length was assumed to be infinite. The effect of the soft under-layer was taken into account as a perfect mirror image. The field strength was calculated at the through-thickness center and normalized by $4\pi M_s$ of the recording layer. The thickness of the recording and seed layers were assumed to be 16 and 10 nm respectively. For the sake of comparison between PMR and DTM recordings, we also assumed that the magnetic write width was 68 nm for PMR and the land width was 48 nm for DTM. It means that the PMR write width was 90% of the track-pitch (Tp) and the DTM land-width was 60% of Tp when Tp was 76 nm. The land-width/Tp ratio of 60% was based on a demonstration by TDK in 2006 [4]. It is clear that the demag-field of DTM is smaller than that of PMR recording layer. For example, the reduction rate was 7% at the track center and 60% at the off-track position of 30 nm. We have studied the effect of the reduction in the demag-field on some recording performances.

Influence on thermal Decay

The demag-field directly affects magnetization stability as well as the recording process. So we have computed a thermal decay process using micro-magnetic simulation. Figure 3 is the calculated signal deterioration depending on elapsed time after writing. Note that the temperature was set extremely high to accelerate thermal switching. It shows that the decay rate for DTM was much smaller than that for PMR in this condition. So DTM recording can be a thermally stable storage system.

Improvement in robustness against adjacent track erasure

Figure 4 indicates the so-called '747-curve' measured for PMR and DTM using spin-stand. Same media material and recording head were used for this measurement. The point at which off-track capability goes to zero can be interpreted as the adjacent write position where the target track vanishes. So the difference of the points between PMR and DTM means that DTM recording is more stable against track squeezing. Reduction in the demag-field at the land edge would be one of the major factors of this characteristic.

One significant limitation of magnetic recording is the super paramagnetic effect. This is the effect where ambient thermal energy can overcome the energy barrier within the media leading to possible read errors. Thermally induced magnetization reversal is also thought to be one of the major sources of adjacent track erasure [1]. As the write head passes close to the pre-written bits, the stray field of the writer lowers the energy barrier of the grains in the neighboring track grains. Any given track must sustain a large number of adjacent write operations. Therefore a weak cross-track stray field may destabilize the magnetization in adjacent grains over the life time of the disk.

Presented here are results of a study on the effect of the write head current on cross track erasure. This work also addresses some basic specifications for media design for maintaining grain stability whilst still providing the highest areal density possible. Focusing on exchange spring media (15nm thick, $J_s = 0.6$ T), where hard (7.5 nm, $K_h = 0.8 \times 10^6$ Jm⁻³) and soft (7.5 nm, $K_s = 0.2 \times 10^6$ Jm⁻³) phases are perfectly coupled, we calculate the energy barrier under the influence of the cross-track stray field using the nudged-elastic band method [2] coupled with a finite element micro magnetic approach [3-4]. The energy barrier is computed for a series of grains, as a function of the distance between the centre of one single grain (6 nm diameter) and the centre of the current track. For comparison the energy barrier of a single grain in zero magnetic field is found to be 45.3kBT300.

The stray field of the writer is non-uniform over the cross section of a grain in the adjacent track. In order to allow for the non-uniformity of the cross-track stray field a novel approach is applied. First the field of a 100 nm wide single pole writer with trailing shield is computed using the Flux3D FEM solver from CEDRAT. Then the energy barrier is calculated using a subdiscretized grain exposed to the non-uniform cross-track stray field. From the energy barrier we estimated the maximum accumulated field exposure time that is allowed before adjacent track erasure occurs due to thermal activation by computing the grain's lifetime with the Arrhenius Neel formula assuming an attempt frequency of 1 GHz. The maximum accumulated field exposure time can be converted into the number of passes the write head can achieve before cross track erasure.

In order to give an estimate of the track density, we assumed a maximum accumulated field exposure time of 1 second that corresponds to 109 passlines. Using this method the track density was calculated for different write currents. It is found that for a current of 45 mA erasure begins to occur at 88 nm from the center of the write head, leading to a track width of 176 nm. This is considerably wider than the write width that was calculated micro-magnetically to be 105 nm for a write current of 45 mA. The comparison with a single phase media shows that adjacent track erasure problem observed experimentally in composite media might be induced by high inter-grain exchange interactions in composite media. Neglecting inter-grain exchange interactions, a single phase shows an erasure distance (distance of the track center to first stable grain for a total field exposure time of one second) of 113 nm as compared to 88 nm for the composite media. For this comparison the anisotropy of the single phase media was carefully chosen so that both single phase and composite media showed the same write width.

For the exchange spring media, the erase distance decreases to 83 nm and 75 nm for write currents of 35 mA and 25 mA, respectively. The reduction of the write current to 35 mA decreases the write width to approximately 88 nm, however no bit is generated at 25 mA.

In summary, we present a method to estimate the track density taking into account thermally induced magnetization reversal and the influence of the cross-track write field. It is also shown that cross track erasure can be reduced allowing a much higher track density for a given writer by carefully controlling the write current.

Study of Overwrite Generated Twisted Transition Written by Trapezoid Shape Single Pole.

S. Hu, Z. Yuan, B. Liu

Data Storage Institute, Singapore, Singapore

A combination of single pole writer and soft underlayer was proposed to be a configuration for perpendicular recording system[1]. It was found later that there is a track edge erasure issue with the single pole writer when the single pole writer is driven by a rotary actuator. A trapezoid single pole writer was then proposed to solve such problem and maintain the track width at large skew angle. The trapezoid shape pole generates a same type of write bubble. The overall superposition of magnetostatic field of trailing edge transition at different off track positions could be different when the write field is in opposite polarity to the media previous magnetization. It can cause the transition to be twisted [2].

This work uses even harmonic ripple effect[3] to modulate the demagnetic field in the perpendicular medium and reveals the phenomenon of overwrite generated twisted transitions at different skew angles.

Experimental investigations were conducted on the Guzik spin stand v2202. Commercial perpendicular disks and trapezoid single pole writer-TMR reader were used in the test.

In this work, the bit length is selected to be equal to the write pole thickness. When the trapezoid single pole writer is at different skew angles, two regions (which are lined by the trapezoid single pole, track edges and the pre-recorded bit boundary) are varied. This is to enable the pre-magnetization of the two regions in the perpendicular medium to make different contribution to the transition shift.

Fig. 1 shows the ripple waveform maps at different skew angles ($0^\circ, \pm 10^\circ$). It is noticed that there are two peak regions in the ripple waveform, the left peak region and the right peak region in the ripple waveform map at skew angle 0° (Fig.1b). As the skew angle increases from 0° to 10° , the two even harmonic peak regions are inclined to one direction. And the left peak region becomes more obvious (Fig. 1a). It shows there is a big even harmonic peak in the left side along the cross track direction. When the skew angle changes from 0° to -10° (Fig. 1c), the ripple waveforms maps are inclined to the opposite directions and the shapes of the two ripple waveform peak regions are changed also. For the given test trapezoid single pole, taking skew angle $+10^\circ$ for example, the right slope side of the trapezoid type pole is aligned to the track right edge. So the pre-magnetization of the left region in the recording medium uncovered by the trapezoid pole will affect the total magnetic field obviously. It can cause transition twisted.

The averaged twisted read-back signal maps at skew angle -10° and $+10^\circ$ are plotted in Fig 2 and Fig 3 respectively. It is noticed that the twisted transitions shown in Fig 2 and Fig 3 are different as skew angle changes. Fig 4 and Fig 5 show the pulse period variations at different positions along the cross track direction at skew angle $\alpha = -10^\circ$. The pulse period time variations increase from track center (label “8u in”) to the track side (label “12u in”).

Reverse DC erase noise analysis on exchange coupled composite PMR media.

S. Hong, Y. Tang, X. Che
SISA, San Jose, CA

Recently, the exchange coupled composite (ECC) media has been proposed to decrease the switching field without degrading the media thermal stability [1]. Furthermore, micromagnetic modeling for the systematic study on the recording performance of ECC media showed that the soft magnetic layer with high saturation magnetization and low anisotropy field cause unfavorable adjacent track encroachment (ATE) performance in recording [2]. It is desirable to experimentally confirm this phenomenon in ECC PMR media. In this work, we applied the reverse DC erase medium noise measurement method to estimate DC noise in ECC media. We also discussed the role of negative nucleation field and writer's return pole field in the ATE performance of an ECC media structure. ECC and conventional PMR media with similar intermediate layer (IL), soft magnetic underlayer (SUL) structure, and different magnetic properties as shown in Table 1 were used in this study. Reverse DC erase medium noise and recording performances were characterized using tapered writer pole with $B_s = 2.3$ T and tunneling magnetoresistance (TMR) read head with a shield gap of about 35 nm.

Normalized rms noise for both ECC and conventional PMR media was shown in Fig. 1. Starting from AC erased background, we first DC erase in one direction then erase with opposite current in different magnitude. The noise after reverse current erasure was recorded. As the opposite erasure current increases, the conventional media showed that the noise power increased, peaked at about 9mA and decrease back to the low noise state. For ECC media, the noise also peaked at about the same current but the increase started earlier than for the conventional media. The earlier start of noise increase is consistent with the relatively low negative nucleation field (H_n) value of the ECC media. Another qualitative noise property difference between conventional and ECC media is at erase current above 30mA. Here ECC media noise increases with write current while conventional media noise does not. This may come from the return field of the write head. Since ECC media has lower H_n , partial erasure can occur at high write current.

Fig. 2 showed ATE quantified by averaging the percentage loss of the track average amplitude (TAA) over the 23 tracks with increased write current. The ECC media with lower negative nucleation field showed much higher ATE compared to conventional PMR media having higher negative nucleation field. Especially, ATE of ECC media is getting worse with increased writing current. One possible interpretation of this poor ATE on ECC media is that, comparing to conventional PMR media, partial erasure occurs at smaller write current as shown in the reverse DC erase noise experiment.

Introduction:

Reader instabilities are known to be a critical factor in the reader design, and are expected to increase in importance as we scale down the read sensor dimensions. Many techniques, such as transverse curves, have been developed to screen sensors with read instability. These techniques, however, offer limited insight on the origin of the instability. In this work the cross track profile of the sensor is used to characterize bad sensors. The advantage of this technique is higher spatial resolution in locating of the source of the instability. The spatial resolution is obtained by subjecting the sensor to the media non-uniform stress field, as described in the procedure below.

Experiment:

First a typical perpendicular media is prepared by recording low frequency pattern on a DC background. The sensor under investigation is then used to generate a readback map as shown in figure 1. A digital oscilloscope was used to collect very high resolution down track samples of the written pattern. The voltage color map is generated by consecutive readback at different off-track positions moving from OD to ID (the offtrack position shown in the x-axis of figure 1) at small, accurate crosstrack steps. The samples were aligned to remove trigger and sampling jitter. This non-destructible method allows for repeated captures with the same components. All the experiments were conducted on a spindown tester at 15000 rpm, and the tracks were written with a fast-rise time written current waveform a square wave pattern. The tester was also equipped with a servo system that helped limit the thermal drift through active piezo-compensation. Heads with known bias asymmetry were selected for the experiments.

Observation:

An asymmetry is observed in the captured read back voltage, and summarized in the cross track profile shown in figure 2. By changing the direction of the scan (moving from ID to OD), the crosstrack profile shows a noisy signature on the ID side of the profile (see figure 3).

The observed hysteretic (ID to OD in fig 2 versus OD to ID in fig 3) and noisy behavior (on the OD side) of the crosstrack profile (fig 2 and 3) is an indication of the existence of metastable state in the reader stack. As the weak region of the reader stack goes over edge of the DC region it is subjected to an additional bias field. This bias field changes the energy barrier for the metastable state leading to a stochastic response of the reader. Depending on the direction of the scan the metastable region of the sensor is subjected to a different history of media contribution to the bias field, which explains the hysteretic behavior of the track profile. Also a noise free crosstrack profile is expected if both the DC field and scan direction are combined to provide a stabilizing field (parallel to permanent magnet field) prior to the free layer approach to the center track. This allows to position the metastable region of the reader stack on the bottom side of stack. This conclusion is to be confirmed by micromagnetic modeling, and further experimental data with different preconditioning of the adjacent tracks, and will be included in the final publication of these results.

A Novel Algorithm for Unknown Periodic Disturbance Cancellation in HDD.

L. Hui^{2,1}, D. Chunling¹, W. Youyi²

1. MRC, DSI, Singapore, Singapore; 2. NTU, Singapore, Singapore

Identification of disturbance frequency in HDDs is usually done in so-called track -following control where the read/write head is positioned at the center of a particular data track. Many methods such as AIM [1] and AFC have been used for this case. In this paper, we propose a new method to cancel periodic disturbances.

In order to cancel the periodic disturbances, we suppose to build a new signal which is approximate to the disturbance and add its opposite value to the command signal.

Fig.1 shows the system structure of proposed algorithm, where u , y and w are the system command, output and disturbance respectively. The internal model principle can effectively estimate the dominate frequency of PES, which is also the fundamental frequency of disturbance; while a disturbance rebuild use the frequency estimation and a signal generated by the difference of output pass through the inverse of plant and input signal to rebuild a signal which approximates the periodic disturbance. Then the disturbance will be cancelled by adding the opposite value of this signal to the command signal.

The frequency estimator derived from the discrete time representation of AIM has a form of $X1(k)=2\cos(\omega T)X1(k-1)-X1(k-2)+Kf(1-\cos(\omega T))(e(k-1)-e(k))$, $X2(k)=2\cos(\omega T)X2(k-1)-X2(k-2)+Kf/\omega \sin(\omega T)(e(k-1)-e(k))$, $\omega(k-1)=\omega(k)-Ke*(e(k)*X1(k))/(X1(k)^2+X2(k)^2)$.

When using AIM method, the frequency estimation will not converge in the first stage if we choose a larger estimation gain Ke in order to achieve high converge speed. While this problem will be solved if we know the range of the disturbance frequency and add an estimator band constrain. Fig.2 shows estimation of disturbance with frequency of 700 Hz and 2000 Hz. When adding 200 Hz and 500 Hz lower band constraints respectively, the frequency estimation speeds have significant advanced.

For disturbance which has single frequency component, magnitude and phase estimation can be achieved by two parameters estimation [2].

Suppose $\Theta(k)=[\alpha(k),\beta(k)]$, which are the coefficients of $\cos(\omega T)$ and $\sin(\omega T)$, then $\Theta(k)$ can be estimated by the recursive least squares parameter adaptation algorithm:

$$\Theta(k)=\Theta(k-1)+F(k)*\Phi'(k)*\varepsilon(k)/(1+\Phi'(k)*F(k)*\Phi(k)), \quad F(k+1)=1/\lambda*[F(k)-F(k)*\Phi(k)*\Phi'(k)*F(k)]/(\lambda+\Phi'(k)*F(k)*\Phi(k))$$

where $\Phi(k)=[\cos(\omega kT), \sin(\omega kT)]'$ and $\varepsilon(k)=P^{(-1)}y(k-1)-u(k-1)-\Theta(k)\Phi(k-1)$, the signals have one sample time delay to achieve plant inverse causal.

For the disturbance which has harmonic components, the frequency estimation in [1] can also get the fundamental frequency. And the similar method can be used to estimate the parameters corresponding to the several main harmonic components. For disturbance which has not harmonic components, there should be several frequency estimators to get the different frequencies, and estimate the corresponding parameters similarly.

Another idea for dealing with multi-frequency case is that each signal can be represented by a non-linear function. Then a 3rd order polynomial function which has coefficients of each power time-varying can approximately represent the signal according to Taylor's series. In this case, following the above method, we just replace the parameter by $\Theta(k)=[a0(k),a1(k),a2(k),a3(k)]$ and $\Phi(k)=[1,kT,(kT)^2,(kT)^3]$, and there is no need to estimate the disturbance frequency.

To support the algorithm, several simulations have been done. Fig.3 reflects the effect of the proposed algorithm dealing with the single frequency disturbance which has phase change and mag-

nitude change. Fig. 3 shows that this method can efficiently cancel the disturbance with single frequency. Fig 4 shows results to deal with multi-frequencies disturbance cases. In Fig 4 (a), a harmonics disturbance was added in the simulation, while Fig 4 (b) presents a disturbance which has several different harmonics and non-harmonic frequency cases. Result presents that the 3rd order polynomial fitting method has better performance and robustness to observer noise. The reason for those phenomena is that for multi-frequencies cases, one frequency estimator can not bring out all the frequencies in disturbance. Even the estimator number is sufficient, it can not be sure that estimator can converge to a different frequency. So the signal fitting will not perform well. The future work will be conducted to improve and verify the multi-frequency estimation method and investigate how the time delays affect on the performance.
