Magnetic tunnel junctions (MTJs) of a highly textured MgO insulating layer recently attracts great attention due to the giant tunnel magnetoresistance (TMR) and accelerates the realization of magnetoresistive random access memory and related spintronic devices. In 2005, Anelva Corporation included a 0.4nm Mg layer at the bottom interface to reduce the resistance-area and enhance the TMR ratio of MgO-based MTJs for read head application in hard disk [1]. Then, several groups have attempted to probe the change of MgO layer texture or interfacial condition due to Mg doping and generally attribute the enhancement of TMR to improved texture of MgO layer or less oxidized surface of the bottom electrode [1-3]. Here, we fabricate MTJs with/without 0.4 nm Mg doping and the corresponding TMR ratios are respectively 4% and 0.76%. We utilize the complex-impedance (CI) and -capacitance (CC) spectra to characterize the texture of MgO layer and interfacial conditions of a MTJ [4]. The CC spectra of MTJs without and with 0.4nm Mg doping are shown in Figure 1(a) and (b). The Cole-Cole type CC spectra, [imaginary part of C^* (C'') in y-axis vs. real part of C^* (C') in x-axis], of MTJs w/wo a 0.4nm Mg discontinuous layer consist of several arcs and a rising tail. We observe the capacitance contributions of arcs decline, but the arcs in high- and low- frequency region respectively are suppressed and grown up for MTJs due to 0.4 nm Mg doping. With the microstructure analysis by high-resolution transmission electronic microscopy (HR-TEM) images [the inset of Figure 1(a)], an equivalent circuit model (ECM) is utilized to analyze the CC spectra of MTJs w/wo 0.4 nm Mg doping. The ECM includes the Debye-type dielectric relaxation contributions (arcs in a Cole-Cole diagram) to describe the relaxation behavior of the textured and amorphous MgO layer as well as a resistance to represent the Schottky barriers at CoFe-MgO interfaces with imperfectly blocking property [5]. The analyzing results indicate the relaxation frequency of textured MgO contribution increases due to 0.4 nm Mg doping, which suggests the improved texture of MgO layer. Meanwhile, the analysis of corresponding CI spectra shows an increase and a decrease of the interfacial resistance and capacitance for 0.4nm Mg doping MTJs. Furthermore, the dc bias dependent CI spectra have also been performed. The CI spectra of MTJs with 0.4nm Mg doping show little sensitivity to dc bias, but the spectra of MTJs without 0.4nm Mg doping are very sensitive to dc bias. The result indicates the interfacial defects are also suppressed due to 0.4nm Mg doping. The results of CI and CC spectra are also consistent with the x-ray reflectivity and HR-TEM results. We conclude the CI and CC technique could be convenient and useful to understand the mechanism for enhancement of TMR due to the Mg doping.

1. Instituto de Investigaciones en Materiales, Universidad Nacional Autonoma de Mexico, Mexico City, Mexico; 2. Fisica Aplicada, Universidad de la Habana, Havana, Cuba; 3. Ciencia de los Materiales, Instituto Politecnico Nacional, Mexico City, Mexico

We present an electron paramagnetic resonance (EPR) study in powder samples of the monoclinic phase of FeNbO₄, in the X-band (8.8-9.8 GHz). For all the temperatures, the EPR spectrum showed a single Lorentzian line attributable to Fe³⁺ ions. A contribution of Fe²⁺ ions in the EPR spectra was detected at low temperatures, originating a broadened signal as compared with the spectrum at room temperature, as shown in Fig. 1.

This behavior can be ascribed to a strong magnetic dipolar interaction between Fe²⁺ and Fe³⁺ ions, as proposed in a study [1] based on the effects of (Fe²⁺/Fe³⁺) mixed valence on the electrical conductivity of FeNbO₄, and confirmed by magnetic susceptibility measurements as a function of temperature.

In addition, we present in this work two techniques based [2-7] on modulated microwave absorption, to obtain further knowledge on this material: magnetically-modulated microwave absorption spectroscopy (MAMMAS) and low-field microwave absorption (LFA). In the MAMMAS measurement, the sample is subjected to a constant dc field, and its microwave absorption behavior is obtained as a function of temperature [2,5-7]. LFA refers to the microwave absorption around the zero DC field range ($-1000 \text{ Oe} < H_{\text{DC}} < +1000 \text{ Oe}$), in an otherwise typical electron paramagnetic resonance setup [2-4,7]. MAMMAS response suggests that the dominant magnetic exchange is antiferromagnetic at low temperatures ($T < 140 \text{ K}$), and has a paramagnetic behavior for high temperatures. The LFA spectra showed straight lines with positive slope and non-hysteretic traces. The profiles obtained by plotting the slope vs. temperature of the LFA line are similar to those detected by the MAMMAS technique, giving evidence that both types of measurement show the same processes of absorption. We conclude that both experiments are therefore a manifestation of the sample response to electromagnetic excitation, in which the same fundamental physical processes take place. The MAMMAS response has an experimental correlation d^2P/dH^2 , with the derivative of the modulated microwave power absorption. A discussion on the usefulness of these techniques in the investigation of a wide range of magnetic materials is also presented.

IrMn/CoFe-SiO₂/IrMn exchange coupled nanostructure for high frequency applications.

N. N. Shams, M. Rahman, Y. Wu, C. Lai

Materials Science and Engineering, National Tsing-Hua University, Hsinchu, Taiwan

Introduction

An approach to increase the performance of integrated inductor used in high speed electronics in the GHz regime is to apply a magnetic film on top of and/or below the RF coil to enhance and confine the magnetic flux. A combination of anti-ferromagnetic (AFM) and ferromagnetic (FM) with high anisotropy, K_u , exchange biased (EB) film is promising candidate as high magnetization ($4\pi M_s$) and large anisotropy field, H_k can be achieved due to exchange coupling[1]. But FM metallic films possess low electrical resistivity which increase the eddy current loss. To overcome this, granular film consisting of FM nanograins embedded in a nonmagnetic insulating matrix, is one of good options. However, the granular films deposited in the presence of oxygen environment causes lower magnetization due to the oxidation of the FM grains[2]. In this research, we introduced a novel AFM/FM-granular nanostructure to improve the magnetic properties of the granular film along with high electrical resistivity. Our EB system is CoFe nanograins embedded into the SiO₂ matrix, which is sandwiched by two IrMn layer. This kind of EB granular nanostructure may be interesting not only for exploring its application in high frequency but also for studying EB nanostructure.

Experimental procedure

The IrMn/FeCo-SiO₂ nanostructure is deposited by sputtering without any substrate heating. The film structure is Ta(3nm)/NiFe(8nm)/Ir₂₀Mn₈₀(12nm)/Co₉₀Fe₁₀-SiO₂(50nm)/Ir₂₀Mn₈₀(12nm)/Ta(3nm). The Co₉₀Fe₁₀-SiO₂ granular layer is deposited by co-sputtering of Co₉₀Fe₁₀ and SiO₂. A Ta/NiFe seed layer is used to promote IrMn(111) texture and Ta overcoat resists surface oxidation. Finally the samples are annealed at 210°C for 30 min in a magnetic field of 1.5kOe to promote EB. The magnetic properties are measured by VSM. The microstructure is characterized by TEM, and the resistivity at room temperature is obtained from a standard 4-point measurement. The resonance frequency is characterized by a network analyzer up to 3 GHz[3].

Result and discussion

The plane-view TEM image(Fig.1) reveals that the CoFe nanograins are separated by amorphous SiO₂. The average grain size is about 5-6 nm. M-H loop of IrMn/CoFe-SiO₂/IrMn, granular film without any AFM layer, CoFe-SiO₂ and the continuous, IrMn/CoFe/IrMn film has been shown in the Fig. 2(a), 2(b) and 2(c) respectively. It is found that both anisotropy field, H_k and exchange field, H_{ex} is increased in granular EB system. The value of $H_k = 80$ Oe and $H_{ex} = 50$ Oe for IrMn/CoFe-SiO₂/IrMn nanogranular film which is even higher than the corresponding value of continuous IrMn/CoFe/IrMn film ($H_k = 50$ Oe and $H_{ex} = 37$ Oe). The value of H_k of CoFe-SiO₂ is only 13Oe. The FM domain size is determined by the competition between the random field due to the interfacial AFM-FM interaction and FM-FM exchange interaction [4, 5]. The presence of nonmagnetic SiO₂ may reduce the exchange interaction between the FM-FM interaction, thus favoring the formation of smaller FM domain, larger net random field, and larger H_{ex} . Table.1 shows the high frequency data for the aforementioned three kind of films. The highest resonance frequency, f_{res} of 2.5 GHz is achieved for the IrMn/CoFe-SiO₂/IrMn film which is even higher compared to the CoFe nanoparticles embedded in SiN matrix [2]. This high f_{res} originates from high H_k of EB granular system. The high quality factor ($Q=\mu''/\mu''$) of IrMn/CoFe-SiO₂/IrMn film may be due to the less eddy current loss as the EB granular film possesses a high resistivity of 132 $\mu\Omega$ -cm while it is 7.5 $\mu\Omega$ -cm for EB continuous film.

Conclusion

We have prepared the EB granular nanostructure simply by sputtering which is convenient to achieve nanostructures over large area compared to the self-assembled synthetic materials or lithography. The EB CoFe-SiO₂ system is found as a superior candidate to the ordinary granular films or continuous FM films. In addition, further modification of any characteristics can be possible by tuning the ratio of CoFe and SiO₂ in the EB CoFe-SiO₂ granular nanostructure.

Permeability of ferromagnetic microwires composites/metamaterials and potential applications.

L. Liu, L. Kong, G. Lin, S. Matitsine

Temasek Lab, National University of Singapore, Singapore, Singapore

1. Introduction

Glass-coated ferromagnetic microwires filled composites or metamaterials attract great interest recently due to high effective magnetic permeability and high loss in radio wave and microwave frequency, and negative permeability due to the ferromagnetic resonance [1, 2]. Since the conductive microwires are coated with a layer of glass which prevents induced current flow across microwires in contact, the materials with microwire inclusions are expected to have low effective permittivity as compared to composites with bare conductive wires. Such feature makes glass-coated ferromagnetic microwires suitable inclusions for many applications, such as EM shielding materials, high attenuation materials and double negative meta-materials (DNM), etc. The microwires fabricated with Taylor-Ulitovsky method comprised an inner metallic core covered by Pyrex-like coating [3].

The aim of this study is to investigate magnetic properties of microwires for high attenuation applications, and also to explore the possibility to use microwires to make Meta-materials of negative refraction index. Anisotropic static magnetic properties are first measured with vibrating sample magnetometer (VSM). Next, the high frequency permeability of composites with regularly distributed microwires is obtained by the impedance method and coaxial line method from 1MHz to 10GHz. Finally, the properties of proposed composite/metamaterials, such as reflectivity and effective permittivity and permeability are evaluated with the theoretical and numerical calculations.

2. Magnetic properties of microwires

CoFeNiSiB amorphous ferromagnetic microwire with various inner and outer diameters was provided by Microfir Tehnologii Industriale. The static magnetic properties along and perpendicular to the axis of microwire were measured with SMI/MEDIA 880 vibrating sample magnetometer (VSM). Both Agilent N5230A vector network analyzer (VNA) with APC-7 coaxial transmission line and Agilent E4991A impedance analyzer were employed to measure the permeability and permittivity. The coaxial line sample has an inner diameter of 3mm, outer diameter of 7mm, and a thickness of about 2mm. The same samples were used in the impedance measurement with impedance analyzer with 16454A magnetic materials test fixture. The measured permeability of composites with 14.2% by volume of microwire ($D=13.3\mu\text{m}/d=9.4\mu\text{m}$) is plotted in Figure 1.

3. Reflectivity and effective refraction index of microwire composites/metamaterials

Reflectivity of a layer of metal-backed composite is calculated using transmission line theory in VHF (Figure 2). Anisotropic composite of microwires oriented along the magnetic field achieves broadband attenuation ($>10\text{dB}$). The thickness of this composite is about 0.4% of the wavelength. However, only incident wave with H-field along the wire axis can be absorbed. The cross polarized component is totally reflected due to high conductivity of microwires.

Composites with regularly or randomly distributed long conductive fibers have negative effective permittivity when frequency is close to the resonance of the included fiber [4]. The negative effective permittivity of metamaterials with containing conductive fibers along E field is obtained from a unit cell by HFSS (a commercial finite element solver) calculation, and verified with free space measurement. Combining the long conductive fibers with microwires may result in metamaterials with both negative permeability and permittivity within certain frequency band. Negative refraction index may possibly be obtained from such kind of metamaterial. However, it is quite difficult to

reduce the dielectric and magnetic loss of the metamaterial due to the intrinsic resonance phenomena of the inclusions.

Microwave permeability of amorphous FeCoSiB thin films on flexible substrates.

M. Han, Y. Ou, L. Deng, J. Xie, H. Lu

State Key Laboratory of Electronic Thin Films and Integrated Devices, University of Electronic Science and Technology of China, Chengdu, China

Soft magnetic thin films with high frequency permeability have found many applications, such as magnetic heads in magnetic recording industry, magnetic cores for planar inductors in power electronics [1], high frequency magnetic sensors [2], et al. However, most reported magnetic thin films were deposited on rigid substrates (silicon or glass), only few films have been deposited on flexible substrates[3]. Magnetic thin films on flexible substrates can find applications in electromagnetic devices, such as electromagnetic wave absorbers, RF noise filters. Compared to bulk magnetic materials, the permeability of magnetic thin films are much larger within GHz range if assuming they have same saturation magnetization and same anisotropy field [4]. The Landau-Lifshitz (L-L) equation is the one frequently used to describe the dynamic behavior of magnetization vector under the alternative changing magnetic field. The solved L-L equation describing the intrinsic permeability dispersion of film with an in-plan anisotropy can be expressed as:

$$\mu_r = \gamma M_s / (\gamma H_k + i\alpha\omega) \times \{1 + \omega^2 / [(\gamma H_k + \gamma M_s + i\alpha\omega)(\gamma H_k + i\alpha\omega) - \omega^2] + 1\} \quad (1)$$

, where γ is the gyromagnetic factor, α is the damping constant, ω is the angular frequency. When the effect of eddy current on permeability is considered and on the basis of the Maxwell Equations, the permeability dispersion should obey the following equation [5]:

$$\mu_r = \mu' - i\mu'' = \mu_i [(1-i)\delta/t] \times [e^{(1+i)t/\delta} - 1] / [e^{(1+i)t/\delta} + 1] \quad (2)$$

, where μ_i is the permeability from equation (1), t is the thickness of film, δ is the skin depth ($\delta = [2/(\omega\sigma\mu_0\mu_i)]^{1/2}$). If eddy current effect is ignored, then equation (1) applies. In this contribution, we will report the microwave permeability of amorphous Fe₆₆Co₁₇Si₁B₁₆ thin film deposited on the Mylar flexible substrates and show the difference when the eddy current is included or not. XRD technique has been employed to show the as-prepared films in amorphous state. The thickness of film was measured to be 610 nm by SEM. The morphology of film has been investigated by AFM. Magnetic hysteresis loop was taken on a vibrating sample magnetometer (VSM). The coercivity was found to be about 11 Oe, see Fig. 1(d). In order to measure the frequency dependence of permeability, the as-prepared film on flexible substrate had been cut into stripes and been wounded into a so-called laminated insulator ferromagnetic on the edge (LIFE) structure [6], see Fig. 1(a). The LIFE structure was then inserted into the coaxial line of an Agilent Vector Networks Analyzer (8720ET). If we assume that the eddy current effect on permeability is ignored for our samples, then the intrinsic permeability can be calculated from the measured effective permeability of thin film composites based on the following equation [6]:

$$\mu_{fi} = 1 + (\mu_{eff} - 1) / V_f \quad (3)$$

, where V_f is the volume fraction of film deposited, μ_{fi} is the intrinsic permeability of film, μ_{eff} is the effective permeability of thin film composites. The measurement frequency range is of 1 GHz - 10 GHz. After the intrinsic permeability (μ_{fi}) values have been extracted, then we use equation (1) and (2) to simulate the intrinsic permeability dispersion spectra to see whether the eddy current effect is playing a role. The measured spectra and the fitted spectra (the dotted lines) are shown in Fig. 1(b). The experimental data agree better with the ones with eddy current effect considered than the ones without considering eddy current effect, but their difference is not significant. More calculation results will be shown that when films thickness is larger than 2 μm , the eddy current effect on their permeability dispersion spectra will be significant, as the one shown in Fig. 1(c), and then Equation (3) can not be used for LIFE structures. According to the fitting results in Fig. 1(b), the

ferromagnetic resonance (FMR) frequency is found to be about 3.2 GHz. The damping constant (α) is fitted to be 0.15.

Magnetic damping in exchange-coupled IrMn/ CoFe multilayers for microwave applications.

R. Jiang¹, C. Lai¹, J. Lin²

1. Department of Materials Science and Engineering, National Tsing Hua University, Hsinchu, Taiwan; 2. Centre for Condensed Matter Sciences, National Taiwan University, Taipei, Taiwan

The antiferromagnetic/ ferromagnetic exchange-coupled multilayers (MLs), uniquely combining with ultimate saturation magnetization ($4\pi M_s$ up to 1.8-2.4 T), ultrahigh anisotropy field ($H_K > 200$ Oe), enhanced ferromagnetic resonance frequency ($f_{\text{res}} \sim 5$ -10 GHz), and suitable real-part permeability ($\mu' \sim 50$ -200), have been proposed to be promising candidates for the magnetic-integrated radio-frequency (RF) devices [1, 2]. Moreover, the importance of another phenomenological parameter, magnetic damping (α), which tends to broaden the FWHM of imaginary-part permeability (μ'') and results in the deterioration of quality factor ($Q = \mu' / \mu''$), in magnetic thin films for RF devices has been clarified [3]. In general, the magnetic damping can be split into two fundamentally different channels: (i) Gilbert-type damping, which leads to a dissipation of energy into the lattice, and (ii) two-magnon scattering, which leaves the energy in the spin subsystem by scattering into magnons with nonzero wave vector ($k \neq 0$) [4]. From the viewpoints, understanding the magnetic relaxation processes in RF devices has become the essential challenges. In this work, the α -value and its effect on high-frequency characteristics of $\{\text{IrMn}/\text{CoFe}\}_N/\text{IrMn}$ MLs for RF devices were studied, by FMR technique and the Landau-Lifshitz-Gilbert (LLG) equation, for the first time.

The magnetic damping α , was extracted as a function of CoFe thickness (t_{CoFe}) in $\text{Ir}_{20}\text{Mn}_{80}$ (8 nm)/ $\text{Co}_{50}\text{Fe}_{50}$ (t nm) bilayers (BLs), Fig. 1(a). The observed $4\pi M_s$ of CoFe was 2.0 T. The H_K increased linearly with $1/t_{\text{CoFe}}$, implying a characteristic of the surface effect. The interfacial exchange strength was 0.35 erg/cm², obtained from the hysteresis loop shift ($J_{\text{CoFe}} = M_s \times t_{\text{CoFe}} \times H_{\text{EX}}$). The α -value was first decreased with decreasing t_{CoFe} , and reached the minimum value of 0.012 when t_{CoFe} was set to be 30 nm. Since the Gilbert-type damping was a material-dependence parameter and relatively small (one to two order of magnitude smaller than two-magnon scattering), the significant change of α -value was considered mainly resulting from two-magnon scattering, correlated to the lattice defects in the volume of CoFe. Therefore, it was reasonable to expect that the two-magnon scattering was decreased with decreasing t_{CoFe} , because the volume part of CoFe was the dominating contribution. However, the α -value increased again for further decreased t_{CoFe} (< 30 nm). This increase originated from the local fluctuations of exchange-coupling at the IrMn/ CoFe interface, which provided an extra mechanism for dissipation of the coherent precession mode, due to the increased ratio of interface/ volume at small t_{CoFe} . To tune the H_K and f_{res} , we prepared the $\{\text{IrMn}/\text{CoFe}(t \text{ nm})\}_N/\text{IrMn}$ MLs with different t_{CoFe} ($t_{\text{CoFe}} = 200, 100, 50, 25, 10$ nm) and stacking number N ($N = 1, 2, 4, 8, 20$), while keeping the total thickness of CoFe at 200 nm. The α -value in MLs showed the similar trend to the BLs: first decreased with decreasing t_{CoFe} , and then increased for further decreased t_{CoFe} (< 50 nm), as shown in Fig. 1(b). Moreover, it was noticed that the minimum t_{CoFe} with the minimum α -value was shifted from 30 nm to 50 nm, and the minimum strength of α was varied from 0.012 to 0.049, which suggested that other energy dissipation mechanisms may exist, i.e., the local fluctuations of exchange-coupling at the extra CoFe/ IrMn interfaces, and inter-layer-coupling between each CoFe, when compared to the IrMn/ CoFe BLs.

Table I summarized the main characteristics of $\{\text{IrMn}(8 \text{ nm})/\text{CoFe}(t \text{ nm})\}_N/\text{IrMn}$ MLs for RF devices. The $4\pi M_s$, H_K , and H_{EX} were obtained by VSM. The α -value was determined by the out-of-plane angular dependences of the resonance field (H_R) and linewidth (ΔH_{pp}) of a FMR spectra

(9.53 GHz). The f_{res} , μ' , and the frequency that satisfied the Q of 5 and 10 (f_{Q5} and f_{Q10}), were analyzed by the LLG equation. The relatively low f_{Q5} and f_{Q10} were observed, though the f_{res} and μ' were extremely high. These results suggest that the reduction of α -value in exchange-coupled MLs is the key factor in obtaining preferable properties for RF devices, in addition to high H_K , optimum combinations of different parameters are important to meet the GHz requirements.

Synthesis of nano-crystalline barium hexaferrite using a reactive co-precipitated precursor.

M. Montazeri-Pour, A. Ataie

School of Metallurgy and Materials Engineering, University of Tehran, Tehran, Iran

Barium hexaferrite magnetic material has significant potential for applications such as permanent magnets and microwave absorbing coatings, because of the adequate combination of high Curie temperature, high coercivity and chemical stability. Fine $\text{BaFe}_{12}\text{O}_{19}$ (BaM) particles also exhibit suitable properties for perpendicular magnetic recording media. Among the non-conventional synthesis methods, co-precipitation is the most attractive due to simple operation and ease of mass production.

The use of a mixed solvent is a new approach in nano-materials synthesis and processing. Diethylene glycol ($\text{O}(\text{CH}_2\text{CH}_2\text{OH})_2$) is a polar solvent which is miscible with water at any ratio, and the addition of diethylene glycol to water can easily change its physicochemical properties.

The objective of the present study is to investigate the influence of using 75% volume diethylene glycol as a co-solvent along with water on the characteristics of BaM processed by co-precipitation method.

$\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$ and $\text{BaCl}_2 \cdot 2\text{H}_2\text{O}$ with Fe/Ba molar ratios of 11 and 12 were dissolved in water/diethylene glycol mixture with volume ratio of 1:3. Two prepared solutions were co-precipitated by the addition of NaOH with OH^-/Cl^- molar ratio of 2 at room temperature. The final pH value of solutions reached to about 11.3. The co-precipitated samples were washed by distilled water, dried and annealed at various temperatures for 1 h. The samples synthesized with Fe/Ba molar ratios of 11 and 12 are named for brevity "DEG11", "DEG12", respectively.

XRD, SEM, DTA/TGA, FTIR and TEM techniques were used to evaluate the products characteristics.

DTA/TGA traces for the DEG11 and DEG12 samples in Fig. 1 show the exothermic peaks attributed to the formation of barium hexaferrite at 695°C and 614°C, respectively. The temperature of 614°C is one of the lowest temperatures has been reported for formation of barium hexaferrite via co-precipitation route. XRD patterns of the DEG11 sample after annealing at various temperatures showed that barium hexaferrite phase became the major phase at 700°C, but some un-reacted intermediate phases like barium monoferrite and hematite still observed. Remaining of barium monoferrite phase up to 900°C in this sample demonstrated surplus barium present in it. XRD results also showed that barium hexaferrite fully formed in DEG12 sample after annealing at 650°C. It can be concluded that using diethylene glycol as a co-solvent along with water significantly lower the formation temperature of magnetic phase.

The presence of the characteristic absorption bands of diethylene glycol in the FTIR spectrum of DEG12 co-precipitated precursor indicated that diethylene glycol acted as capping agent and stabilizer, limiting particle growth and prohibiting agglomeration.

From SEM images, the mean particle size of the DEG12 sample annealed at 800°C was measured as 70 nm. Barium hexaferrite crystallites with mean size of 35 nm, which is approximately consistent with size obtained from XRD line broadening technique, could be seen in TEM image of DEG12 sample annealed at 700°C (Fig. 2).

Development of anisotropic NdFeB bonded magnet MAGFINE with high heat resistance for automobile use.

K. Noguchi, C. Mishima, H. Matsuoka, Y. Honkura
Aichi Steel Corporation, Tokai-shi, Aichi-ken, Japan

Anisotropic NdFeB bonded magnets called MAGFINE which has the possibility of the world's strongest bonded magnet with a maximum energy product of 199 kJ/m³ are interested in application for household appliance and automobile use[1]. Conventional small motor has been new designed to achieve down sizing of 50% and weight reduction of 40% by using MAGFINE magnet[2], and the new motor called MF motor has been launched in 2005. In the case of automobile use, the high stability under 150 – 180 deg.C is required for the magnet in the long term. To improve the durability properties, the authors have studied on the improvement of the coercivity force and rectangularity on the raw magnet material, and the additional magnet coating to avoid from oxidation.

The newly developed MAGFINE has higher coercivity force of 1,430 kA/m than that of 1,114 kA/m compared with conventional one with heat resistance of 100 deg.C. Moreover, the protection coating against oxidation by O₂ and H₂O under exposure atmosphere was newly developed. In the result of this additional coating, the newly developed MAGFINE showed the smaller flux losses than that of the conventional one on the exposure test under 150 deg.C after 1,000 hr. It is obvious that the newly developed MAGFINE has high heat resistance properties of 150 deg.C and has possibility for automobile use like as window motor, blower motor and so on.

Effects of conventional HDDR process and the additions of Co and Zr on anisotropy of HDDR PrFeB-type magnetic materials.

J. Han, C. Wang, H. Du, H. Chen, Y. Yang
School of Physics, Peking University, Beijing, China

The hydrogenation disproportionation desorption recombination (HDDR) process is well known as an effective way for producing anisotropic Nd₂Fe₁₄B-type magnetic powders. Pr₂Fe₁₄B-type alloys are comparable in terms of their intrinsic magnetic properties and phase relations with the advantages of a much lower spin reorientation temperature, so HDDR process is tried to prepare anisotropic Pr₂Fe₁₄B-type magnetic powders. It has been showed that both anisotropic ternary Pr-Fe-B and Pr-Fe-B powders with alloying additions can be prepared by appropriate solid-HDDR process. However, the origin of anisotropy is unclear till now. Gutfleisch et al. found that there exist intermediate phase Fe₃B and Pr(Fe,Co)₁₂B₆ in the solid disproportionated products of Pr_{13.7}Fe_{80.3}B₆ and Pr_{13.7}Fe_{63.5}Co_{16.7}Zr_{0.1}B₆ alloys, respectively, and the amount of intermediate phase is related to the degree of anisotropy in the final products. However, they did not find the above two intermediate phases in the corresponding conventional disproportionated products. Cannesan et al. observed the intermediate phase Pr(Fe,Co)₁₂B₆ in the Pr_{13.7}Fe_{63.5}Co_{16.7}Zr_{0.1}B₆ conventional disproportionated products processed at 860°C and above, and advanced the intermediate phase may play a role in inducing texturing on further treatment of the materials. The present authors also investigated the preparation of anisotropic ternary Pr₁₃Fe₈₀B₇ powders using solid-HDDR process and mechanism on the formation of anisotropy. It is found that the degree of anisotropy in HDDR Pr₁₃Fe₈₀B₇ materials is related to the disproportionation time, and the short disproportionation time is helpful for obtaining high anisotropy while long disproportionation time will lead to isotropic powders. At the same time, according to investigation for the disproportionated products of Pr₁₃Fe₈₀B₇ alloys, no other phases except PrH₂, Fe and Fe₂B are found, and the origin of anisotropy is found to be related to the early rod-like disproportionation microstructure.

To further understand the preparation of HDDR anisotropic Pr-Fe-B powders and how the anisotropy is formed. The effects of conventional HDDR process and the alloying additions on the anisotropic Pr-Fe-B magnetic powders are further investigated in the paper. The results show that the degree of anisotropy in conventional HDDR Pr₁₃Fe₈₀B₇ materials decreases monotonically with the prolonging disproportionation time, and short conventional disproportionation time is helpful for preparing highly anisotropic Pr₁₃Fe₈₀B₇ material. However, it is notable that the degree of anisotropy in conventional HDDR Pr₁₃Fe₈₀B₇ materials is smaller than that in solid HDDR Pr₁₃Fe₈₀B₇ materials under the same disproportionation time. At the same time, it is found that the addition of Co and Zr may make the HDDR PrFeB materials have higher anisotropy compared with the HDDR pure ternary PrFeB materials under the same HDDR process, but their degree of anisotropy will also decrease monotonically with the prolonging disproportionation time, and be close to zero when the disproportionation time is greater than 20 h. Based on this, the origin of anisotropy is discussed by XRD investigation for the disproportionated products of the above alloys. The results show that the origin of anisotropy in HDDR Pr-Fe-B materials with the addition of Co or Zr may differ from that in HDDR pure Pr₁₃Fe₈₀B₇ materials, and the former maybe from the residual “Pr₂(Fe,Co,Zr)₁₄B” nucleus while the latter is not. Finally, it is also found that HDDR Pr-Fe-B materials with Co or Zr can obtain high magnetic properties even if the high desorption temperature is used, and this shows the addition of Co and Zr may make the HDDR process more relaxed.

Magnetic properties and structure for bonded magnet using Dy-F coated NdFeB powder.

M. Komuro, S. Yuichi

Energy and Environment Laboratory, Advanced Research Laboratory, Hitachi, Japan

Introduction

Bonded and sintered NdFeB magnets are now commonly used for various magnetic circuits including motors, generators, medical instruments, hard disk drives and measuring devices because of their high magnetic performance. In the field of HEV motors, a high temperature resistance is necessary for the NdFeB magnet. One of the weak points for the NdFeB bonded magnet is large temperature dependence of coercivity. In order to compensate the weak point, large coercivity NdFeB bonded magnet has been produced for magnet motors by adding with Dy to NdFeB. Recently, the grain boundary diffusion process using Dy₂O₃ or DyF₃ powders was reported for NdFeB magnets with 2mm thick (1-3). According to the report (3), the Dy distribution width around the grain boundary was almost comparable to the width of the Nd-rich grain boundary phase. In this paper Dy-F solution has been used for surface diffusion process instead of the Dy₂O₃ or DyF₃ powders for NdFeB MQ powder. The magnetic properties and composition distribution was evaluated in this study.

Experimental

Rare-earth fluoride solution was synthesized from a rare-earth acetic acid and fluoric acid. An alcohol was used as the solvent for the Dy-F solution without corrosive elements. The MQ powders were mixed with the Dy-F solution. The Dy-F solution on the magnet powder was dried in a vacuum chamber, leading to the growth of the Dy-F layer with grain diameter of 20nm. The magnet powder coated with 2.6wt% Dy-F layer were heated at 973K for 2 hours for the diffusion. The Dy-F coated powder was compacted at 353K after mixed with resin. The size for bonded magnets was 10x10x7mm³. Demagnetization curves were measured by VSM (Vibration sample magnetometer) after magnetizing at the magnetic field of 3.2 MA/m. The temperature dependence of magnetic properties was measured by VSM under the air. SEM observation was performed for a cross-sectional specimen by S3500N with a wavelength-dispersive X-ray spectroscopy.

Results

The cross sectional view near powder surface was observed as shown in Fig. 1. The coated layer can be seen at the surface of powders shown in Fig. 1(a). The composition distribution was measured for F and Dy for the same position of Fig. 1(b) and (c), respectively. Both F and Dy were detected at the surface of powders, resulting Dy-F layer was grown on the surface of MQ powders. F and Dy were not seemed to exist homogeneously in the powders in Fig. 1.

The temperature dependence of residual magnetic flux density (Br) and coercivity (iHc) are shown in Fig. 2. The coercivity for Dy-F coated bonded magnet is larger than that for the non-coated bonded magnet between 293K and 473K. Coercivity difference between Dy-F and non-coated bonded magnets becomes larger with rising temperature. On the other hand, Br for Dy-F coated bonded magnet is slightly smaller than that for the non-coated bonded magnet below 373K. Above 423K, Br for Dy-F coated bonded magnet is larger than that for non-coated bonded magnet. The average temperature coefficients between 293K and 473K for iHc and Br were -0.22%/K and -0.08%/K for Dy-F coated bonded magnet. The corresponded values for non-coated bonded magnet were -0.30%/K and -0.16%/K, respectively. Compared these values, the temperature coefficient for iHc and Br were reduced by 26% in each 50% compared with these for the non-coated bonded magnet. The both values of iHc and Br for Dy-F coated bonded magnet showed higher than these for the non-coated bonded magnet above 423K. The higher magnetic properties for the Dy-F coated bond-

ed magnet are thought to be caused by the oxidization prevention by the coated layer and increase of anisotropy by Dy.

Effect of grain size and hot-deformation temperature on texture in die-upset Nd-Fe-B magnet.

H. Kwon, J. Lee

Materials Science and Engineering, Pukyong National University, Busan, South Korea

1. INTRODUCTION Magnetic performance of a permanent magnet is determined by a combination of high coercivity and high remanence, together with a good squareness of the demagnetisation curve. For the high remanence and good squareness a good alignment of magnetic grain (good texture) is essential. One of the most common techniques being used to align the Nd₂Fe₁₄B grains in the Nd-Fe-B material is a die-upset or hot deformation technique. The die-upset technique is usually applied to the melt-spun Nd-Fe-B material. The melt-spun material is hot-pressed first in to a high density compact, and then the compact is subjected to the die-upset to cause a severe deformation. The die-upsetting leads to a good texture of the nanocrystalline Nd₂Fe₁₄B grains with their easy magnetisation c-axis is parallel to the compression direction. The formation of texture is known to take place via the stress-induced preferential grain growth. Considering the texture formation mechanism, the grain size before the die-upsetting is believed to play an important role. In the present study, the hot-pressed compacts with various grain sizes ranging from several tens of nm to several hundreds nm were prepared, and then they were subjected to a die-upsetting. The effect of grain size in the hot-pressed compact on the texture in die-upset magnet was investigated. The effect of hot-deformation temperature on the texture in die-upset magnet was also investigated.

2. EXPERIMENTALS

Starting alloy of Nd_{13.5}Fe₈₀Ga_{0.5}B₆ was prepared by an arc-melting using high purity elements. The prepared alloy was melt-spun with surface velocity of 40 m/s. The obtained ribbon was briefly milled for 5 min using a mortar and pestle, and the powder was compacted by a hot pressing. The hot pressing was carried out under vacuum at various temperatures in a closed die for 2 min with pressure of 1 T/cm². The hot-pressed compact was subsequently die-upset with strain rate of 5.8 × 10⁻³/sec in an open die at various temperatures to achieve height reduction of around 75 %. Texture in the die-upset magnets was evaluated by a magnetic means. A cube (2 × 2 × 2 mm³) was cut from the die-upset sample. Demagnetization curve was measured along the direction parallel and perpendicular to the pressing direction using a VSM at room temperature after pre-magnetizing with pulsing field of 50 kOe. The obtained demagnetization curve was corrected to compensate the demagnetizing field of the specimen using a proper correction factor. Texture in the die upset sample was evaluated using the ratio of $M_{(//)}/M_{(\perp)}$, where, $M_{(//)}$ and $M_{(\perp)}$ are the magnetization at 7 kOe along the directions parallel and perpendicular to the pressing direction, respectively. Microstructure of the material at various conditions was examined using HRSEM and TEM.

3. RESULTS AND DISCUSSION

In order to prepare the hot-pressed compacts with different grain size, the powder material was hot-pressed at different temperatures. The compacts hot-pressed at 750 °C, 770 °C and 820 °C had grain size of around 50 nm, 100 nm and 200 nm, respectively. These compacts with different grain size were die-upset at 750 °C and the texture in the die-upset samples was examined. Fig. 1(a) shows the effect of grain size in the hot-pressed compact on the texture in the die-upset sample. It appears that the die-upset sample from the hot-pressed compact with fine grain size (50 nm) exhibited much higher texture with respect to the samples from the hot-pressed compacts with coarser grain size (100 nm and 200 nm). Meanwhile, the effect of die-upset temperature on the texture in the die-upset sample was investigated using the compact hot-pressed at 770 °C, and the results were shown

in Fig. 1(b). It appears that the sample die-upset at lower temperature of 700 °C had lower texture, so did the sample die-upset at higher temperature of 900 °C. The samples die-upset at modest temperature range from 750 °C to 850 °C showed much higher texture. The dependence of texture in the die-upset samples on the initial grain size and hot-deformation temperature is to be explained based upon the dissolution and precipitation mechanism.

Fig. 1. Effects of (a) grain size and (b) die-upsetting temperature on the texture in the die-upset Nd_{13.5}Fe₈₀Ga_{0.5}B₆ sample.

Boron enriched stoichiometric melt spun $\text{RE}_2(\text{Fe,Co})_{14}\text{B}$ -based alloys with enhanced coercivity.

I. Betancourt^{1,2}, T. Schrefl¹, H. Davies¹

1. Department of Engineering Materials, University of Sheffield, Sheffield, United Kingdom; 2. Departamento de Materiales Metalicos y Ceramicos, Instituto de Investigaciones en Materiales, Universidad Nacional Autonoma de Mexico, Mexico, Mexico

Hard magnetic alloys are the precursor materials for fabrication of permanent magnets, which can be used for a very wide range of applications including: loudspeakers, levitation systems, actuators, motors and recently, biomedical devices (cardiac valves, magnetic catheters, dental care) [1,2]. In particular, nanograined hard magnetic rare earth (RE)-iron-boron-based alloys have attracted considerable scientific and technological interest over the past 20 years due to their outstanding combination of magnetic properties, which can be tailored by suitable control of phase constitution and its relative grain sizes. In this work we present B-enriched, stoichiometric, melt spun (NdPr)FeB alloys with intrinsic coercivity iH_c values above 1000 kA/m and energy densities between 120-140 kJ/m³, studied by XRD, TGA, VSM and micromagnetic simulations.

The alloy series: $\text{Nd}_2\text{Fe}_{82}\text{B}_6$, $\text{RE}_{12}\text{Fe}_{82}\text{B}_6$, $\text{RE}_{12}\text{Fe}_{78}\text{B}_{10}$, $\text{RE}_{12}\text{Fe}_{76}\text{Zr}_2\text{B}_{10}$ and $\text{RE}_{12}(\text{Fe}_{0.9}\text{Co}_{0.1})_{76}\text{Zr}_2\text{B}_{10}$ (with $\text{RE}=\text{Nd}_{0.75}\text{Pr}_{0.25}$) was obtained by a devitrification annealing of initially fully amorphous alloy ribbons produced by chill block melt spinning technique with a roll speed of 30 m/s. X-ray diffractograms for all the alloy series indicated only 2/14/1 peaks. Magnetic Thermogravimetric Analysis (MTGA) was used to determine the Curie temperature (T_c) for the whole alloy series, showing the following results: $\text{Nd}_{12}\text{Fe}_{82}\text{B}_6$ (311 °C, in accord with the reported value of 312 °C for the 2/14/1 phase [1]); $\text{RE}_{12}\text{Fe}_{82}\text{B}_6$ (307 °C); $\text{RE}_{12}\text{Fe}_{78}\text{B}_{10}$ (307 °C); $\text{RE}_{12}\text{Fe}_{76}\text{Zr}_2\text{B}_{10}$ (282 °C) and $\text{RE}_{12}(\text{Fe}_{0.9}\text{Co}_{0.1})_{76}\text{Zr}_2\text{B}_{10}$ (350 °C).

Demagnetising J-H curves for all the compositions are shown in Fig.1, for which an increasing trend of iH_c is observed with the composition sequence showed in the Figure caption, starting at 713 ± 7 kA/m for the reference $\text{Nd}_{12}\text{Fe}_{82}\text{B}_6$ alloy to a maximum of 1176 ± 31 kA/m for the $\text{RE}_{12}(\text{Fe}_{0.9}\text{Co}_{0.1})_{76}\text{Zr}_2\text{B}_{10}$ ribbon sample. The remanence J_r exhibited a monotonous diminishing tendency after Pr substitution, from 0.98 ± 0.02 T down to a minimum of 0.83 ± 0.01 T for the Co-containing alloy. The energy densities values observed were > 120 kJ/m³ for all the cases, with a maximum for the B-enriched alloys of 140 ± 4 kJ/m³ corresponding to the $\text{RE}_{12}\text{Fe}_{76}\text{Zr}_2\text{B}_{10}$ ribbon sample.

Micromagnetic simulated J(H) curves are shown in Fig.2 for the (a) $\text{Nd}_2\text{Fe}_{82}\text{B}_6$ (b) $\text{RE}_{12}\text{Fe}_{82}\text{B}_6$ and (c) $\text{RE}_{12}\text{Fe}_{78}\text{B}_{10}$ alloys. Although consistently higher iH_c values were obtained compared with the experimental curves (due to the Brown paradox), the coercivity enhancement after Pr substitution is clearly manifested, as a consequence of the higher anisotropy constant K_1 used (with $K_1 = 0.75K_1(\text{Nd}) + 0.25K_1(\text{Pr})$). On the other hand, a further increase in iH_c for the B-enriched alloy is observed by assuming the presence of small precipitates (presumably Fe_3B) in a volume fraction lower than the limit detection of the XRD analysis (i.e. < 4%). These small crystallites are afforded by the excess of B, which is segregating outside the 2/14/1 grains, as it is suggested by the constant T_c observed for the $\text{RE}_{12}\text{Fe}_{78}\text{B}_{10}$ alloy respect to the stoichiometric $\text{RE}_{12}\text{Fe}_{82}\text{B}_6$.

Therefore, considerable enhancement of iH_c in stoichiometric melt spun alloys is feasible by means of excess of B content (10 at%) preserving high J_r values and thus, energy densities > 120 kJ/m³. High T_c values are also attainable by means of partial Fe substitution by Co.

2. Materials Science, Zaporozhye State University, Zaporozhye, Ukraine

Abstract

A correlation between microstructure, phase composition, microhardness and magnetic properties of NdFeB magnets alloyed by carbon, titanium and copper has been investigated. Permanent magnets with nominal composition of Fe₇₆Nd₁₆B₈ were produced and heat-treated according to standard technology. It was found that coercivity of magnets produced from alloy with Cu addition is considerably rise and reached value 15 kOe. It was shown that permanent magnets have considerable level of properties at minimum content of carbon fibre. The coercivity of 15,8 kOe and remanence of 10-11 kGs were reached after heat treatment. The bonded magnets were produced from rapid quenched ribbons with combined addition of powder carbon, copper and titanium. After heat treatment the obtained bonded magnets have higher microhardness and homogeneity with high coercivity of 18 kOe.

Experimental

High purity elements were induction melted under protective argon atmosphere to produce Nd₁₆Fe₇₆B₈ master alloy. Master alloy were crushed in vibrating milling to obtain powder with particles size less then 10 µm. Before powder compacting the carbon fiber were introduced to alloy. For Cu- and Ti-containing magnets preparation powder copper and titanium were introduced together with carbon fiber during compacting stage. Sintered and bonded magnets of following types were produced: 1 – carbon fiber added, 2 – Cu-powder added, 3 – carbon fiber and Cu-powder added, 4 - carbon and copper powders added, 5 – powders of C, Cu and Ti added. Nominal compositions of produced magnets are listed in table.

2 Result and discussion

Magnets exhibit multiphase microstructure consisting of Nd₂Fe₁₄B grains, α-Fe, NdFe₄B₄ phase and Nd-rich grains. After minor addition of carbon fiber the gray-dark colored intergranular phase appeared in intergranular regions. It was found that with increasing carbon content the magnetic flux measured in search coil decreases and W=0 for xC=0,8 wt. %[1].

It was found that Cu-doping enhances magnetic properties substantially. The optimal for magnetic properties amount of Cu addition is 2 wt.%. The Cu-doped magnets exhibit multiphase microstructure. According to EDS data matrix phase represent Nd₂Fe₁₄B grains and occupy 90% of total amount. The NdFe₄B₄ phase, Nd-rich and Nd_{44,68}Fe_{13,84}Cu_{38,31} (at.%) phase were observed [1].

Negative effect of carbon fiber addition to Cu-doped magnets can be explained by presence of main magnetic phase grains of two different axis c orientations. During sintering carbon diffuse to matrix phase from the fiber. That part of grain that was in close contact with fiber is enriched with carbon, boron diffusion to intergranular region is occurred simultaneously. Carbon may dissolves in matrix phase by introducing ore displacement type. The matrix Nd₂Fe₁₄B is strongly oriented to applied field direction, but new Nd₂Fe₁₄(B,C) phase is randomly oriented during grain grows stage [2]. From the above data analyses it can be concluded that after diffusion to phase component carbon lead to critical point lowering on the phase diagram e.g. to eutectic with low melting point formation. The triple low-melting eutectic presence lead to Nd₂Fe₁₄(B,C) phase crystallization from liquid during cooling. Addition of Cu without carbon fibre lead to sharp increase of coercivity due to

better isolation of main magnetic phase grains. Combine addition of Cu and C lead to arbitrary oriented Nd₂Fe₁₄(B,C) grains formation and residual textured Nd₂Fe₁₄B grains presented in the structure. As result of different oriented grains existence the demagnetization curves has platform part.

The next step for magnetic properties enhancement copper, carbon with Ti was introduced to master alloy in the powder form before sintering. Powders of C, Ti and Cu are located on Nd₂Fe₁₄(B,C) phase grain boundaries during compacting and favors to TiC carbides formation (fig.1). Paramagnetic carbides and Cu-containing phase formation at intergranular regions lead to better isolation of Nd₂Fe₁₄(B,C) grains and prevent Nd₂Fe₁₄(B,C) phase formation. It may be concluded that the main high coercivity state mechanism for investigated magnets is pinning of inverse domains nucleation. So, the negative effect of carbon must be suppressed by combine alloying with Ti. The minor carbon addition to Nd-Fe-B magnets may be one of the ways for coercivity enhancement due to metallo-ceramic system formation with unique physic-mechanical properties.

Effect of heat treatment on the magnetic property and microstructure of sintered Nd-Fe-B magnets.

W. Li¹, T. Ohkubo^{1,2}, K. Hono^{1,2}

1. National Institute for Materials Science, Tsukuba, Japan; 2. CREST, JST, Japan

Introduction

Post sintering heat treatment has been known to be effective in enhancing the coercivity of sintered Nd-Fe-B magnets [1]. Since the coercivity is strongly influenced by the microstructure, it can be expected that important microstructure changes occur during the aging treatment. Although a lot of efforts have been made to study the microstructure change by aging, there is little information on the structure and chemistry of the grain boundaries which play a dominant role in the hard magnetic properties. In this work, we have focused the change of the grain boundary structure before and after the aging treatment of sintered Nd-Fe-B magnets. To study the microstructure of the grain boundaries, SEM, TEM and 3-dimensional atom probe (3DAP) have been employed.

Experimental details

Commercial sintered magnets with a (BH)_{max} of 48 MGOe were provided from a manufacturer. The composition of the magnets were Nd_{11.7}Pr_{2.8}Fe_{76.8}B_{6.0}Al_{0.5}Cu_{0.1}O_{2.1}, which were produced following the standard process of sintered magnets, i.e., strip casting - jet milling - magnetic alignment and pressing - sintering. After sintering, one was annealed, while the other was not. The microstructures have been investigated by SEM, LEO 1550 and CrossBeam 1540 EsB, TECNAI G2 F30 TEM equipped with energy filter and EDS, and laser assisted 3DAP.

Results and discussion

The coercivity of the magnet is increased from 9 kOe to 11 kOe by optimal post sinter aging. Figure 1 shows TEM energy filtered images of the as-sintered and aged samples. The zero loss images of the two samples clearly show the presence of a grain boundary in the center of the view. In both as-sintered and optimally annealed samples, Nd enrichment can be detected along the grain boundaries in the Nd jump ratio maps. The HRTEM image of the grain boundary in the as-sintered sample (Fig. 2(a)) does not show clear feature corresponding to the Nd-enriched phase along the grain boundary, and the Nd rich region does not appear to be continuous. Fragmented grain boundary phase of about 3 nm is seen. On the other hand, a thin continuous amorphous layer can be clearly seen in the grain boundary of the aged sample (Fig. 2(b)). The thickness of the amorphous grain boundary phase is approximately 5 nm, which is thought to be thick enough to cut the exchange coupling between the grains. Figure 3 shows the 3DAP composition profiles across a grain boundary of the aged sample. The composition variation near the grain boundary can be clearly detected. In the grain boundary, there is a Cu and Nd enriched layer of about 5 nm. The compositions are about 25% and 30%, respectively.

Also in this work, the compositions and structures of the Nd rich phases usually showing different contrast in SEM observation have also been determined by detailed TEM and EDX analysis. Eutectic lamellae of Cu enriched and depleted phases have also been found in the Nd-rich grains. It indicates the wetting of the Nd-rich phase along the grain boundaries may be due to the melting of the Nd-rich phase by the eutectic reaction with Cu.

Conclusion

The microstructure investigation shows that there is a systematic presence of continuous Nd rich layer in the grain boundaries in the optimally annealed sample. While in the as-sintered one, the Nd rich region in the grain boundary is not continuous, thus the Nd₂Fe₁₄B grains cannot be well

decoupled. The 3DAP result indicated that a substantial amount of Cu is enriched along the thin grain boundary phase.

These is an imperative need to develop a nature-friendly electric vehicle (EV) as an alternative transportation. Sintered Nd-Fe-B magnets are the most promising materials for a driving motor of the hybrid EV and the forthcoming pure EV. Since the operating temperature of magnets in these high-power motor applications reaches beyond 200°C, a very large value of coercivity H_c is necessary at room temperature. Current Nd-Fe-B magnets commercially available for such high H_c applications, therefore, contain a huge amount (~10 wt.%) of Dy to enhance H_c . But, this method has at least two crucial disadvantages. First problem is an estimated short supply of Dy in the EV mass-production stage owing to its low natural abundance as compared with that of Nd. The second inferiority in using Dy arises from the antiparallel coupling of Dy and Fe moments, which results in smaller magnetization and much-reduced energy product values. It is well known that a heat treatment around 600°C is indispensable to obtain a high coercivity in the sintered Nd-Fe-B magnets. This process is thought to cause some microstructural change in the grain boundary [1]. We have found that the coercivity in sintered Nd-Dy-Fe-B magnets can be further increased by applying a high magnetic field during the annealing [2]. In the Dy-free Nd-Fe-B magnets, we have found that such a coercivity enhancement phenomena occurs [3] only when a small amount of Cu is added, and when the annealing temperature is around 500°C or around 550°C. We have demonstrated [3] that these annealing temperatures are corresponding to eutectic points of Nd-Cu and Al-Cu phases, respectively. In this work, we report a more systematic study of the annealing-field dependence of coercivity for a series of Nd-Fe-B magnets with different amounts of Dy.

The heat treatments were carried out by using a furnace installed in a cryocooled superconducting magnet which generates magnetic fields of up to $H_a = 100$ kOe. We modified the furnace system so as to enable a rapid quenching of the samples immediately after the field annealing. Magnetization measurements were performed after the induction method in fields of up to ± 100 kOe.

When we fixed the annealing temperature at $T_a = 500^\circ\text{C}$, we observed a gradual enhancement of H_c as the field value during annealing, H_a , was increased. Figure 1 shows the room temperature values of H_c as a function of H_a for samples with Dy 2 wt.% and 6.8 wt.%. In spite of a slight scattering of data points, there is an apparent tendency for H_c values to increase linearly with H_a in both samples. The rate of increase in the Dy 6.8 wt.% sample is significantly larger than that in the Dy 2 wt.% sample. We made a least-squares fitting on these data by using a linear equation, $H_c = H_c(0) + \alpha H_a$, and deduced a slope α which corresponds to a coercivity enhancement factor. In Fig. 2, we plotted the α value against the Dy content. Although very small, the α has a positive finite value in samples with Dy 0 wt.% and 2 wt.%. It should be noted that, for higher Dy content, α increases rapidly and reaches about 0.05 for Dy 10.6 wt.% sample. It is natural to assume that Nd is partly replaced by Dy not only in the main $\text{Nd}_2\text{Fe}_{14}\text{B}$ phase but also in the Nd-rich intergranular phase. Since a Dy^{3+} ion has a larger single-ion anisotropy than that of a Nd^{3+} , the magnetic energy of intergranular phase during a field annealing becomes larger in Dy-containing samples. According to the field alignment model we proposed [1, 2], the critical grain size d_c of Nd(Dy)-rich intergranular phase therefore decreases with increasing Dy content. This would be the reason for the rapid increase in the α value with increasing Dy content. If the number of field-aligned Nd(Dy)-rich particles increases owing to the decrease of d_c , then a deterioration of surface magnetic anisotropy at

the outermost Nd^{3+} ion of a main $\text{Nd}_2\text{Fe}_{14}\text{B}$ phase would be diminished, resulting in the coercivity enhancement.

Sintered Nd-Fe-B magnets are the most promising materials for a driving motor of the hybrid electric vehicle (HV). In these kinds of application, a large value of the room-temperature coercivity as high as $H_c = 30$ kOe is required, because the operating temperature of the magnets reaches beyond 200°C. As a symptomatic treatment, Nd has been replaced partly by a heavy rare-earth element Dy to enhance H_c . But the problem is an estimated short supply of Dy in the HV mass-production stage due to its low natural abundance. Since the coercivity value in Dy-free Nd-Fe-B magnets is about 10 kOe, they are only applicable in low temperature circumstance such as MRI. However, it is possible, in principle, to achieve much higher coercivity without using Dy, since anisotropy field of $\text{Nd}_2\text{Fe}_{14}\text{B}$ main phase reaches $H_A = 90$ kOe at room temperature [1]. Therefore, it is very important to know the reason for a serious gap between H_c and H_A . It is widely accepted that the coercivity of sintered Nd-Fe-B magnets is highly dominated by the intergranular Nd-rich phase, which is reported [2] to change from discontinuous to continuous arrangement by annealing around 500~600°C. We have recently shown that the coercivity in sintered Nd-Fe-B magnet can be further increased by applying a high magnetic field during the annealing [3,4]. We found that such a coercivity enhancement phenomena occurs only when a small amount of Cu is added, and when the annealing temperature is around 500°C or around 550°C. We have demonstrated that these annealing temperatures are corresponding to eutectic points of Nd-Cu and Al-Cu phases, respectively [5]. In order to investigate the relation between the H_c increase and change of interface nanostructure, we started a small angle neutron scattering (SANS) study. SANS technique has an advantage over microscopic methods. That is, we can non-destructively obtain quantitative information averaged over a bulk sample. The pioneering SANS work by Fujii *et al.* was reported in 1987, stating that there are film-like precipitates along the grain boundaries where the thickness decreases from 6 nm to 4 nm by annealing at 600°C [6]. In this paper, we report SANS data for Dy-free Nd-Fe-B magnets annealed with and without high magnetic fields, and investigate a correlation between the interface nanostructure and the coercivity.

Two kinds of sintered Nd-Fe-B samples with and without Cu and Al additives were prepared. The 99% enriched ^{11}B isotope was used to avoid high neutron absorption of ^{10}B in natural boron. The samples were cut into plates with dimensions $15 \times 18 \times 1.5$ mm³, in which the tetragonal c -axis of $\text{Nd}_2\text{Fe}_{14}\text{B}$ grains was aligned parallel to the 15 mm side. Samples were annealed at various temperatures between $T_a = 450 \sim 650^\circ\text{C}$. External magnetic field applied during the annealing was 0 or 100 kOe. SANS experiments were performed with SANS-J and PNO apparatus of JRR-3 at the Japan Atomic Energy Agency (JAEA) in which the incident wavelength of neutrons were 0.65 and 0.2 nm, respectively. The incident beam was normal to the 15×18 plane of the sample. In order to separate the magnetic scattering contribution from nuclear one, all the samples were magnetized in 100 kOe field prior to the experiments. The two dimensional detector in SANS-J enabled

us to obtain a whole set of SANS intensities $I(q_{\parallel}, q_{\perp})$, where q_{\parallel} and q_{\perp} are scattering vectors along the directions parallel and perpendicular to the c -axis of $\text{Nd}_2\text{Fe}_{14}\text{B}$, respectively.

The main results are summarized as follows. We found that, in all the samples examined, the intensity I of scattered neutrons was proportional to the q^{-4} for $q < 0.5$ nm⁻¹, irrespective of the direction of q . For $q > 0.5$ nm⁻¹, on the other hand, the intensity was markedly higher than that expected from the q^{-4} dependence. These results show that there exists a neutron scatterer with a dimension of less than 10 nm, which is considered to be a Nd-rich grain boundary phase in the matrix of $\text{Nd}_2\text{Fe}_{14}\text{B}$ phase. It should be noticed that, in the sample with Al and Cu additives, we observed a small but finite increase of intensity as compared with the sample without Al and Cu additives for the q range of $0.1 < q < 1$ nm⁻¹. Since Al- and Cu-containing samples have higher coercivity, this result suggests that there is a correlation between the density of neutron scatterer at a Nd-rich grain boundary and the coercivity. In order to investigate this correlation more systematically, we measured the SANS intensity in this q range for various Al- and Cu-containing samples, which have different H_c values ranging from 13 to 16 kOe owing to different field annealing conditions. We then analyzed the data with the $I = A q^{-4}$ equation. We found that the value of prefactor A increases with increasing H_c . Such an increase in the A value suggests a solid formation of the Nd-rich phase in the matrix of $\text{Nd}_2\text{Fe}_{14}\text{B}$ phase. Thus, this result is a direct evidence of correlation between interface nanostructure and coercivity in sintered Nd-Fe-B magnets.

Reduction of sensitivity to sintering temperature for Nd-Fe-B magnets through co-doping Zr and Nb.

M. Yan, X. Cui, L. Yu, T. Ma

Department of Materials Science and Engineering, Zhejiang University, Hangzhou, China

Introduction

Sintered NdFeB magnets have been widely applied in various fields due to their outstanding magnetic properties. Further improvement of the magnetic properties is always the major objective of all researchers [1, 2]. It has been known that optimum magnetic properties are obtained when the average grain size is about 5~6 μm , which is primarily dominated by the sintering temperature [3]. Since the local temperatures in sintering furnaces are inhomogeneous, it is vitally important to decrease the sensitivity of green compacts to sintering temperature for production of magnets with high consistency of properties. In this work, an attempt has been made to decrease the sensitivity of green compacts to sintering temperature.

Results

Fig.1 shows the effect of sintering temperature on magnetic properties of Nd_{13.3}Dy_{0.48}Fe_{81.5}Al_{0.24}Ga_{0.1} magnets. It can be seen that magnetic properties showed poor consistency of properties. The difference of maximum energy product (BH)_m among the magnets sintered at each temperature exceeded 30 kJ/m³, and the difference of intrinsic coercivity iH_c ranged from 65 to 140 kA/m, reflecting the high sensitivity to sintering temperature. The effect of sintering temperature on magnetic properties of magnets containing 0.07 at. % Nb and 0.07 at. % Zr is shown in Fig. 2. When the sintering temperature was 1373K, the energy product and coercivity difference of the magnets were only 9.4 kJ/m³ and 24.4 kA/m. It indicates that the Zr and Nb co-doped magnets possessed much better consistency of properties than Nd_{13.3}Dy_{0.48}Fe_{81.5}Al_{0.24}Ga_{0.1} magnets. Moreover, both iH_c and (BH)_m of the Zr and Nb co-doped magnets increased with increasing the sintering temperature, and reached maximum values at 1373K. A high energy product with the value of 404 kJ/m³ was obtained.

The reduction of sensitivity to sintering temperature and the improvement of magnetic properties through Zr and Nb co-doping are explained as follows. Firstly, the addition of Zr is beneficial to inhibit abnormal grain growth. For the magnet without Zr, abnormal grain growth occurs at the sintering temperature of 1373K, as can be seen in Fig.3 a. For the magnet containing 0.07 at. % Zr, no abnormal grain growth is observed at higher sintering temperatures, as shown in Fig. 3b. Secondly, the addition of Nb can regularize grain shape and optimize microstructures, thereby improving the magnetic properties [4]. Moreover, it is considered that the formation of intragranular precipitates containing Zr or Nb is beneficial to enhance the pinning of the domain walls, resulting in the improvement of coercivity [5].

Structure and magnetic properties of low neodymium magnets containing minor addition of molybdenum.

M. Spyra, M. Leonowicz

Faculty of Materials Science and Engineering, Warsaw University of Technology, Warsaw, Poland

Magnetic nanocomposites have been intensely studied since their developed in late 80-ties of the XXth century. They usually consist of a nanoscale mixture of hard and soft magnetic phases. According to the basic calculations, for optimal magnetic coupling between the both magnetic phases, the grain size should be 10 nm and 20 nm, for the hard and soft phase, respectively. Such a microstructure can be produced by rapid solidification of a molten alloy, however, the direct quenching requires application of a very narrow window of the process parameters. Thus, an alternative method is based on the processing of overquenched (amorphous) ribbon alloys with their subsequent annealing. We have been already published studies on the $\text{Nd}_9\text{Fe}_{77-x}\text{B}_{14}\text{Ti}_x$, $x=2,4,5$ system in which we obtained, for the $\text{Nd}_9\text{Fe}_{73}\text{B}_{14}\text{Ti}_4$ alloy $J_H = 907 \text{ kA/m}$ and $(BH)_{\max} = 99 \text{ kJ/m}^3$ without loss of the remanence [1].

In this study the $\text{Nd}_9\text{Fe}_{77-x}\text{B}_{14}\text{Mo}_x$ ribbons ($x = 0, 2, 3, 4, 5$) were prepared by rapid solidification of molten alloys by melt-spinning with the roll speed 20 m/s. The overquenched ribbons were annealed at 983 K for 20 min. The phase constitution was evaluated using x-ray diffraction (XRD) (PHILIPS PW 1830, $\text{Cu} - \text{K}\alpha$) and Mössbauer spectroscopy. The magnetic properties were measured using a LakeShore 7410 vibrating sample magnetometer in maximum external field 3T.

The nanostructure in the alloys was produced by annealing the amorphous precursors. The onset of the crystallization temperature of the amorphous phase grew from 933 K for the Mo-free alloy up to 993 K for the 5 at% Mo alloy.

The XRD phase analysis revealed in the $\text{Nd}_9\text{Fe}_{77}\text{B}_{14}$ alloy the existence of magnetically soft $\alpha\text{-Fe}$ and magnetically hard $\text{Nd}_2\text{Fe}_{14}\text{B}$ phases, whereas in the alloys containing Mo, additionally the MoB_2 and Mo phase could be present (Fig. 1). This was broadly confirmed by Mössbauer spectroscopy.

Addition of the third element to the Nd-Fe-B alloys often leads to the increased coercivity, however, this effect is usually accompanied by a substantial decrease of the remanence, due to incorporation of a nonmagnetic element. In our case the remanence is close to 0.8T for the Mo-free alloy and decreases to 0.75 T for 4 at% Mo addition. The maximum energy product $(BH)_{\max}$ increases for the alloys containing Mo, reaching maximum value 88 kJ/m^3 for 4 at% Mo. The hysteresis loops are smooth and the shape of the initial magnetization curves indicates a change of the coercivity mechanisms giving rise for pinning of domain walls for the Mo containing alloys (Fig. 2). The improvement of the magnetic properties we attribute to the, observed by TEM, substantial refinement of the grain size.

Concluding we can state that small addition of molybdenum, 2-4 at%, to the $\text{Nd}_9\text{Fe}_{77-x}\text{B}_{14}\text{Mo}_x$ alloys leads to increase of the coercivity and maximum energy product, without markedly affecting the remanence. The highest properties: $J_r = 0.75 \text{ T}$, $J_H = 1013 \text{ kA/m}$, $(BH)_{\max} = 88 \text{ kJ/m}^3$ have been achieved for the $\text{Nd}_9\text{Fe}_{73}\text{B}_{14}\text{Mo}_4$ alloy.

Improvement of the magnetic properties for the alloys containing Mo addition is caused by the change of the phase morphology of the Nd-Fe-B alloys, mainly by a formation of an uniform nanocrystalline microstructure.

Multi-tooth Flux Switching PM Brushless ac Machines for High Torque Direct-Drive Applications.

Z. Zhu¹, J. Chen¹, D. Howe¹, S. Iwasaki², R. Deodhar²

1. University of Sheffield, Sheffield, United Kingdom; 2. IMRA UK Research Center, University of Sussex, Brighton, United Kingdom

High torque density is one of the development trends of permanent magnet (PM) brushless machines, e.g. for aerospace and automotive applications. Multi-tooth structure is often employed to increase the torque / power density of the machines, such as hybrid stepping machines and multi-tooth switched reluctance machines [1][2] and a multi-tooth flux-switching machine which was briefly discussed in [3] as a stepping motor. A high electric loading may be required in order to achieve high torque density, especially for machines having magnets on the stator, such as flux-switching PM (FSPM) machines, in which the temperature rise of magnets may be more easily managed [4].

In this paper, multi-tooth FSPM brushless ac machines are investigated and compared with conventional FSPM brushless machines. As can be seen from Fig.1, in both machines, concentrated stator winding is employed, the stator core consists of modular “U”-shaped laminated segments between which are placed circumferentially magnetised permanent magnets, the rotor is similar to that of a switched reluctance machine, which is simple and robust. Their major difference is that there is more than one tooth of stator segments in the multi-tooth FSPM machine, Fig. 1. In this paper, the general stator and rotor slot/pole combinations will be derived, and the electromagnetic performance of a 2-tooth, 6-stator slot and 19-rotor pole FSPM brushless ac machine, in which the total number of stator small teeth and their width are equal to those in a conventional 12-stator slot and 10-rotor pole FSPM machine, is predicted by finite element analysis and validated by experiment. It is shown that (1) the number of magnets in 2-tooth FSPM machine is only half of that in the conventional machine; (2) predicted phase back-emf waveform of the 2-tooth machine is sinusoidal and ~40% larger than that of the conventional machine, Fig. 2(a); (3) the torque ripple are negligible in the 2-tooth FSPM machine and its electromagnetic torque is larger than that of the conventional machine at rated current; (4) the 2-tooth flux-switching machine exhibits higher torque density at light electric loading, but it becomes saturated more quickly with current than that of the conventional machine, Fig. 2(b), due to high armature reaction.

Optimum Design of Transverse Flux Linear Motor for Weight Reduction and Improvement Thrust Force Using Response Surface Methodology.

D. Hong, B. Woo, D. Kang

Korea Electrotechnology Research Institute, Changwon, South Korea

Linear motor has a few partial limitations. The major reason is the low power density due to the inherent large air gap. For the application of linear motors to high power system, therefore, Permanent Magnet (PM) type Transverse Flux Linear Motors (TFLMs) can be considered because this motors can develop high magnetic thrust and reluctance thrust in relatively small air gap [1-2]. TFLM has two important electromechanical components, a linear actuator and springs for refrigeration application. By controlling the operating frequency of the actuator around mechanical resonance frequency, it has higher efficiency than the conventional rotary type compressor. This paper presents the shape optimum design of transverse flux actuator for linear compressor using Response Surface Methodology (RSM). Generally RSM is used with 2 or 3 design variables ; however, in this paper, Fig. 2 shows that eight design variables using the table of mixed orthogonal array are utilized. For each parameter combination, the response value is determined by 3-D Equivalent Magnetic Circuit Network (EMCN) method.

For this reference model, the comparison of the static force obtained from 3-D EMCN, 3-D FEM simulation and experiment is shown in Fig. 1. From the results the use of 3-D EMCN is validated as it can be observed, since 3D EMCN shows good agreement with experimental tests.

Table I shows the design variables and flux path. In order to determine the equations of the response surface, several experimental designs have been developed to establish the approximate equation using the smallest number of experiments. Equation (1) shows the two fitted second order polynomial of object functions for the eight design variables. Table II shows the adjusted coefficients of multiple determination R^2_{adj} for three responses are YW (99.9 %), YT (99.9 %), and YD (99.7 %). In Table III and IV, the optimal point is searched to find the point of less than 12.63 % of the weight and greater than 6.87 % of the thrust force maintaining the detent force of initially designed PM type TFLM. The simulation result of predicted optimum set is shown Table II with good agreement. The Pareto chart of thrust force, detent force and weight shows influential design variables in Fig. 3.

In this paper, The performance of optimized PM type TFLM is improved when compared with the initial model. Therefore, when this proposed approach is applied, it is more efficient to raise the precision of optimization and reduce the number of iteration of experiment in the optimization design by RSM.

2D analytical calculation of the no-load induced EMF in an axial flux slotted permanent magnet machine.

J. Pérez¹, F. Frechoso^{1,2}

1. Electrical Engineering, Universidad de Valladolid, Valladolid, Spain; 2. Member, IEEE, Valladolid, Spain

Introduction: Three methods are proposed and compared in order to obtain the induced electromotive force (EMF) in an axial flux slotted permanent magnet machine under no-load conditions. Each method solves the Laplace equation via magnetic scalar potential and, based on a two-dimensional approximation of the magnet geometry, takes into account the slotting of the machine.

An axial flux machine with three phases, eight poles, and 24 slots was chosen. The inner rotor has 8 permanent magnets surface mounted, which are axially magnetised. The two outer slotted stator cores have an infinite permeability. Looking radially inwards onto the machine and ignoring curvature, allows the machine to be represented as a lineal one, where the x-coordinate represents the circumferential direction and the y-coordinate the axial direction. This model assumes the radial direction to be infinite. By symmetry, only a half of the geometry is studied.

Analytical models: The two-dimensional Laplace equation for the magnetic scalar potential, v , is: $\delta^2 v / \delta x^2 + \delta^2 v / \delta y^2 = 0$

The most general solution can be written as:

$$v = \sum [A_n \cos(\beta_n x) \cosh(\beta_n y) + B_n \cos(\beta_n x) \sinh(\beta_n y) + C_n \sin(\beta_n x) \cosh(\beta_n y) + D_n \sin(\beta_n x) \sinh(\beta_n y)]$$

where the constants A_n , B_n , C_n , D_n and β_n can be determined by imposing appropriate boundary conditions. Once the magnetic scalar potential is defined, other parameters, such as the magnetic flux crossing any given area or the induced EMF can then be computed.

1st method: Fourier series method:

This method consists on considered interconnected rectangular regions, where the solution can be obtained by applying the superposition theorem and defining several simpler problems. In the common boundary to two regions the magnetic scalar potential and its spatial derivate must be continuous across the boundary [1]. The problem is solved in two steps: a) Assume an arbitrary potential distribution along the boundaries in terms of some unknown Fourier coefficients. Solve the field equations in the regions. b) Obtain the unknown coefficients by matching the normal derivate of the potential function along each boundary.

2nd method: magnetization profile in an even air-gap + slot permeance:

This method obtains the analytical expressions for the flux density distributions in the air-gap and in the magnets, solving the Laplace and Poisson equation respectively via the magnetic scalar potential, by taking into account the symmetry conditions, the boundary conditions and the magnetization profile [2]. The magnetization distribution is represented by its Fourier series expansion, as follows: $M_y = (B_r / \mu_0) \sum [b_n \sin(\beta_n x)]$ The expression of the magnetic scalar potential in the air gap, is: $v_g(x, y) = \sum (K_{yn} / \Delta \beta_n) \sin(\beta_n x) \sinh[\beta_n (l_s - y)]$ where $\Delta = \cosh(\beta_n g) + \mu_r \sinh(\beta_n g) \tanh(\beta_n l_m / 2)$, $\beta_n = n\pi / \tau_p$, and $K_{yn} = 0$ if n is odd and $K_{yn} = [4B_r \cos(n\pi) / \mu_0 n\pi]$ if n is even, being B_r the remanence, μ_r the relative recoil permeability, μ_0 the vacuum recoil permeability and τ_p the pole pitch.

The effect of slotting on the field produces by the magnets is incorporated by means of a slot permeance coefficient, which consist of evaluating the above expression with the air-gap modified so as to take into account that the magnetic field over the slot must travel further to reach the stator [3].

3rd method: magnetic scalar potential in an even air-gap + slot permeance:

In this third method, we have considered an even air-gap with fixed magnetic scalar potential in the magnet and stator surfaces ($+V_0$ in the north face, $-V_0$ in the south face and null in the stator sur-

face), and the slot are take into account by the permeance coefficient. The expression of the magnetic scalar potential in the air-gap is: $v_g(x, y) = \sum [P_n / \sinh(\beta_n g)] \sin(\beta_n x) \sinh[\beta_n (l_s - y)]$ where $P_n = 0$ if n is odd and $P_n = -4V_0 / \tau_p \beta_n$ if n is even.

Results: In order to compare the proposed methods, we have calculated the flux linkage and the induced EMF in a coil with an span of 3 slots. Figure 1 shows the flux linkage and the induced EMF, respectively, obtained with each method.

Conclusions: Three different analytical methods are proposed and compared. The difficult of first method increasingly with the number of interconnected regions, although the technique is quite straightforward. In order to reduce this difficult, another two methods are proposed in whose the slotting effect is represented by a permeance coefficient. The flux linkage and the induced EMF calculated by the three methods show a good agreement.

Modeling permanent magnet axial flux machine with Lie's symmetries.

L. T. Loureiro¹, J. R. Zabada², A. F. Flores¹, R. P. Homrich¹

1. Electrical Engineering, Universidade Federal do Rio Grande do Sul, Porto Alegre, Brazil; 2. Nuclear Engineering, Universidade Federal do Rio Grande do Sul, Porto Alegre, Brazil

Abstract: A permanent magnet axial flux machine was designed, built and tested. Analytical model with Lie's symmetries and numerical model were developed for the machine and comparisons were carried out. An analytical model and comparison results will be presented.

Key words: Electrical Machine. Torus machine. Permanent Magnets. Axial flux. Analytical model. Electrical Machine Testing. Lie's Symmetries.

Introduction

The axial flux machines tend to present a larger air gap than the radial ones, therefore they require higher excitation. The excitation can be provided by per-manent magnets. A machine with rated rotation 450 RPM, torque of 3 Nm and outside diameter of 0.16 m was built. A finite element software was used to carry out the numerical simulation. Analytical models for the windings and permanent magnets inductions were developed. Along with the permanent magnet induction were also calculated the electromotive force and the torque.

Description of Machine

The Torus machine, object of this paper, is an axial flux, disc-type machine, with a stator mounted between two external rotors. Its construction is rather simple, compact and has reduced axial length. This characteristic is interesting for applications that have space restrictions.

The machine has a stator with eighteen coils that are connected in three groups with six coils in series, which are energized sequentially. Each rotor has six permanent magnets that interact with the stator coils. The excitation of coils groups is carried out through a converter that energizes the coils sequentially. In this way, the stator magnetic induction moves along with the permanent magnet magnetic induction. The permanent magnets poles in front of the stator have the same polarity in corresponding positions.

Figure 1 shows the frame, cores, magnets and the complete machine.

Figure 1a Frame, Cores and Magnets Figure 1b Complete Machine

The main characteristics of Torus machine are presented in the table:

Analytical Model

The windings behavior is described by the following equation;

The solution of this equation in air gap and winding region, along with application of boundary conditions and Lie's translation symmetry admitted by equation, results in winding magnetic induction:

The calculated and simulated values are shown in figure 2a.

The air gap scalar magnetic potential was modeled through gaussian curves, equation (3).

The sum of these functions verifies the Laplace equation in long periods. The substitution $x=x+Iz$ and $y=y+Iz$ makes the combined function become function of x , y and z . The expression of permanent magnet induction is derived after carrying out some mathematical operations and application of a Lie's scale symmetry. The values of permanent magnet induction corresponding to the simulation, the analytical model and the measurements are shown in figure 2b.

Figure 2a Winding Magnetic Induction Figure 2b Magnets Magnetic Induction

Conclusions

The comparison shows that analytical modeling produced results compatible with the numerical simulation and measurements. The utilization of Lie's symmetries is powerful method in electromagnetic systems and can have a wider application.

Optimal Design of an SPM Motor Using Taguchi Method and Genetic Algorithms.

C. Hwang¹, L. Lyu¹, P. Li¹, C. Liu²

1. EE, Feng Chia University, Seatwen, Taichung, Taiwan; 2. EE, National Sun Yat-sen University, Kaohsiung, Taiwan

INTRODUCTION

This paper presents the use of the Taguchi method [1] and genetic algorithms-based (GAs) optimization techniques [2] in optimizing an surface-mounted permanent magnet (SPM) motor for use as a fan motor in air-conditioners. In this application, the SPM motor is designed to provide high efficiency and low cogging torque for the requirement of high EER and low noise operation.

DESIGN OF EXPERIMENT

There are eight factors, A, B, C, D, E, F, G and H, corresponding to eight design variables which are chosen as shown in Fig. 1, and each at three levels except factor A that has two levels. Where A is the magnetization of magnets (radial, r or parallel, p), B (lso) is the slot opening in mm (levels 2.0, 2.2 and 2.4), C (η_m) is the ratio of angular magnet pitch to angular pole pitch (levels 1.0, 0.96 and 0.92), D is the thickness of magnet in mm (levels 5.0, 5.5 and 6.0), E (g) is the air gap length in mm (levels 0.4, 0.5 and 0.6), F (l_{mcc}) is the position for cutting the magnet in mm (levels 0, 1 and 2), G (θ_{mcc}) is the angle for cutting the magnet in electrical degrees (oE) (levels 20, 30 and 40), and H (l_{mc}) is the distance from motor center used as the center of a circle for magnet in mm (levels 0, 1 and 2). To obtain the peak to peak values of cogging and efficiency for each case, two-dimensional FEA is conducted. Table I shows the values of three settings of three design parameters and the motor performance indexes.

ANALYSIS OF RESULTUS

After conducting the analysis of means and analysis of variance, average peak to peak values of cogging torque (T_{cog}) and efficiency (Eff) for all levels of all factors are tabulated in Tables II and III.

It is noted in Tables II and III that the best combination of design parameters for minimum cogging torque and maximum efficiency are determined to be (A2, B3, C2, D1, E1, F1, G1, H3). Finally, GAs is applied to find the optimal values of the design variables. They are B = 2.35 mm, C = 0.967, D = 4.96 mm, E = 0.412 mm, F = 0.12 mm, G = 19.85oE, and H = 1.95 mm. The final results are found using the FEM analyses. The peak to peak values of cogging torque and efficiency of the original, the Taguchi design, and Gas are 6.7846 mNm, 0.8497 mNm, 0.6626 mNm, and 66.30 %, 71.21 %, and 72.56 % respectively.

On the Material and Temperature Impacts of Interior Permanent Magnet Machine for Electric Vehicle Applications.

A. Wang¹, H. Li¹, C. Liu²

1. Electrical Engineering, North China Electric power university, Baoding, China; 2. Electrical Engineering, National Sun Yat-Sen University, Kaohsiung, Taiwan

1. Introduction

Due to its high efficiency, high torque density, lower torque ripple, and lower cogging torque features [1], [2], Interior Permanent Magnet (IPM) machine with neodymium-iron-boron (NdFeB) material has attracted increasing interests among researchers and designers in many high-performance applications such as traction motors used in hybrid electric vehicles [3]. However, with its different applications and operational environments, impacts of the overall machine system performance at various permanent magnet (PM) materials and temperatures have seldom been assessed. The objective of this paper is to present the detailed investigations on these impacts, such that the design and application guidance of selecting different PMs in an IPM motor for electric vehicles can be provided.

2. IPM Machine

As shown in Fig. 1, a 55 kW IPM machine has been designed with a single layer of buried rotor magnets, 6 slots per pole for possible hybrid electric vehicle application. The rotor pole contains V-shape buried magnets that are magnetized along the d-axis, while the stator slots are embedded with double layer distributed windings to produce the desired magneto-motive forces. The pilot design parameters are given in Table I and the transient model analyses have been performed at one pole by 2D finite element method (FEM). The resultant flux lines at one time instance with the rotor pole being 3 slots apart from the energized stator at a speed of 2000 rpm are depicted in Fig. 2 for illustration.

3. Investigations of the PM and Temperature Impacts

Table II provides the five NdFeB materials, namely HS_43EH, HS_36EH, HS_35EH, HS_40FH and HS_32GH, that are potential selections for the desired IPM applications. Based on these material information and 2D FEM, comparison system performance were thoroughly calculated and illustrated in Figs. 3~5. As can be observed, though the HS_43EH PM will provide the maximum averaged and minimum ripple torques at all temperatures, with at least 30% higher cogging torques than the others, such material will only be competitive for the low-cost large torque applications. While for the operating environments with higher temperature, though with higher cost, the HS_40FH PM will provide almost the same levels of maximum averaged and minimum ripple torques, and much lower cogging ones for the desired applications. Similarly, if cost and cogging effects are the main concerns, it can be seen that the HS_35EH PM will provide a relatively better solution.

Fabrication and properties of FePt thick films for micro-machine application.

P. Jang¹, B. Lee¹, K. Rhie², S. Choi²

1. Div. of Applied Science, Cheongju University, Cheongju, South Korea; 2. Department of display, semiconductor and physics, Korea University, Chochiwon, South Korea

1. Introduction

Due to their very high magneto-crystalline anisotropy energy (7×10^6 J/m³) and excellent chemical stability, FePt films are one of the potential candidates for future magnetic recording media and micro-machine application. However, FePt films should be thicker than several tens micrometer for some micro-machine applications such as micro-magnet, micro-undulators or wiggler. Because of very poor workability of ordered L10 FePt alloys, it is almost impossible to fabricate the FePt thick films with several tens micrometer by rolling FePt bulk materials directly. Recently multilayer technique was proposed, in which Fe and Pt foils were stacked on stainless tube to obtain nano-composite materials and then rolled by a reduction ratio of 10,000 followed by post-annealing [1]. In thin film processes it has been known that it is impossible to grow the films thicker than several tens micrometer because of very high residual stress. In this study we have successfully grown the FePt films thicker than ten micrometer on Fe substrates by sputtering with the help of HF surface treatment.

2. Experimental procedure

We had first proposed a probability of micro-undulator for T-Hz sources [2]. The structure of the micro-undulator is very similar to that of double layered perpendicular recording media, so that FePt films thicker than ten micrometer were sputtered at 400°C on 99.9% bulk Fe substrates with very smooth surface. For the 10 μ m FePt, Fe-Pt composite targets were sputtered for 11 hr with a sputtering power of 100 W. To improve adhesion between FePt and Fe substrates, 50 – 100 nm thick intermediate layers such as Ti, Hf, W, Fe and others were tried. And HF surface pretreatment was also tried because it is known that hydrogen termination forms on Si dangling bonds on the Si surfaces [3]. The films were annealed on a vacuum better than 2×10^{-5} torr in order to transform disordered FePt phase to L10 ordered phase.

3. Results and discussion

Ti is known as an element to improve adhesion between thin films and substrates. For films thinner than 3 μ m Ti was effective to increase adhesion. However, in films thicker than 10 μ m, Ti is not effective to increase adhesion between FePt and Fe. Other elements such as W, Hf, and Fe are less effective than Ti. Even though 10 μ m FePt thick films were successfully sputtered on the Ti layer, the FePt films were peeled off during annealing process. All the intermediate layers used in this study could not acquire a successful FePt film. It is known that hydrogen terminated H-Si bonds was kept for several minutes in the air and for several hours in ultrahigh vacuum when Si wafer was pre-treated in HF dilute aqueous solution by pull-dry method. Even though bond structure of Fe was different from Si, pull-dry dry method was tried. After treating the Fe substrate with HF solution, 11 μ m thick FePt films were successfully grown on Fe bulk substrate. Figure 1 shows XRD diffraction patterns of 11 μ m FePt films on Fe and Ti substrates. It can be shown that the formation of L10 phase was confirmed from the (001) super-lattice peak. The ordering parameter of the two samples was calculated to be around 0.82. XRD patterns of two samples are nearly same, which means that the growth or preferred orientation of the FePt thick films is not affected by the orientation of substrate surface. A low degree of (111) preferred orientation was confirmed in Fig. 1. In SEM observation very coarse and deep columnar structure was observed so that the film was not continuous and the surface was not reflective. Figure 2 shows VSM loops of the FePt films. From

non-existence of kinks in the in-plane loop it can be seen that the film shows single-phase magnetic behavior. In-plane and perpendicular coercivities are 7.5 and 2.5 kOe, respectively, which are much higher than those of cold rolled FePt foils. The reason for the higher coercivity seems to be due to a deep columnar structure. In conclusion, FePt films thicker than ten micrometer was successfully sputtered on Fe substrates and the developed FePt thick films are thought to be applied to micro-machine application.

Optimum Design of 60 W Longitudinal Flux Linear Motor for Weight Reduction and Improvement Performance Using DOE.

D. Hong, B. Woo, D. Kang

Korea Electrotechnology Research Institute, Changwon, South Korea

In order to increase the power density, permanent magnet (PM) type longitudinal flux linear motors (LFLMs) can be considered for the application of the linear motors in high power density systems. Since LFLMs can produce high magnetic thrust and reluctance thrust with relatively small air gap. There are several practical examples of LFLM in [1-2]. Fig. 1 shows the structure of the developed LFLM. It has two important electromechanical components, a linear actuator and resonance springs for refrigeration application. By controlling the operating frequency of the actuator around mechanical resonance frequency, it has higher efficiency than the conventional rotary type compressor.

Fig. 1 shows the prototype of PM type TFLM for compressor. Fig. 2 shows the flow chart of optimization procedure. Fig. 3 shows design variables of the PM type LFLM. The effective factors are DV1, DV2, DV3 by table of orthogonal array, Pareto chart and RSM. Table I shows the design variable and level of effective factors in central composite design (CCD). The CCD is used. CCD is frequently used for fitting second-order response model. The adjusted coefficients of the multiple determination R^2_{adj} for two responses are weight (100 %) and FThrust (100 %) in Equation (1). This paper presents the optimum design of longitudinal flux actuator for linear compressor using RSM. Its design goal is to reduce the weight of the machine with the constraints of thrust and detent force with respect to the initial machine. At first step, most influential design variables and their levels should be determined and be arranged in a table of orthogonal array. Each response value is determined by 2-D finite element method (FEM). With the use of reduced gradient algorithm (RGA), finally, the most desired set is determined, and the influence of each design variables on the objective function can be obtained. The weight can be reduced by 9.58 %, thrust force improved by 5.11 % and detent force maintained of initially designed PM type LFLM in Table II.

Optimal Design of a Small PM Wind Synchronous Generator for Wide Range of Winds Speed.

B. Ebrahimi¹, J. Faiz¹, M. Rajabi Sebdani¹, M. A. Khan²

1. Department of Electrical and Computer Engineering, University of Tehran, University of Tehran, Tehran, Iran; 2. Department of Electrical Engineering, University of Cape Town, Cape Town, South Africa

Due to the design introduced of permanent magnet synchronous generator (PMSG) in [1], the 12-blade turbine is replaced with a 3-blade one. So the torque, in new generator, is increased and the speed, voltage and frequency is decreased. In this paper, the generator presented in [1] is redesigned so that the voltage level of the generator output is increased considerably, while keeping the rated frequency of the generator output close to that of the grid. It's note worthy that this way, the volume of the PM used in generator is decreased and this will affect greatly on the find cost of the generator manufacture. This paper presents a multi objective optimization method to improve, terminal voltage, power factor and PM volume in use. For this purpose, the analytical model of the machine is utilized to calculate the excitation voltage, power factor and PM volume and Effects of them are investigated via this model. PMSG parameters and dimensions are then optimized using genetic algorithm incorporated with an appropriate objective function. The results show an enhancement in PMSG performance. Finally 2D time stepping finite element method (TSFE) is used to evaluate the analytical results in opera2d.10.5. The comparison of results validates the optimization method.

Some of the typical PMSG and dimensions are selected as design variables where values are determined through on optimization procedure. In this paper, design variables are axial length, remanent flux density of the PMs, specific electric loading, efficiency, power factor, terminal voltage and wind speed. To have a more realistic design, some constraints are applied to design variables listed in table I. The pole pairs, rated frequency, number of blades, the main fixed specifications in the design procedure are (250 rpm), 50 Hz and 3 respectively. In this paper roulette wheel method is used for selection and each step elite individual sent directly to the next population. Table II shows genetic algorithm parameters used in this paper. A three phase PMSG for handling materials application is chosen as the basis of design optimization. The minimum value of the terminal voltage, PM volume and power factor in the algorithm is chosen close to their initial values of the non-optimized generator. The results of optimization are summarized in table III. The variations of calculated terminal voltage (Ref. [1] and proposed design) with time, using TSFE, are illustrated in figs 1 and 2.

Introduction

This paper presents the analytical analysis of magnetic field and back electromotive force (back EMF) calculation in an axial flux permanent magnet synchronous generator (AFPMSG) without stator core. For the verification, the numerical calculation (finite element method (FEM)) of magnetic field is accomplished and comparison between analytical and numerical solution of magnetic field is presented. The paper also presents the comparison between analytical and numerical (FEM) solution of back EMF using Faraday's law. The validity of the proposed analytical method is additionally confirmed with measurements of back EMF on prototype AFPMSG with coreless stator.

The prototype AFPMSG for wind energy application consists of internal stator and twin external rotor. Permanent magnets (PMs) are glued to the rotor steel discs and the coils are built in the non-magnetic stator using polypropylene and epoxy. The AFPMSG excitation is accomplished by 10 sectors of NdFeB magnets on the both parts of rotor, respectively.

The finite element method allows an accurate analysis of magnetic field considering geometric details and non-linearity of magnetic material, but they are time consuming and poorly flexible in the early design stages. On the other hand, the analytical methods of magnetic field analysis cannot consider geometric details, but can achieve time saving and flexible computation when performing magnetic field and back EMF calculation.

Methods of analysis

In this paper an analytical solution of Maxwell's equations and constitutive equation is used to evaluate magnetic flux density by PMs in the centre of air-gap region with central radius of PMs [1,2]. Due to the coreless stator, the final whole magnetic field (magnetic flux density) at constant radius can be obtained by the superposition of magnetic fields produced by PMs and armature current. Magnetic field densities produced by PMs (for each part of rotor) and armature current can therefore be calculated separately and analysis model can be replaced by three independent analysis models.

The back EMF of the AFPMSG at no-load condition has been calculated using Faraday's law of electromagnetic induction based on the time variation of magnetic flux: The magnetic flux can be obtained through the magnetic flux density B on the cross-section surface inside the each coil. A detailed description of the proposed analytical method for the magnetic field distribution and EMF calculation will be presented in final paper.

Results and discussion

The comparison between analytical and FEM solution of magnetic flux density distribution under no-load condition calculated at the central radius of PMs in the centre of air-gap is presented in Fig.1. Analytical, FEM and measurement results of the back EMF under no-load condition according to displacement are presented in Fig.2. The final paper will also present the analytical calculation of magnetic flux density and back EMF in dependency on both, armature current and mechanical angle. EMF calculation will be verified by the FEM and measurements.

Conclusion

In order to obtain the analytical solution of magnetic flux density, the program environment Matlab is used. For the verification of the analytical solution of magnetic flux density the FEM is accomplished using Ansys program package.

Analytically calculated magnetic flux density is in very good agreement with the results obtained by FEM, while the analytical solution of back EMF is in good agreement with measurements and FEM. Moreover, the FEM and measurements confirm the validity of the proposed analytical method. The main advantage of this method is more than 500 times shorter computational time and more flexible computation for the back EMF calculation in comparison to FEM.

The analytical method presented in this work is very convenient for comprehensive studies and have already been incorporated into design and optimisation processes of the coreless AFPMSG.

Theoretical and experimental studies of structural characteristics, magnetic response and electronic properties of $\text{Sr}_2\text{FeMnO}_6$ double cubic Perovskite.

J. A. Rodriguez, D. A. Landinez-Tellez, R. Cardona, F. E. Fajardo, J. Roa-Rojas
Physics Dept., Universidad Nacional de Colombia, Bogotá, Colombia

The aim of this work is to carry-out calculations in order to predict the main electronic and structural properties of $\text{Sr}_2\text{FeMnO}_6$. We have found that the $\text{Sr}_2\text{FeMnO}_6$ presents a metallic behavior. On the other hand, structural features were studied on polycrystalline samples synthesized by solid state reaction method. This study was carried through Rietveld analysis on X-ray diffraction (XRD) pattern. From the results, we conclude that it crystallizes in the FCC structure (space group #225).

Samples were synthesized by means of the standard solid state reaction method. Precursor powders of SrO , FeO and MnO_2 (Aldrich 99.9%) were stoichiometrically mixed according to the nominal composition $\text{Sr}_2\text{FeMnO}_6$. X-Ray diffraction was made by means a PW1710 diffractometer with $\lambda_{\text{CuK}\alpha} = 1.5406 \text{ \AA}$. Rietveld refinement of the pattern was made by means of code GSAS. Magnetic response was investigated through DC magnetic susceptibility measurements by using a Quantum Design model 2000 MPMS SQUID system.

We use the wien2k [1], which is a program based on Density Functional Theory (DFT) [2,3] in the GGA approximation. The unitary cell volume was optimized by minimization of energy, but the internal parameter x (O-coordinate) was optimized by means of the minimization of global forces on the atoms. The minimum of force on the oxygen atom was about of 12.5 mRy/a.u. and the parameter x was equal to 0.250953. The muffin-tin radii used, in ua, were 1.87, 2.20, 1.86 and 1.69 for Fe, Sr, Mn and O respectively. Other parameters of wien2k were: RMT×Kmax = 8.0 and Gmax=14.0. We used 165 k-points over the irreducible Brillouin zone and the maximum angular momentum was $l=10$.

From the fitting to the Murnaghan's state equation of the energy as a function of volume, we obtain the value of 3656.585 ua^3 (541.850 \AA^3) for the volume total cell, lattice constant equal to 15.406 ua (8.153 \AA) and bulk modulus $\sim 9 \text{ MBar}$. Rietveld analysis, reveals that $\text{Sr}_2\text{FeMnO}_6$ has the characteristic superstructure of a cubic perovskite type with $\text{A}_2\text{BB}'\text{X}_6$ formula. The matching between experimental and calculated results for the lattice constant parameter is 98.6%.

Figure 1 shows the spin-polarized total density of states (DOS) and DOS projected on the like-atomic orbitals of Fe, Mn and O. Fermi level is the reference for energies. It is observed that the material behaves as a metallic system. The metallic characteristic of the material is due to a little DOS above the Fermi level. That little DOS is due to the $\text{up-}P_z\text{-O}$, $\text{up-}D_{eg}\text{-Fe}$ and $\text{dn-}P_x+P_y\text{-O}$ orbitals. The material exhibits a total magnetic momentum of $\sim 7.6 \mu_B$ in the cell. By chemical formula the magnetic momentum is $\sim 1.9 \mu_B$. That value is mainly due to Fe and Mn atoms with a contribution of $\sim 43.7\%$ and $\sim 56.3\%$ for Fe and Mn respectively. In the figure we observe that the contribution of the D-orbitals of Fe and Mn are the most important for the total magnetic momentum. Magnetic response of $\text{Sr}_2\text{FeMnO}_6$ has been investigated by measuring the DC magnetic susceptibility in the temperature range 5 to 300 K and at an applied magnetic field of 5 kOe. Figure 2 shows the temperature dependence of the DC magnetic susceptibility. Experimental data of this picture can be fitted well with the Curie-Weiss law $\chi = \chi_0 + C/(T - \theta_c)$, where $C = N\mu_{\text{eff}}^2/3k_B$ is the Curie constant, N is Avogadro's number, μ_{eff} is the effective magnetic moment, k_B is the Boltzmann constant, θ_c is the paramagnetic Curie temperature and χ_0 is the temperature independent susceptibility term. We obtain that χ_0 is $1.67 \times 10^{-3} \text{ emu/mol}$, $C = 1.01289 \text{ emu K/mol}$, $\theta_c = 1.9995 \text{ K}$ and the effective magnetic moment per unitary formula $\mu_{\text{eff}} = 2.80 \mu_B$.

Manganites, with a general formula of $\text{T}_{1-x}\text{D}_x\text{MnO}_3$, where T is a trivalent rare earth element and D is a divalent alkaline earth element still challenge our understanding. Much attention has been devoted to these perovskite compounds due to their peculiar magnetic and electronic properties. The entanglement between lattice, spin, charge and orbital degrees of freedom leads to phenomena like phase separation, polaron clusters and charge ordered (CO) states that occur not only at a macroscopic level but also appear at the nanometer scale. To achieve a better understanding on the small bandwidth manganites, where the mentioned phenomena tend to be more pronounced, a local probe study was performed in $\text{Pr}_{1-x}\text{Ca}_x\text{MnO}_3$. In order to obtain the desired local scale information on the different magnetic and electronic states along the system phase diagram a hyperfine field systematic study was carried out using Perturbed Angular Correlation spectroscopy (PAC) via the $^{111}\text{m}\text{Cd}$ probe. This nuclear hyperfine method is specially effective to sample atomic scale environments and its efficiency is temperature independent allowing to explore a wide range of temperatures. The measurement of the Electrical Field Gradient (EFG) tensor and the Magnetic Hyperfine Field (MHF) at the Ca/Pr site was performed in a series of samples ranging from $x=0$ to 1, in the 10 K to 1000 K temperature range.

The macroscopic characterization of the produced polycrystalline samples shows good agreement with the literature results. As expected, our structural analysis revealed that samples stabilize in an orthorhombic structure [1,2]. The study of the magnetic properties, also in good agreement with the literature [1,3,4], allowed to determine the characteristic Curie-Weiss, Néel (T_N), Curie (T_C), and charge-order (T_{CO}) temperatures.

The macroscopic information was correlated with systematic PAC measurements performed in the same samples. At room temperature the principal component of the EFG, V_{zz} , decreases with increasing Ca content, i.e., with the decrease of the orthorhombic distortion. Moreover we found that the CO region of the phase diagram delimits distinct regimes for the dependence of EFG parameters on Ca content. For samples that belong to the region of the phase diagram where CO effects occur (in the 151 K to 275 K temperature range) we found that the EFG parameters depend strongly on Ca content. As mentioned above, although a decrease of V_{zz} with Ca content could be expected in terms of the trend of the lattice parameters, a sharp decrease around $x=0.32$ (where CO effects appear) was surprisingly found. This shows that at the Pr/Ca lattice site, contributions to V_{zz} other than the static lattice contribution become important. The observed sharp decrease around $x=0.32$ can be understood when the temperature dependence of the EFG of the whole system is considered. This study revealed that samples outside the CO region of the $\text{Pr}_{1-x}\text{Ca}_x\text{MnO}_3$ phase diagram have the expected increase of V_{zz} with decreasing temperature without any noticeable anomaly. On the other hand, for samples within the CO region, the common increase of V_{zz} with decreasing temperature is only observed for temperatures above $T' \gg T_{CO}$. Below T' a clear anomalous decrease of V_{zz} is found when decreasing temperature and this feature remains till the

charge-order temperature is reached, showing that CO effects are preceded by anomalous lattice dynamic effects. It is also shown that this anomalous decrease of V_{zz} when decreasing temperature is responsible for the sharp decrease of V_{zz} vs Ca concentration, observed at room temperature in the CO region.

The study of the magnetic hyperfine field for the $\text{Pr}_{1-x}\text{Ca}_x\text{MnO}_3$ system was also performed and the low T measurements on the end-members revealed the presence of a hyperfine magnetic field $B_{hf}=1.2\text{ T}$ at 10 K in PrMnO_3 compound while no measurable MHF is present in CaMnO_3 . Both systems are quoted in literature as having a pure antiferromagnetic arrangement of the Mn ions [5, 6], thus the MHF should vanish at the probe site. The MHF measured below 77 K for PrMnO_3 may be associated to the onset of magnetic order of Pr moments. This ordering is refereed in literature [7] as being responsible for a small canting of both the Pr and Mn magnetic sub-lattices yielding a non vanishing magnetic field at the probe site. For samples with low Ca concentrations ($x<0.14$) a small MHF ($B_{hf}<0.7\text{ T}$) was detected at 77 K in accordance with the spin canted magnetic state [6] whereas for $x=0.95$ no MHF was found, although some reports claim the existence of a small percentage of ferromagnetic domains embedded in an antiferromagnetic matrix [8]. Below T_C , in the $x=0.25$ compound, a $B_{hf}=4.4\text{ T}$ at 11 K was measured, compatible with a fully ferromagnetic environment. In the CO $x=0.35$ compound we had to consider also the presence of a MHF. In literature either a canted AF-CE-type magnetic structure [4, 6] or a AF-CE/FM phase coexistence [4, 8] has been reported. To ascertain about the existence of a canted AF-CE-type magnetic structure or a AF-CE/FM phase coexistence we performed two distinct fits for spectrum at 11 K. Our MHF results suggest that the magnetic configuration of the Mn ions should be a canted AF-CE-type. Similar conclusions are drawn for the compound with $x=0.32$.

Ever since Colossal Magnetoresistance was discovered in $\text{Ln}_{1-x}\text{A}_x\text{MnO}_3$ systems (Ln = lanthanide and A = alkaline-earth)[1] an extensive research on compositional variations of manganese perovskite related oxides has been performed allowing a deeper knowledge of the intriguing composition-structure-properties relationship on these materials. In this way, compositional variations in the anionic sublattice of $\text{La}_{0.5}\text{Sr}_{0.5}\text{MnO}_3$ have been introduced in order to stabilize a new manganite superstructure with $\text{La}_{0.5}\text{Sr}_{0.5}\text{MnO}_{2.5}$ composition.[2] Structural characterization by means of X ray and electron diffraction confirms brownmillerite structure for $\text{La}_{0.5}\text{Sr}_{0.5}\text{MnO}_{2.5}$, where oxygen deficiency is accommodated along [101] and in this sense, this material can be understood as an intergrowth of alternating octahedral and tetrahedral layers along b direction.

A neutron diffraction study was performed in order to know the magnetic structure. The analysis date reveals a G-type antiferromagnetic (AFM) structure at 5 K where the magnetic moments of Mn are AFM coupled not only in the Mn-O layers but also between them. The thermal evolution confirms this ordering is kept to 140 K where paramagnetic state is reached. However, a magnetometry study reveals an evident Ferromagnetic (FM) contribution to room temperature[2]. This behaviour would be related to double exchange interactions in the octahedral layers thanks to Mn^{4+} and Mn^{3+} presence. FM interactions are not detected by neutron diffraction probably due to the short range character which provides a too weak signal. Moreover, the AC susceptibility measurements show a cusp at temperature close to 70 K. The position of this cusp depends on the frequency of the AC magnetic field which could be related to spin glass behaviour.

Anisotropic magnetoresistance in ferromagnetic manganites.

M. Granada, J. Rojas Sánchez, L. B. Steren, J. D. Fuhr, B. Alascio
Centro Atómico Bariloche (Comisión Nacional de Energía Atómica) and CONICET, San Carlos de Bariloche, Argentina

Magnetoresistive phenomena are of great interest due to their potential applications in spintronics devices. The anisotropic magnetoresistance (AMR), which describes the dependence of the resistivity with the angle between the electric current and the magnetization, is a general property of ferromagnetic (FM) materials. This dependence can be written as [1]

$$\rho(\theta) = 1/3\rho_{\parallel} + 2/3\rho_{\perp} + (\cos 2\theta - 1/3)(\rho_{\parallel} - \rho_{\perp}), \quad (1)$$

ρ_{\parallel} and ρ_{\perp} being the resistivity with the electric current \mathbf{I} applied parallel and perpendicular to the magnetization \mathbf{M} , respectively, and θ the angle between \mathbf{M} and \mathbf{I} . The AMR is defined as the ratio $\text{AMR} = \Delta\rho/\rho_{\text{ave}} = (\rho_{\parallel} - \rho_{\perp}) / (1/3\rho_{\parallel} + 2/3\rho_{\perp})$, (2)

usually multiplied by 100 for the results to be expressed in percent.

This effect is also present in FM manganites and it has been studied by many authors [2]. However, the results are commonly discussed on the basis of an existing model that has been developed for transition metals [3], where the conduction mechanism is completely different from that of manganites. In this work we performed a study of the dependence of the AMR with temperature in manganite films and based on this results we envisage a model to describe the anisotropic transport in manganites. We deposited $\text{La}_{0.75}\text{Sr}_{0.25}\text{MnO}_3$ films of different thicknesses on SrTiO_3 (001) single crystalline substrates by dc sputtering. X-ray diffraction patterns show that the samples grow textured in the (001) orientation of the substrates. Magnetization curves indicate that the Curie temperature T_C of the samples is close to 300 K and the saturation is near the nominal one.

The electric transport measurements were performed in the standard four lead configuration with the electric contacts aligned in the (100) direction on the plane of the films. A magnetic field $H = 10$ kOe, well above the saturation field, was applied on the plane of the films during the AMR measurements. In this way we can ensure that the magnetization is oriented parallel to the magnetic field, and thus the angle θ can be measured as the angle between \mathbf{H} and \mathbf{I} . We measured $\rho(\theta)$ curves at different temperatures. Each curve was fitted with eq.(1), and from the parameters obtained we calculated the AMR for each temperature, using eq.(2).

In fig.1 the AMR, as well as the parameters $\Delta\rho = \rho_{\parallel} - \rho_{\perp}$ and $\rho_{\text{ave}} = 1/3\rho_{\parallel} + 2/3\rho_{\perp}$, are presented for three different samples. The behavior is similar in all the cases. At low temperatures, the AMR (fig.1.a) is nearly constant and negative, decreasing abruptly at temperatures close to T_C (magnetization curves are shown as an inset in fig.1.c). The ρ_{ave} curves (fig.1.b) reproduce the $\rho(T)$ measurements; the metal-insulator transition is above room temperature and so, the resistivity increases monotonously below 300 K. The difference $\Delta\rho$ is negative (i.e. $\rho_{\parallel} < \rho_{\perp}$) in all the temperature range, presenting a minimum and then a drop at T_C (fig.1.c). This drop is to be expected since the magnetization, which is at the origin of AMR, disappears.

It is clear that the sign of the AMR and its decrease at T_C are related to the behavior of $\Delta\rho$. We analyzed the dependence with temperature of the obtained parameters in order to get some insight on the origin of the anisotropy. We studied the particular case of the 20 nm thick film. At temperatures lower than 250 K, $\rho(T)$ curves can be described by

$$\rho(T) = A + BT^2 + CT^5, \quad (3)$$

corresponding A to scattering of electrons with impurities and defects, BT^2 to electron-electron scattering and CT^5 to scattering of electrons with phonons. From fitting eq.3 to $\Delta\rho$ and ρ_{ave} , we

obtained the parameters A , B and C for ρ_{\parallel} and ρ_{\perp} . The contribution of the BT^2 term to the resistivity is larger than the CT^5 one for $0 < T < 200$ K. All of the coefficients of ρ_{\perp} are larger than those of ρ_{\parallel} , but the difference is more important in the coefficient B . This indicates that the origin of the anisotropy lays on electron-electron interactions. Inspired in this idea, we propose a model that takes into account the effect of the spin-orbit interaction on the electronic states of the ferromagnetic manganite. Preliminary calculations performed at 0 K (half-metallic state), are in agreement with the experimental result $\rho_{\parallel} < \rho_{\perp}$. Work is in progress for introducing the temperature dependence in the calculations.

The magnetic ordering in electron-doped ($x > 0.5$) manganites $\text{La}_{1-x}\text{Ca}_x\text{MnO}_3$ shows a strong anti-ferromagnetic (AFM) component and a charge ordered (CO) state upon heating. In particular, bulk $\text{La}_{0.4}\text{Ca}_{0.6}\text{MnO}_3$ (LCMO) compound has the critical temperatures of such transitions $T_N \sim 150$ K and $T_{CO} \sim 260$ K [1]. Lu et al [2] claimed that the reduction of the LCMO samples dimension down to nanometer scale changes dramatically their magnetic ordering: ferromagnetic (FM) like ground state with spontaneous magnetization $M_S \sim 1 \mu_B/\text{f.u.}$ at 5 K appeared in LCMO powders with grain sizes of 60 and 20 nm. The AFM/CO state in bulk LCMO is known to be stable against external perturbations, so the data by Lu et al seems to be questionable.

To explore the size effect in LCMO, the dc magnetic and electron magnetic resonance (EMR) measurements were carried out on bulk and nano LCMO in the ranges $5 \text{ K} \leq T \leq 350 \text{ K}$ and $5 \text{ K} \leq T \leq 600 \text{ K}$, respectively. Bulk samples were synthesized by solid state reaction at highest $T = 1350^\circ \text{C}$ in an air. To check the influence of non-stoichiometry, two bulk samples with slightly different compositions: $(\text{La}_{0.4}\text{Ca}_{0.6})_{0.99}\text{MnO}_3$ and $\text{La}_{0.4}\text{Ca}_{0.6}\text{MnO}_3$ (labeled further as Cer1 and Cer2) were studied. The LCMO nano-powder with mean grain size of 17 ± 2 nm was prepared by the sonication-assisted co-precipitation [3] and subsequent crystallization at 900 K. The single phase nature of the samples structure being described by the P_{nma} space group, is shown by XRD. The lattice parameters are closed to each other, but demonstrate some compression of unit cell in nano LCMO, see Table.

The M versus T dependences measured at dc magnetic field $H = 1 \text{ T}$ reveal the maxima at critical $T_{CO} \sim 260 \text{ K}$ and $\sim 267 \text{ K}$ in Cer1 and Cer2, respectively. The low-T frustration of magnetic state - the difference between field-cooled (FC) and zero field-cooled (ZFC) curves is observed below $\sim 200 \text{ K}$ in both ceramics. The M vs. H hysteresis loops measured at $T = 5 \text{ K}$ and at $H \leq 5 \text{ T}$ demonstrate that non-collinear magnetic ordering with non-saturated M and very small $M_S \sim 0.02 \mu_B/\text{f.u.}$ is characteristic of both Cer1 and Cer2 samples. The pronounced size effect is registered - for nano LCMO M vs. T curve shows the shoulder near 260 K and the broad maximum at $\sim 200 \text{ K}$. The difference between FC and ZFC magnetizations is observed just below $T_{CO} \sim 260 \text{ K}$ and the low-T M_S increases up to $\sim 0.05 \mu_B/\text{f.u.}$ These results definitely contradict the data by Lu et al [2]. However, they agree with our EMR measurements.

E.g., the doubly integrated intensity of EMR signal (DIN) of bulk Cer1 and nano LCMO correlates pretty well with their M vs. T dependences - the maximum at $T_{CO} \sim 260 \text{ K}$ and the shoulder at this temperature together with maximum at $T \sim 185 \text{ K}$ are observed in these samples, respectively. Moreover, the sharp decrease of DIN vs. T (which is usually attributed to appearance of low-T AFM ordering [4]) is recorded for all samples studied upon cooling. However, such decrease is less pronounced in nano LCMO, which means that its low-T FM component, though small, is stronger comparing to the bulk samples.

The nature of magnetic correlations and magnetic ordering in bulk and nano LCMO was studied also by means of the model fittings [5] of electron paramagnetic resonance (EPR) parameters. It appears that DIN^{-1} vs. T (at PM state DIN is proportional to susceptibility) obeys a Curie-Weiss

(CW) law with positive CW temperatures Θ_{CW} , see Table. Independent fitting of the PM line width vs. T with the Huber model [6] resulted in the Θ_{CW} values close to those obtained from the DIN^{-1} fits. The characteristic high-T asymptotes $\Delta H_{\text{pp}}(\infty)$ for the two ceramics are close to each other being smaller than this one for nano LCMO, see Table. Validity of the model [6] means that the ion-ion spin relaxation mechanism prevails in all samples studied.

In summary, the XRD data shows that both the cation composition and oxygen stoichiometry in bulk and nano LCMO are close. The AFM/CO order remains stable upon the reduction of the samples sizes. However the low-T FM component proves enhanced in nano LCMO as compared to its bulk counterparts, supposedly due to strong surface and inter-grain interaction effects. FM correlations in all LCMO samples are strong at PM state (large positive Θ_{CW}), which is an electron-doping effect. The domination of ion-ion spin relaxation at PM state and drastic fading of the FM correlations upon cooling mean that the excess electrons are localized - the lower T the deeper the localization. Even small changes of the oxygen stoichiometry notably influences magnetic ordering in LCMO that allows us to suppose that FM like order in nano LCMO reported by Lu et al [2] may be induced by a non-stoichiometry in their sol-gel prepared samples.

EMR probing of magnetic ordering in $\text{Pr}_{1-x}\text{Sr}_x\text{MnO}_3$ ($x = 0.22, 0.24, 0.26$) manganite single crystals.

A. I. Shames¹, E. Rozenberg¹, Y. M. Mukovskii², G. Gorodetsky¹

The $\text{Pr}_{1-x}\text{Sr}_x\text{MnO}_3$ (PSMO) compounds are known to mimic in many ways the behavior of the prototypical $\text{La}_{1-x}\text{Ca}_x\text{MnO}_3$ (LCMO) system of doped manganites [1]. The two systems have the same sequence of magnetic phases upon doping, and comparable percolation threshold x_c , i.e., the critical doping level at which a crossover from a localized-type conductance to the itinerant one occurs [2,3]. This crossover is accompanied by transition from inhomogeneous to homogeneous ferromagnetic (FM) ground state. However, recent studies of magnetic and transport properties [4], as well as neutron diffraction (ND) measurements [5], carried out on PSMO single crystals with Sr-doping level in the vicinity of $x_c = 0.24$, reveal some notable differences between LCMO and PSMO, e.g., specific charge ordering of Mn^{4+} and Mn^{3+} ions, as well as low-temperature FM like order of Pr-subsystem in the PSMO.

To obtain a deeper insight into the nature of magnetic ordering in near-critically doped PSMO, the X-band ($\nu = 9.4$ GHz) electron magnetic resonance (EMR) measurements were carried out in the temperature interval $5 \text{ K} \leq T \leq 600 \text{ K}$ on single crystalline samples of PSMO ($x = 0.22, 0.24, 0.26$) grown by a floating zone technique, using radiative heating [6], labeled here as PSMO-22, PSMO-24 and PSMO-26. The T -dependences of the following EMR spectra parameters: the resonance field H_r , peak-to-peak line width ΔH_{pp} and the doubly integrated intensity (DIN, proportional to the EMR susceptibility χ_{EMR}) were analyzed. The results obtained were compared with those on dc/ac magnetic and transport properties reported for these PSMO crystals in Ref. [4]. The FM Curie temperatures $T_C = 168 \pm 1 \text{ K}$, $177 \pm 1 \text{ K}$ and $203 \pm 1 \text{ K}$ are characteristic for PSMO-22, PSMO-24 and PSMO-26, respectively.

In the paramagnetic (PM) region far above the T_C , the single Lorentzian like resonance line is observed. Its resonance field H_r is T -independent and close to 340 mT, corresponding to the PM g -factor of 1.98 ± 0.01 for all samples studied. At a certain temperature the low field shift of the signal occurs and the line distorts, which results in appearance of multiline spectra at low T . Namely, two signals with distinct low and high field H_r having different T dependences are observed in all samples below about 200 K. In addition, the third EMR signal becomes observable below $\sim 85 \text{ K}$ (PSMO-24) and $\sim 100 \text{ K}$ (PSMO-26).

The intensity of EMR absorption (DIN) increases upon cooling, shows maxima at $T \sim 185 \text{ K}$ in PSMO-26 and at $T \sim 145 \text{ K}$ in both PSMO-22 and PSMO-24 crystals. Further cooling results in vanishing of DIN in PSMO-22 below 30 K, whereas DIN in PSMO-24 and PSMO-26 remains observable down to the lowest temperatures. Moreover, the low- T shoulder is detected on DIN vs. T dependences of both PSMO-24 and PSMO-26, reflecting the appearance of the third low- T EMR signal. It is important to note that definitely non-linear dependences of inverse DIN vs. T are observed in wide interval of PM temperatures $\sim 300 - 600 \text{ K}$ in all samples studied. The line width ΔH_{pp} versus T shows minima at $\sim 180 \text{ K}$, 200 K and 225 K in PSMO-22, PSMO-24 and PSMO-26, respectively and increases upon further heating.

Using our previous results regarding EMR in near-critically doped LCMO [7], we analyzed the data obtained in terms of specific ferromagnetic insulating (FMI) phase, appearing in PSMO below T_C . This suggestion is strongly supported by the outcomes of very recent ND studies carried out on PSMO ($x = 0.22$ and 0.24) crystals [5]. In particular, it was directly shown that specific quasi-stat-

ic charge ordering of “1/4-type” occurs in these samples. This, in turn, means that the localization of charge carriers takes place in full agreement with the model of FMI phase appearance. It seems that the FM like order of Pr-subsystem, detected by magnetic measurements in Ref. [4], manifests itself in appearance of the third low- T EMR line in PSMO-24 and PSMO-26 crystals. Its absence in PSMO-22 may be connected with the enhanced effects of charge ordering and FMI state of Mn-subsystem in this sample, being in insulating like state within the whole T -interval of our measurements.

The non-linear dependences of inverse DIN vs. T at PM state agrees pretty well with the inverse ac magnetic susceptibility vs. T curves detected in Ref. [5] on PSMO crystals. This means that the strong short-range order persisting at PM state of PSMO leads to notable deviation of inverse DIN/susceptibility vs. T curves from a linear Curie-Weiss like dependence. E.g., the short-range charge ordering was observed in PSMO at least up to 350 K in Ref. [5]. Let us note that the line width ΔH_{pp} vs. T curves at PM state demonstrate increasing contribution of charge carriers spin relaxation mechanism [8] with increasing of Sr content. All these facts allow us to conclude that replacing of the lanthanum ions by the praseodymium ones weakens the double exchange and favors the persistence of localized nonmetallic states of charge carriers in both FM and PM states of near-critically doped PSMO.

Magnetic and magnetoresistive properties of $\text{Pr}_{1-x}\text{Ca}_x\text{CoO}_3$ ($x=0.3, 0.5$) cobaltites.

I. G. Deac¹, R. Tetean¹, D. Andreica^{1,2}, E. Burzo¹

1. Physics, Universitatea Babes-Bolyai, Cluj-Napoca, Romania; 2. Laboratory for Muon-Spin Spectroscopy, Paul Scherrer Institut, Villigen, Switzerland

Since the discovery of the “colossal” magnetoresistance MR effect in manganites, the search for the next MR materials has been widely conducted in various transition-metal oxides. Doped cobaltite perovskites $\text{Ln}_{1-x}\text{A}_x\text{CoO}_3$ (Ln = rare earth and A = Ca, Sr, Ba), have recently attracted much attention due to their unique feature to change the spin-state of the Co^{3+} ion. The spin-state of undoped LnCoO_3 exhibits a gradual crossover with increasing temperature, from the low-spin (LS) state ($t_{2g}^6 e_g^0$) to the intermediate-spin (IS) state ($t_{2g}^5 e_g^1$) or to the high-spin (HS) state ($t_{2g}^4 e_g^2$) [1]. Upon doping A^{2+} ions into LnCoO_3 , some of trivalent Co ions become tetravalent, and these also contain a mixture of low and higher spin states. Both double and superexchange interactions are present in these compounds. The competition of different kinds of interactions leads to a highly inhomogeneous ground state characterized by the coexistence of FM regions, spin-glass regions, and hole-poor LS regions [2,3].

In the present work, the physical properties of perovskite cobaltites, $\text{Pr}_{0.7}\text{Ca}_{0.3}\text{CoO}_3$ and $\text{Pr}_{0.5}\text{Ca}_{0.5}\text{CoO}_3$ have been investigated. The polycrystalline samples were prepared by the conventional ceramic method. The samples were single perovskite phase of orthorhombic $Pbnm$ symmetry. Electrical measurements were carried out by the four-probe method. The magnetization measurements were done in a cryostat by using DC extraction method. The μSR (muon spin rotation/relaxation/resonance) experiments were performed at the GPS spectrometer at the Paul Scherrer Institute.

Preliminary measurements of the magnetization in 1 T field for the samples, with $x = 0.3$ and $x = 0.5$, do not show distinct ferromagnetic transitions down to about 50 K and 70 K, respectively. There are some slight changes in the magnetization as a function of temperature, but these cannot be seen as genuine ferromagnetic transitions (Fig. 1.). The shape of $\chi - T$ curves is rather complex, not typical of normal ferromagnets. A paramagnetic Curie temperature (θ_p) can be estimated from the linear part of the reciprocal susceptibility, to be -25 K, while the effective paramagnetic moment is $3.71 \mu_B$ for the sample with $x = 0.3$. The ac susceptibility measurements show a sharp, frequency dependent peak for both the real χ' and the imaginary χ'' components of the complex susceptibility at 16 K, for the sample with $x = 0.3$ when $H_{ac} = 1$ Oe (Fig. 1.). For the sample with $x = 0.5$, a broad maximum was found in ac susceptibility at about 75 K. The μSR measurement showed a missing asymmetry below 55 K for $\text{Pr}_{0.7}\text{Ca}_{0.3}\text{CoO}_3$ indicating the presence of magnetic clusters. In the $x = 0.5$ sample a decrease of asymmetry occurs below 70 K, suggesting the onset of magnetic order. A paramagnetic insulating phase was found to develop and to coexist with the ferromagnetic one below 30 K [3]. Generally, the magnetic measurements indicate that these cobaltites are magnetically inhomogeneous, with small ferromagnetic clusters or domains being present in a paramagnetic and/or an antiferromagnetic matrix, as a consequence of the spin-state transition of $\text{Co}^{3+}/\text{Co}^{4+}$ ions. The resistivity decreases with increasing temperature for both samples, in spite of their low “metallic” values. The sample with $x = 0.3$ has a low negative magnetoresistance MR, of a few percents, while for the sample with $x = 0.5$ we found $\text{MR} \sim 22\%$ (Fig. 2). The electrical behavior of the studied samples has the main features of conduction in a phase separated system: it shows negative magnetoresistance and it is controlled by grain-boundary effects.

The growth of heterostructures combining oxide materials is a new strategy to design novel artificial multifunctional materials with interesting behaviors ruled by the interface. In heterostructures involving oxide superconductors and colossal magnetoresistance (CMR) ferromagnets interfaces are especially complex, with ferromagnetic (F) and superconducting (S) properties at the interface depressed over nanometer length scales. Recently, F/S structures made of YBa₂Cu₃O₇ (YBCO) and La_{0.7}Ca_{0.3}MnO₃ (LCMO) have attracted considerable attention [1,2]. The critical temperature of the superconductor depends on the relative orientation of the magnetization of the F layers, giving rise to a new giant magnetoresistance (GMR) effect which might be of interest for spintronic applications. Large positive magnetoresistance peaks occur for antiparallel (AP) alignment of the manganite layers, much resembling the GMR in metallic superlattices, resulting from enhanced interface scattering in the AP configuration.

Detailed study of the magnetic properties of the ferromagnetic manganite thinfilm electrodes are necessary in order to gain a better understanding of the functioning of these F/S devices. Manganite monolayers as thin as 3 nm exhibit clear ferromagnetic hysteresis loops (Fig. 1, left panel). The saturation magnetization does not diminish in thin manganite films indicating a lack of a pronounced magnetic dead layer. The coercive field increases drastically in thinner films, indicating the possibility of fabricating trilayers with AP configuration. Nevertheless, the field of saturation is also larger in thinner films raising the possibility that the magnetization lies out of the film plane. Temperature dependent resistivity is shown in the right panel of Fig. 1. Films thicker than 6 nm behave metallically at low temperature with well defined metal insulator transition, although the thinnest films remain insulating at low temperature.

As the AP configuration in low external magnetic field is needed for the GMR effect, it is important to know the direction of easy axes of magnetization in the individual F layers. Using ferromagnetic resonance we map the direction of the in-plane easy axes in 5 and 15 nm thick LCMO films and find that both exhibit biaxial symmetry, similar to LSMO films [3]. Nevertheless, the symmetry direction in the two films is rotated by 45 degrees with respect to the crystallographic directions. In the 5 nm film the in-plane easy axes are the (100) and (010) while in the 15 nm film the easy axes are the (110) and (1-10), indicated by the minimum values of the resonance field (Fig. 2).

As the thickness of the manganite thinfilm is shown to be responsible for dramatic changes in the magnetic and metallic behaviour of the electrode, it is important to study the properties of manganite thinfilms as they form part of various F/S bilayer structures. The YBCO underlayer in particular may alter the magnetic properties of the manganite thinfilm. The coercive field of 15 nm thick manganite thinfilms grown on STO with YBCO on top are much smaller (around 50 Oe) than that of similar manganite thinfilms grown on YBCO (150-300 Oe). The saturation magnetization is reduced considerably in manganite thinfilms grown on YBCO (~320 emu/cm³) vs. those grown on STO (~580 emu/cm³).

In-situ strain effect on extrinsic electrical transport and magnetotransport in $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ films.

R. Gangineni, L. Schultz, I. Mönch, K. Dörr

Institute for Metallic Materials, Leibniz Institute for Solid State and Materials Research Dresden, Dresden, Germany

In recent years, grain boundaries in conducting ferromagnetic manganites have been studied extensively for their spin-polarized electron tunneling associated with large magnetoresistance. In this work, we focus on the change of extrinsic electric transport and magnetotransport properties with respect to in-situ strain of epitaxial $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ films grown on PMN-PT ($0.72\text{Pb}(\text{Mg}_{1/3}\text{Nb}_{2/3})\text{O}_3-0.28\text{PbTiO}_3$) containing etched steps. Application of an electric field E along the substrate normal allows reversible control of the in-plane piezoelectric strain. A reversible strain of about 0.11% is acquired with an application of 10 kV/cm to the piezoelectric substrate [1,2]. The steps on PMN-PT substrate are defined by optical lithography and ion beam etching with a height between 300 and 600 nm and a step width of 25 μm . Films of 20 to 70 nm thickness are grown using off-axis pulsed laser deposition. The piezoelectrically induced biaxial in-plane strain can be compressive or tensile. With decreasing temperature (T), the electric coercive field (E_C) increases considerably, enlarging the field range $|E| < E_C$ available for the in-plane expansion. Strain-dependent loops of resistance (R) recorded during one cycle of the electric field for several temperatures are shown for sample A (20 nm) in Fig.1. The in-plane expansion reaches large values for $E < 0$. This is reflected in the extremely large R enhancements observed at 70 K and 90 K for negative E . Left axis of Fig.2 represents the temperature dependent R of a 20 nm film with respect to applied strain of 0.05% and in no applied strain. On right axis of Fig.2, temperature dependence of gauge factor Γ (defined as the ratio of the relative R change and the change in strain) is displayed. The change in resistance with respect to applied strain varies according to thickness of the film. The strain-induced R change of the film (20 nm) is large (20-25%) for $50\text{ K} < T < 300\text{ K}$ in contrast to the strain response of the film on the step free substrate [1]. The effect of strain in magnetic fields up to 5 T is shown in Fig.3 for sample A (20 nm). The high-field part of the grain boundary MR has been attributed to field-induced magnetic ordering of Mn spins in a magnetically less ordered layer at the grain boundaries [3]. The effect of strain on the magnetism of these layers is an interesting question, addressed in earlier work [4]. Decrease in MR ($H = 5\text{ T}$) in the compressed state ($E = 7.1\text{ kV/cm}$) and increase in the expanded states ($E = -1.8$ to -7.1 kV/cm) in comparison with the piezo strain-free case ($E = 0$) is observed [2]. In summary, reversible strain variation in step edge junctions in spin-polarized $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ films has been demonstrated utilizing piezoelectric substrates of PMN-PT. Both R and MR decrease (increase) significantly upon in-plane compression (expansion). Further, the results obtained from the effect of strain on polycrystalline films and films deposited on single steps of PMN-PT substrates are compared.

Electron-doped manganites such as $\text{La}_{1-x}\text{Ca}_x\text{MnO}_3$ ($x > 0.5$) with Mn(IV)/Mn(III) ratios greater than one are typically insulators which exhibit several interesting properties including a charge-ordering (CO) transition followed by an antiferromagnetic ordering at lower temperatures.[1] Since this CO state is accompanied by a lattice stiffening, its formation and stability are very sensitive to how the spin, charge, and lattice degrees of freedom interact and compete. Thus the substitution of another 3d-element at the Mn-site can have a dramatic effect on the magnetic properties including the total suppression of the CO state and the appearance of a low-temperature ferromagnetic phase. Even an insulator-to-ferromagnetic metal transition accompanied by a colossal magnetoresistance (CMR) has been observed.[2,3] Moreover, recent investigations have shown that phase separation can occur at the local level in various doping regimes such that the appearance of a CMR effect might also arise from the coexistence of ferromagnetic metallic regions with these CO insulating domains.[4,5] Cr substitution is a particularly interesting substitution as Cr^{3+} is isoelectronic with Mn^{4+} and the magnetic interaction $\text{Cr}^{3+}\text{--O--Mn}^{3+}$ is known to favor ferromagnetism through the superexchange mechanism. Hence, the effect of Cr substitutions on the structural, magnetic, and electrical transport properties of electron-doped $\text{La}_{0.3}\text{Ca}_{0.7}\text{Mn}_{1-y}\text{Cr}_y\text{O}_3$ ($y = 0.0, 0.10, 0.15, 0.20$, and 0.25) polycrystalline samples prepared by sol-gel technique have been investigated between 5 and 300 K in magnetic fields ranging from 0 to 5 Tesla. The CO transition at 260 K and the antiferromagnetic transition at 170 K observed in the parent manganite ($y = 0.0$) are gradually suppressed and occur at lower temperatures while the onset of a ferromagnetic remanence grows with the addition of Cr until only ferromagnetic-like behavior is observed in the $y \geq 0.20$ manganites. These features along with a magnetic hysteresis and irreversibility indicate that ferromagnetic clusters coexist with an antiferromagnetic/CO phase for the lower Cr-doped manganites ($y \leq 0.15$) as the magnetic hysteresis curves are offset from the origin for these Cr-doped samples. However, for the higher Cr-doped manganites ($y \geq 0.20$), the antiferromagnetic/CO phase is completely suppressed as the hysteresis curves are not offset and only the ferromagnetic cluster glass phase is present. The electrical resistivity for the Cr-doped samples in zero magnetic field exhibit an exponential temperature dependence that is consistent with the small polaron hopping model above 100 K and the Mott's hopping mechanism at lower temperatures. Unlike the parent compound $\text{La}_{0.3}\text{Ca}_{0.7}\text{MnO}_3$, a small negative magnetoresistance is observed in all Cr-doped samples at temperatures below the onset of the magnetic remanence. The appearance and magnitude of this magnetoresistance are consistent with spin dependent hopping between spin clusters and/or between ferromagnetic domains, and not with any insulator-to-metallic transition typically associated with a colossal magnetoresistance effect.

A fundamental interest in mixed-valence manganese perovskites arises from their strongly spin-dependent conductivity and pronounced manifestations of phase separation (PS). In a complex and rich phase diagram of $\text{La}_{1-x}\text{Ca}_x\text{MnO}_3$ (LCMO) manganites the critical doping level $x_c=0.225$ separates ferromagnetic (FM) insulating ground state at $x < x_c$ from FM metallic ground state above x_c . In the doping range $0.17 < x < 0.25$ a mixed FM state composed of insulating and metallic FM phases with different levels of orbital ordering appears below Curie temperature T_c [1]. Therefore, physical mechanisms dominating transport properties of low-doped LCMO became remarkably different when the temperature is changing[2].

Interesting metastable resistivity states in low doped LCMO single crystal can be induced when current flow exceeds some threshold currents [2], depending on the history of the sample. Some of these metastable resistance states are relatively very stable and can only be removed by heat treatments at temperature much higher than T_c . Noise measurement is a well known technique to study the dynamical property of physical system. In such complex system as low-doped LCMO one expects that noise data will allow to get a deeper insight into the dynamics of dissipation processes associated with different transport mechanisms. In this report we use noise technique to probe the dynamical property of low-doped LCMO single crystals at three different states, i.e. pristine state and two current-induced metastable resistance states.

The experiments were performed with $\text{La}_{0.82}\text{Ca}_{0.18}\text{MnO}_3$ single crystals grown by a floating zone method. Two states were induced by two current-pulse treatments at 78 K, a pulse of 10 V and 5 seconds and a pulse of 30 V and 5 seconds. Resistance, Current-voltage characteristics, differential resistance, and noise spectra were measured at various temperatures in variable temperature cryostat using a standard four-point contact arrangement. 1/f low frequency noise is found in all experimental ranges.

Resistance measurements show that the current-pulse treatments shift the Resistance vs Temperature curves to higher resistance level. The induced high resistance states are stable within the experimental temperature range. When the resistance is normalized by the resistance at T_c , the resistance vs. temperature curves at three different states collapse together.

The noise measurement result at the pristine state is shown in Figure 1. S_v is I^2 dependant with exception at 77 K, which means that the observed noise is caused by current independent resistivity fluctuations. Noise intensity at 77 K initially increases as I^2 but around 1 mA starts to decrease. After a 10 V pulse treatment, the noise spectral density is enhanced, but the behavior of the noise is similar to the results at the pristine state, as shown in Figure 2. However, after the 30 V pulse treatment, deviation of S_v from I^2 dependence were observed at all temperatures below and around T_c .

The results were interpreted in terms of spin-polarized tunnel conduction mechanism, and current-induced modification of PS along the percolation path.

In summary, we have observed 1/f voltage noise at three different states of LCMO single crystals in a wide range of currents and temperatures corresponding to markedly different magnetic and

transport properties of the system. Non-equilibrium noise appears and decreases with increasing bias at situation where transport is dominated by tunneling mechanism. The pulse treatments don't change the behaviors of the static transport property, but induce significantly change in the dynamical transport property.

We report in this paper the effects of SrTiO₃ (STO) substrate orientation on magnetic anisotropy and 1/f noise in La_{0.7}Sr_{0.3}MnO₃ (LSMO) thin films. Films of various thicknesses have been deposited by pulsed laser deposition on STO (001), STO (110) and vicinal STO (001) substrates, where the vicinal angles were 2, 4, 6, 8 and 10° from the [001] direction towards [110]. The structural properties of the films were studied using X-ray diffraction in symmetrical and asymmetrical X-ray configurations. Reciprocal space maps (RSM) of the regions around (002), (103) and (223) STO reflections were performed in order to measure the strain in the films. Atomic Force Microscopy (AFM) and Scanning Tunnelling Microscopy (STM) clearly revealed the effect of substrate orientation on the surface morphology of the films. 80 nm large terraces were typically observed on STO (001) substrates, whereas (100) elongated grains appeared on STO (110) substrates (fig.1) and terraces of variable width depending on the miscut angles appeared in the case of the vicinal substrates (fig.2). The root mean square roughness was found in the 0.132 – 0.328 nm range for all the investigated samples. SQUID magnetometer measurements revealed a Curie temperature of about 350K. Kerr Magneto-Optical microscopy was used to investigate the magnetic anisotropy, the magnetic domain arrangement and the magnetization reversal in the films. LSMO films on STO (001) showed an in-plane biaxial magnetic anisotropy along the [110] and equivalent directions. LSMO films on STO (110) and on vicinal substrates, if the miscut angle is higher than 4°, showed an uniaxial anisotropy with the easy axis along the [100] axis on STO (110) and along the step direction on vicinal STO, respectively. Finally, 1/f noise measurements, and resistivity versus magnetic field characteristics will be presented. Possible devices making use of the magnetic anisotropy will be discussed.

500 nm * 500 nm STM image of a 40 nm thick LSMO film deposited on a STO(110) substrate showing elongated grains along (100)

500 nm * 500 nm STM image of a 40 nm thick LSMO film deposited on a 10° vicinal STO substrate showing 30 nm large regular terraces.

Room temperature giant magnetoimpedance in La_{0.67}Sr_{0.33}MnO₃.

M. Ramanathan

Department of Physics, National University of Singapore, Singapore, Singapore

The discovery of colossal magnetoresistance (CMR) in manganites of the general formula $R_{1-x}A_xMnO_3$ (R = trivalent rare earth ion, A = divalent alkaline earth ion) in early 90's stirred excitement among scientific community due to possible application of these materials in novel spintronic devices [1]. While several exotic electronic and magnetic phases exhibited by these oxides shifted recent interest in these materials towards more fundamental studies on strongly correlated electron systems, technological exploitation of the CMR effect at room temperature has been hampered by the need of magnetic field of $H > 1$ Tesla to induce more than 10 % magnetoresistance (MR). It was suggested that extrinsic MR arising from spin-polarized tunneling of charge carriers between misaligned ferromagnetic grains in polycrystalline materials can be exploited for practical applications at low magnetic fields (~ 0.5 T) compared to the intrinsic MR which peaks at the ferromagnetic Curie temperature but becomes negligible much below T_C [2]. Though the extrinsic MR is large ≈ 30 -35 % at 10 K and at 0.5 T, it decreases rapidly while approaching the room temperature[3,4]. Extensive efforts are underway in different laboratories to enhance the magnitude of magnetoresistance at low fields, particularly in milli and micro tesla range using techniques such as artificial grain boundary in epitaxial films, trilayer tunnel junctions and step edge junctions.

In this report, we explore the possibility of enhancing the magnetoresistance in mT range using a different approach. Although magnetoresistance in various manganites with dc current has been extensively studied during the past one decade, high frequency magnetotransport in these materials is hardly investigated. In this work, we have investigated the magnetic field response of the ac impedance in La_{0.67}Sr_{0.33}MnO₃ by directly passing r.f. current in the sample.

Our recent study of temperature dependence of high frequency electrical impedance ($f = 100$ Hz - 5 MHz) in La_{0.75}Sr_{0.25}MnO₃ established that magnetic transition masked by scattering of charges can be detected with radiofrequency electrical impedance [5]. In this report we study the complex impedance $Z(f, H) = Z'(f, H) + jZ''(f, H)$ of La_{0.57}Sr_{0.33}MnO₃ over an extended frequency range ($f = 0.5$ MHz - 30 MHz) as a function of dc magnetic field (-100 mT $\leq H \leq 100$ mT) at 300 K. We show that the ac magnetoresistance ($\Delta Z'/Z'(0)$) in a small field of 100 mT is much larger (≈ 47 % at $f = 2$ MHz) than the dc magnetoresistance (< 1 %). It is also shown that the ac magnetoreactance, $\Delta Z''/Z''(0)$, as a function of magnetic field exhibits a transition from a single peak to a double peak behavior with increasing frequency beyond 20 MHz and even change of sign from negative to positive in contrast to the ac magnetoresistance which is negative and exhibits only a single peak centered around the origin for all frequencies (see figure 1). The observed magnitude and features of magnetoimpedance are shown to be strongly dependent on the length of the sample. We attribute the observed enhancement of ac magnetoresistance to the suppression of the transverse permeability under the external dc magnetic field. Our study suggests that radio frequency magnetotransport can be exploited not only for low-field magnetic sensing at room temperature but it can also be used to probe dynamical transverse permeability in these compounds.

Figure 1: Magnetic field dependence of the ac magnetoresistance ($\Delta Z'/Z'(0)$, top panel) and the ac magnetoreactance ($\Delta Z''/Z''(0)$, bottom panel) at various fixed frequencies for $f = 0.5 - 15$ MHz((a) & (c)), and $f = 20 - 30$ MHz ((b) & (d)). Note that the single peak in $\Delta Z''/Z''(0)$ transforms into double peaks at $\pm H_p$ and H_p shifts up in field with increasing frequency.

Electroresistance in mixed valence manganites.

N. Biskup, A. de Andrés, M. Garcia Hernandez
ICMM, Madrid, Spain

Transition metal oxides, having strongly correlated electron systems, show unusually drastic phase transitions (Mott transitions) under external perturbation, including ferromagnetism, superconductivity, and others. Because of the strong coupling between spin, charge, and orbital degrees of freedom, the perovskite manganites (general formula: $R_{1-x}A_xMnO_3$, with $0 < x < 1$; $R=La, Pr$; $A=Ca, Sr$), typically exhibit a rich variety of electronic and magnetic properties, such as ferromagnetism with metallic conduction, and charge/orbital ordering, depending on carrier concentration. Historically, the most studied phenomenon in manganites is magnetoresistance (MR), the magnitude of which ranges from “giant” 10%–20% to colossal 10⁸% in charge ordered $Pr_{1-x}Ca_xMnO_3$, $x=0.3-0.5$ [1]. Recently, a more debated phenomenon is electroresistance (ER), i.e., nonlinear current-voltage (I-V) characteristics. Similar to MR, the magnitude of ER varies in different compounds, reaching equally colossal values in $Pr_{0.7}Ca_{0.3}MnO_3$ [2]. ER and MR are shown to be coupled, i.e., the voltage/current necessary to trigger insulator-metal transition decreases with magnetic field. Since this initial report in 1997, a significant number of publications report nonlinear I-V effects in manganites. Initially, investigations were limited to materials with charge order (CO) ground state. Different interpretations for these nonlinearities included depinning of CO state, depinning of charge density waves, or change in the orientation of orbital ordering (OO). Indeed, nonlinear effects were subsequently found in materials without CO and recent reports tend to interpret the nonlinear I-V characteristics in manganites as the consequence of Joule heating due to the large currents [3].

We have shown that all narrow-bandwidth (insulating) manganites show strongly nonlinear I-V characteristics, including negative differential resistance (NDR) [4]. NDR is always accompanied by heating which makes it difficult to extract its origin. However, in systems with CO/OO, we have observed the discontinuous transitions between low and high resistive states (LR→HR) that are caused by charge/orbital rearrangements and not by heating [5]. Moreover, in $La_{0.9}Sr_{0.1}MnO_3$ these discontinuous transitions are found only in the ferromagnetic state, thus linking the ER with magnetic order [6]. We will show that the magnetic ordering, i.e. LR→HR transitions are the cause of heating due to the transfer of entropy on the switch between ordered and disordered magnetic states.

In spite of the interconnection between magnetic order and electroresistance, magnetic field and electric field can induce different states. We show that, while the magnetic field enhances the orbital order in $La_{0.9}Sr_{0.1}MnO_3$ and concomitantly induces higher resistive state (larger electron gap), electric field is able to suppress the orbital order and the system enters into the metallic state. This leads to a colossal ER at low temperatures while MR is almost absent.

Impedance spectroscopy of magnetoresistive manganite films exhibiting electric-pulse-induced resistance switching.

T. Nakamura, K. Homma, T. Yakushiji, K. Tachibana

Department of Electronic Science and Engineering, Kyoto University, Kyoto, Japan

Magnetoresistive manganites have been attracting considerable interest for their unique magnetic and electric properties such as half-metallicity and colossal magnetoresistance (CMR). Recently, a large resistance change by the application of an electric pulse was observed at room temperature in metal oxides such as $\text{Pr}_{1-x}\text{Ca}_x\text{MnO}_3$ (PCMO). This effect provides a possibility of a next-generation nonvolatile memory, called resistance random access memory (ReRAM). ReRAM is highly expected due to its low power consumption, small bit cell size, and fast switching speed. In this work, PCMO films were deposited on $\text{Pt}/\text{SiO}_2/\text{Si}$ and SiO_2/Si substrates by rf magnetron sputtering or by metalorganic chemical vapor deposition (MOCVD). The electrical-pulse-induced resistance switching behavior was investigated in the PCMO-based devices. In order to study the switching mechanism in the PCMO-based devices, the frequency response of complex impedance of the devices was measured under various DC biases.

PCMO films were deposited from $\text{Pr}_{0.7}\text{Ca}_{0.3}\text{MnO}_{3-\delta}$ targets using rf magnetron sputtering. The distance between the target and substrate was maintained at 70 mm. After the chamber was evacuated to a high vacuum of about 1×10^{-6} Torr, working gas of argon was introduced. Before the deposition, the target was pre-sputtered for 30 min to obtain a clean target surface. The process pressure was controlled at 20 mTorr during the sputter deposition. The rf power was 100 W. The deposition temperature was 600 °C.

Polycrystalline PCMO films were also deposited by liquid-source MOCVD. We used tris(dipivaloylmethanato)praseodymium [$\text{Pr}(\text{DPM})_3$], bis(dipivaloylmethanato)calcium [$\text{Ca}(\text{DPM})_2$], and tris(dipivaloylmethanato)manganese [$\text{Mn}(\text{DPM})_3$] as the source materials. These source materials were dissolved in tetrahydrofuran (THF, $\text{C}_4\text{H}_8\text{O}$) at a concentration of 0.1 mol/l. After each dissolved source was introduced into a vaporizer by N_2 carrier gas at 200 sccm, the vaporized source was transported into the MOCVD reactor and subsequently mixed with O_2 oxidant gas. The optimal proportion of the flow rates of the liquid sources was determined using *in situ* infrared spectroscopic monitoring. The pressure in the reactor was maintained at 10 Torr.

The film thickness was obtained by cross-sectional scanning electron microscopy (SEM). All films were about 100 nm thick. The atomic composition of the PCMO films was evaluated by energy dispersion X-ray spectroscopy (EDS).

On top of films grown on SiO_2/Si substrates, two metallic electrodes of Al were deposited by thermal evaporation. We also prepared layered structures composed of PCMO sandwiched between Pt bottom electrode and top electrodes of Al. Electrical pulses were applied to the sample through the electrodes and the resistance was measured after each pulse. All the electric measurements have been done at room temperature.

We measured I - V characteristics in the Al/PCMO/Pt devices. The I - V characteristics exhibited nonlinear, asymmetric, and hysteretic behavior. The resistance switching of the PCMO films was measured by applying a single positive electric pulse and single negative electric pulse alternatively to the Al top electrode. The pulse amplitude was 5.0 V, and the pulse width was 500 ns. Positive or negative pulses reversibly switched the resistance of the PCMO films between the high resistance state and the low resistance state. The resistance switching ratio was between 100 and 1000.

The frequency response of complex impedance of the PCMO-based devices was measured under different DC biases. In order to reproduce observed spectrum by theoretical simulation, three sets

of parallel RC components in series were required as an equivalent circuit. These three components can be assigned to grain bulk, grain boundary, and film-electrode interface. Therefore, impedance spectroscopy indicates whether the overall resistance of the device is dominated by bulk, grain boundary, or interface component. Figure 1 shows typical impedance spectra of the PCMO-based device as a function of dc bias. As dc bias increased, the interface component decreased. The bias dependence of the Cole-Cole plots suggested that the resistance switching in the PCMO-based devices was mainly due to the resistance change in the interface between the film and the electrode. Impedance spectroscopy is a promising technique for characterizing the resistance switching in magnetoresistive manganite films.

Figure 1. Impedance spectra of the PCMO-based device as a function of dc bias.

Strain effect on MnO₆ octahedrons in the colossal magnetoresistance (CMR) films.

C. Wu, H. Chou, F. Yuan

National Sun Yat-sen University, Kaohsiung, Taiwan

The metal-insulator transition temperature(T_p) and the ferromagnetic-paramagnetic transition temperature(T_c) of doped manganese CMR films can be altered by the strain effect [1-4]. The strain effect suppresses the T_c of LaMnO₃ doped Ca(or Sr) films with the decreasing films' thickness, whereas the T_c of La_{1-x}Ba_xMnO₃ films is found to increase for $x \leq 0.2$ in thinner films. Up to now, the mechanism of the strain effect has not been fully understood.

La_{0.67}Ca_{0.33}MnO₃ (LCMO) and La_{0.8}Ba_{0.2}MnO₃ (LBMO) films with thickness of (200, 50 and 20 nm) and (150, 45 and 15 nm) were grown on SrTiO₃(100) (STO) substrates by a radio frequency magnetron sputtering system. The electric and magnetic properties were characterized by a four-point probe and a superconducting quantum interference device (SQUID), respectively. The crystal structures were studied by a X-ray diffraction (XRD) and an extended X-ray absorption fine structure (EXAFS). The Orbital structures were studied by X-ray absorption near-edge structure (XANES). The XAS measurements are taken by beam-line of the National Synchrotron Radiation Research Center in Taiwan.

The XRD confirms that the LCMO and LBMO thin films are epitaxial, and their (T_p) is very close to (T_p). The strain effect of the substrate on films suppresses the transition temperature of LCMO films while enhances that of LBMO films. The Mn K-edge EXAFS measured by the fluorescence yield mode at 11 K is shown in Fig. 1. Three structures can be identified as the distribution of: (A) O around Mn, (B) La(Ca or Ba) around Mn and (C) the multi-scattering from the Mn to the next Mn. For LCMO films, Fig. 1(a), the average distance dMn-O increases for the thinner film, the distribution of La(or Ca) for thinner film increases to a larger range and the scattering of (C) structure can barely be seen. This implies that the strain effect in LCMO does change the MnO₆ octahedron that increases the average bond length, dMn-O, in a way that opens up a wider space for smaller Ca cations to distribute. Within this strain effect, the MnO₆ octahedrons become more off-alignment that reduces the Double Exchange (DE) coupling and, thus, the transition temperature. For LBMO films, Fig. 1(b), the strain effect decreases the average bond length, dMn-O, and increases average bond length, dMn-La(sites), and exhibits stronger multi-scattering from the core Mn ion to the next Mn ions. This indicates that the MnO₆ octahedrons in LBMO thinner film is also changed according to the strain effect. The alignment of MnO₆ octahedrons becomes better for the thinner LBMO film that enhances the multi-scattering of the structure (C). All these effects enhance the DE coupling and the transition temperature. XANES measured by a total electron yield mode at 78 K which exhibits the hybridizations of the unoccupied O 2p and Mn 3d orbital. Due to the crystal field and the Jahn-Teller distortion effect, these states experience splitting into many states. The structure (D) and (E) are the hybridizations of O 2p and Mn 3d. The separations of these two structures can be corresponded to the splitting energy of Mn 3d (t_{2g}) and (e_g) bands due to the crystal field, which are 0.75 eV for both thick films and then increases 0.1 eV for LBMO thinner film and decreases 0.1 eV for LCMO thinner films. The increasing of separation of (D) and (E) structure can be looked as the enhancement of crystal field on the Mn ion. This coincides with the observation in Fig. 1.

We found that the strain effect does affect the shape and the alignment of MnO₆ octahedrons, and, as a result of this, the DE coupling is suppressed for LCMO films and enhanced for LBMO films. By comparison with our earlier study which indicate the dopants at La sites are the matter of the strain effect, the correlation between the dopants, Ca and Ba in La sites, and the different response of MnO₆ octahedrons in LCMO and LBMO films is not clear at this stage.

Pulsed current induced multi level resistivity switching in two magnetodielectrics: antiferromagnetic Nd_{0.5}Ca_{0.5}MnO₃ and ferromagnetic La₂NiMnO₆.

M. Ramanathan

Physics, National university of Singapore, Singapore, Singapore

Electrically addressable non volatile memory devices are currently attracting enormous attention due to their potential applications in compact data storage. In particular, recent observations of voltage polarity dependent resistivity switching, i.e., high resistance state (“OFF” state) for positive voltage pulses and low resistance state (“ON” state) for negative voltage pulses found in Pr_{0.67}Ca_{0.33}MnO₃ capacitor like structures deserves a particular attention [1].

The magnitude of electroresistance was found to depend on the polarity, amplitude and number of pulses. However, the effect of pulse width or period on the I-V characteristics and CER effect has been hardly investigated. We demonstrate pulse current induced bi-level and multi-level switching of electrical resistance triggered by variation in pulse width or period for a fixed low current in two magnetodielectric insulators with different ground states: charge-orbital ordered antiferromagnetic Nd_{0.5}Ca_{0.5}MnO₃ and charge disordered ferromagnetic LaNi_{0.5}Mn_{0.5}O₃. It is found that resistance increases abruptly by as much as 50 % upon a sudden change of period from 0.2 s to 1s for a fixed pulse width (25ms) or decreases abruptly upon increase of pulse width for a constant period. It is shown that multiple resistive states can be induced by a sequence of controlled pulse width or period as shown in the figure and this approach can be exploited for non volatile resistive random access memory [2]. We discuss possible origins of the observed results. It is shown that multiple resistive states can be induced by a sequence of controlled pulse width or period and this approach can be exploited for non volatile resistive random access memory.

A non-contact rapid charging type inductive power supply (IPS) system has been developed and tested as a charger for electric-driven vehicles (EVs). By using the developed system, EV charging can be carried out safely, easily, and in a short period. Optimizing the track and pick up design of the IPS achieved significant improvements in efficiency, weight, thickness, and air gap length. The results obtained are listed below.

a) The design optimization of the track/pickup part for an IPS having a plane core and round shape was conducted by means of finite-element electromagnetic field analyses in consideration of external drive circuit. Based on this study, we arrived at parameters such as drive frequency (22 kHz), inner core diameter (90-mm radius), and core thickness values (4.0 mm for the track side, 2.0 mm for the pickup side). In addition, with the objective of ensuring high-precision analyses, we devised a technique of separately evaluating the eddy current loss and the hysteresis loss in the magnetic material.

b) Based on the results of electromagnetic field analyses, an actual IPS was fabricated. Through non-contact power transmission experiments, the attainment of a 92% total efficiency was confirmed during 30 kW power transmissions. Also, slimming (33 mm), weight reduction (35 kg), and a long air gap (100 mm) were successfully accomplished.

An Analytical Model of the Electromagnetic Efficiency of Litz-Wire Windings for Domestic Induction Heating Systems.

J. Acero¹, R. Alonso², J. M. Burdio¹, L. A. Barragán¹, J. I. Artigas¹

1. Electronic Engineering and Communications, University of Zaragoza, Zaragoza, Spain; 2. Applied Physics, University of Zaragoza, Zaragoza, Spain

Domestic induction hobs basically consist of a planar winding situated below a metallic vessel and supplied by a medium-frequency power source, normally operated between 20 kHz and 70 kHz. In Fig. 1 an induction system comprising the planar inductor and the load is shown. The inductor consists of n litz-wire concentric turns, each one of them having a_i radius. The litz wire comprises an isolated number of n_o strands, being Φ_o the strand diameter. The load is a semi-infinite medium characterized by its conductivity σ_l and its relative magnetic permeability μ_{rl} .

The induction efficiency of this system is defined as: $\eta_{ind} = \Delta R / (R_o + \Delta R)$, where ΔR is a resistance representing the power dissipation in the load for heating purposes; and, R_o is a resistance which represents the non-desirable warming-up of the windings. In its turn, R_o is further divided into the conduction resistance, R_{cond} , related with the *skin effect*; and the induction resistance, R_{ind} , which represents the losses by the called *proximity effect*, i.e. the currents induced in the wires by the alternating fields in which they are immersed, [1]. Note that ΔR and R_o are not independent; rather, they are related through the unique solution of the magnetic field of the system. This field depends on the electromagnetic and geometric parameters of the whole system.

Some models of the induction efficiency based on a Finite Element Analysis (FEA) calculation of the losses in both the work piece and the winding have been proposed [2]-[3]. However, the FEA calculations may become unpractical, specially for windings consisting of several turns of litz wire with a large number of strands and a small diameter, because they could involve high computational cost.

Recently, on the one hand it has been proposed an analytical model of the impedance for a planar circular induction system [4]; and, on the other hand, a frequency-dependent model of losses for litz-wire planar windings, [5]. Considering simultaneously both models, an analytical model of the induction efficiency is developed and experimentally verified. Thus, [4] provides the required ΔR . However, the main contribution of the present work is that from the equations of [4] it has been deduced the field at the positions of each turn, H_{oi} , which is needed to estimate the proximity losses in windings [5]. Besides, also through [5], R_{cond} is calculated, having therefore the terms of R_o . Thereby, the model includes the operating frequency, the properties of the load, the geometry of the windings, and several litz-wire parameters like the number of strands, the strand diameter and the packing factor.

An experimental setup was built to verify the model. Frequency-dependent tests have been performed based on resistance measurements by means of a precision LCR meter (Agilent 4284A). The tests were performed with a 23-turn litz-wire flat winding geometry, corresponding to the inductor currently manufactured to deliver up to 3500 W in a commercial induction heating appliance ($a_1 = 25$ mm, $a_{23} = 105$ mm). The litz wire has been manufactured with strands of $\Phi_o = 0.5$ mm. Three different kinds of loads have been tested: aluminium copper, and ferromagnetic steel. Considering the ferromagnetic load operating at 25 kHz and using the developed model, the optimum number of strands of the litz wire has been calculated and results are shown in Fig. 2 (a). For this application we have selected $n_o = 20$. The experimental results of η_{ind} are also shown in Fig. 2 (b). It must be noted the lower efficiency achieved with non magnetic loads. As it can be seen, measured and calculated results exhibit a very good agreement.

Department of Electrical and Computer Engineering, University of Toronto, Toronto, ON, Canada

Abstract—This paper discusses the design and analysis of a high frequency coaxial transformer (HFCT) for a DC/DC converter used in solar PV power systems. The experimental results demonstrate that the transformer voltage ratio is in good agreement with the turns ratio. The low leakage impedances measured for this transformer at various frequencies up to 500 KHz indicate the advantages of the coaxial transformer structure. This unique winding structure also provides a small capacitive coupling between the primary and secondary windings. The simulation results confirm the uniform distribution of magnetic flux in the magnetic core, and the uniform distribution of eddy current density in the windings.

Index Terms— High Frequency Coaxial Transformer, Eddy Current, Magnetic Flux,

I. INTRODUCTION

Photovoltaic arrays are coupled to the grid using a dc-ac converter and an isolation transformer. The isolation transformer is typically large given that the operating frequency is the utility frequency. A way of avoiding the use of a large transformer is to employ a dc-ac-dc converter with a high frequency (HF) link isolation transformer. In this event, the transformer is designed for HF operation and hence its size can be reduced significantly. Higher output power from multiple solar PV modules is achieved by connecting each PV array to its own resonant dc-ac converter and single phase transformer. The dc-ac resonant converter output signals are phase shifted with respect to each other by 120 degrees. The secondaries of the HF link transformers are connected in a three phase wye configuration and the output is connected to a three phase rectifier, as shown in Fig. 1. The transformers with small size and high power efficiency at high operating frequency are often required in DC/DC converter systems. Conventional transformer designs cannot perform well at HF because the insertion loss and eddy current loss are too high. The HFCT presented in this paper can address the aforementioned problems and provide a better performance in HF applications.

II. TEST RESULTS FOR THE COAXIAL TRANSFORMER

Figure 1 (a) shows the HFCT construction (right side at bottom) and the packaging of a three phase system (top image of right side). The solar PV system requires an isolation transformer therefore the number of turns on the primary and secondary windings is the same and equal to 6 at a frequency of 500 kHz and a voltage of 450 V. Each winding is comprised of 7 thin insulated wires that are used to form a litz wire. The turns ratio ($a=6/6=1$) is in good agreement with the voltage ratio (V_1/V_2) from 100 kHz to 1 MHz. The measured results from 100kHz to 1MHz indicate that the leakage inductance, Leq ($0.689\mu H$) is relatively small compared with a conventional transformer ($3.53\mu H$) at 500kHz, while Req increases slightly with frequency due to the skin depth effect. The leakage inductance decreases in a linear fashion over the frequency range of interest. The magnitude of the magnetizing inductance tracks the frequency response of the permeability, μ , which rises in the high frequency range. The coupling capacitance (20.9 pF) between primary and secondary windings is much smaller than the values (210 pF) observed in conventional transformers with a similar rating. The coaxial transformer performed well over an extended frequency range (100 kHz to 1MHz), while the leakage inductance and winding loss of a conventional transformer increase rapidly above a frequency of 200 kHz.

III. MAGNETIC FIELD ANALYSIS OF COAXIAL TRANSFORMER

A FEM-based numerical method was used to determine the magnetic flux and eddy current distributions. The excitation source is applied to the outer winding and the inner winding was open circuited. Figure 1 (b) shows the current distributions in both the primary and secondary windings, where the eddy current density in the outer (primary) winding is somewhat higher than the one in the inner (secondary) winding. The peak current density including eddy current was determined at the surface of the outer winding; $743A/cm^2$ for the open circuit case, and $810A/cm^2$ for the short circuit case. The maximum current densities in the inner (secondary) winding for both open circuit and short circuit cases were found to be less than $61.63A/cm^2$ and $60.7A/cm^2$ respectively.

IV. CONCLUSION

A HFCT using uniformly distributed litz wire winding structure has been investigated. The turns ratio and voltage ratio in the HF range of interest are in good agreement with each other. The minimum leakage inductance ($0.689\mu H$) and coupling capacitance ($20.9pF$) have been achieved by using such winding structure. The flux and eddy current distributions were uniform and the high current density appeared at the surface of the outer winding, and was $743A/cm^2$ for the open circuit case, and $810A/cm^2$ for the short circuit case. The current densities in the inner winding were over 10 times smaller than the outer winding.

Novel EU core variable inductor.

M. Xianmin¹, L. Fengchun¹, W. Jianze², J. Yanchao²

1. Department of Electrical and Electronics Engineering, DaLian University of Technology, DaLian, China; 2. School of Electrical Engineering and Automation, Harbin Institute of Technology, Harbin, China

Introduction

Recently, many types variable inductor have been widely used in SVC system. Orthogonal-core, three legged core, and parallel-laminated core designs have been presented for variable inductors[1,2]. These devices worked in saturation state by a DC current control, so increases the harmonics of the AC current. Recent investigation indicated that the current distortion of an orthogonal-core variable inductor with partial gaps is decreased[3]. One configuration use tow orthogonal-core variable inductor worked in half wave of source can also be reduced[4].

In this paper, the authors propose an EU core variable inductor, which is a simple structure without partial gaps, designed to decrease current distortion. The operating principle is also described in this paper. The EU core variable inductor can configure to single phase and three phase application. We present their basic structure and basic characteristics and give an examples. The main characteristics were verified with a single phase and a three phase prototype.

Single phase EU core variable inductor

EU core variable inductor is made by one E-shaped core and one U-shape core assembled at 90° one from other and a winding wound on each core. Figure 1 shows the single phase configuration of the device. Linear reluctances in the magnetic equivalent circuit can be ignored because the non-linear reluctance is the major factor of effecting flux distribution. Figure 2 shows magnetic equivalent circuit. In the figure $R_1, R_2, R_3, R_4, R_5, R_6$ is the magnetic reluctance of E-core and U-core interface part. The magnetic equivalent circuit can be simplified to figure 3. This simplified magnetic equivalent circuit is same as presented in[5].

Divided the core to 68 parts employed 3-D reluctance network method proposed in[5], construct the simulation model of single phase EU core variable inductor. Experiment result indicated its harmonic component is small than convention orthogonal core variable inductor. Because the 6 interface parts of device worked in different saturation state, the single phase variable inductor can decrease the harmonic current output.

Three phase EU core variable inductor

Three phase EU core variable inductor use same core of single phase one. In the figure 4, mount one winding in the every lamb of E core. The configuration is simple used in the three phase motor starter neednot to single phase control. Same as single phase one, build the 3-D simulation model of three phase EU core variable inductor. Experiment result indicated the output current of AC winding not include 3rd harmonic component because of unique magnetic path.

Conclusion

In this paper EU core variable inductor has been verified by construct a single phase prototype and a three phase one. The novel EU core variable inductor has some important features. (a) Single phase variable has a lower harmonic component characteristic. (b) Three phase variable inductor simple topology, increased credibility of the system application.

Stability analysis of contact-less electrical energy detachable transformer.

H. Chen, Q. Yang, J. Li, S. Yang, S. Hou
Hebei University of Technology, Tianjin, China

I. INTRODUCTION

In many applications, the Contact-less Electrical Energy Transmission (CEET) technique has distinct advantages over the conventional energy transmission method which uses wires and connectors owing to the following reasons.

- (1) An electric connector may not appropriate due to the dangerous environment (humidity, under-water, gas, dust).
- (2) Energy has to be supplied to moving objects or to implanted medical devices through the intact skin.
- (3) Reliability is improved by avoiding mechanical contacts in battery chargers.

A typical CEET system consists of primary converter, detachable transformer and secondary converter. The detachable transformers are difficult to design and optimize because of these variables: a): The distance between the windings cannot be considered as a constant b): Windings could not be facing to each other all the time. c): The loads are variable, depending on whether the electronic device that acts as a load is working or not.

II. SIMULATION MODEL AND RESULTS OF DETACHABLE TRANSFORMER

Mutual inductance model is applied to analyze the energy transmission behavior of detachable transformer.

The equivalent circuit of detachable transformer can be obtained as shown in Fig. 1 (a), (b).

The dimensions of E-E detachable transformer model are shown in Fig.2. The broken line is symmetry axis. The amplitude of voltage source is 100 V. The primary and secondary of detachable transformer consist of 54 turns of Litz wire.

A. The Influence of Displacement on Coupling Rate

This paper calculates the coupling rate of E-E type detachable transformer with gaps of 5 mm and 10 mm respectively. Fig. 3 shows the calculated coupling rate of detachable transformer as a function of horizontal displacement of secondary system. Overall, the coupling coefficient decreases rapidly as the displacement increases.

As shown in Fig. 3, the coupling rate has little change (about 0.85 and 0.94) when secondary winding displacement is smaller than 20mm (keep the detachable transformer gap unchanged during the simulation). In this case, the designed detachable transformer has a relatively stable ability.

B. Parameter Analysis

The structure of E-E type detachable transformer are optimized and the output voltage, power and efficiency at different transmission frequency are calculated.

Fig. 4 shows output voltage, power, and efficiency as a function of operating frequency. The efficiency strongly increases with the frequency nearly the same way as the output power. The optimized detachable transformer attains maximum results at about 60 kHz. But, if keep on to increase frequency, both of them decrease remarkably. This may due to increasing core loss caused by higher frequency and copper loss by increased alternating winding resistance

III. CONCLUSIONS

In this paper, a high-frequency, high-stability and high-efficiency detachable transformer suitable for applications with a wide input range and wide load range in CEET system is described. Through the study of coupling rate of transformers with horizontal and vertical displacement, an optimized structure of detachable transformer is obtained and the operational stability is improved. Finally, the performance evaluation results as a function of frequency are presented using a diagram in which the transformer achieved the optimum efficiency at the frequency of 60 kHz.

A Forced Vibration Analysis of Cable-type Power Transformer Winding by the Pseudospectral Method.

J. Ha, H. Chung, S. Woo, P. Shin, J. Lee
Hongik University, Jochiwon, South Korea

Vibration analysis of high voltage power transformer is very important for design of the mechanical structure of the insulation system as well as for diagnostics of the power system. In this paper, the electromagnetic force generated by the interaction of short-circuit current with the leakage flux is calculated by the Maxwell stress method based on the finite element analysis of the equation: $\nabla \times (1/\mu) \nabla \times \mathbf{A} = \mathbf{J} - j\omega_c \sigma \mathbf{A} + \omega_c^2 \mathbf{A}$, where \mathbf{A} is magnetic vector potential, σ electrical conductivity, ω_c power frequency, μ permeability, respectively. And then the vibration forces of the windings are calculated by the pseudo spectral method[1,2], which is straightforward and it has novel advantages in its conceptual simplicity over other computational methods. The equations of the winding motion(circular helical systems) are based on the Timoshenko beam theory and are consist of 6 equations for internal forces(T) and moments(M) in the tangential(t), normal(n) and binormal(b) directions. To the binormal direction the two equations are given as $(dT_t/ds) + \tau T_n = -\omega^2 \rho A U_b$, $(dM_t/ds) + T_n + \tau M_n = -\omega^2 \rho I_b \Omega_b$ for a harmonic motion at the natural frequency ω , tortousity τ , and density of winding ρ . U represents the displacement and Ω is the rotation. The equations of motion are approximated by the series expansions of the Chebyshev polynomials and are collocated at the Gauss-Labatto collocation points[2,3].

The boundary condition is considered as the side constraint, which is merged into the governing equations to form the set of algebraic equations.

To verify the method a distribution power transformer of helical winding of cylindrical type, which is operated for 60 Hz, 6600V/380V and 100kVA, is analyzed for various boundary conditions. The short-circuit current and electromagnetic force are calculated by FEM program and the results are verified with theoretical formula and PSPICE program. The simulation results are fairly good agreement with the other verified methods within 5 % error rate. The turn-to-turn short-circuit current is 500 times of the rated current and the electromagnetic force is about 20-200 times.

For the forced vibration analysis of the cable-type winding, the calculated forces from FE analysis are put into the equations of the winding motion(see Fig.1). The equations are also solved by the proposed pseudo spectral method and analyzed the vibration modes and forces under the various boundary conditions. Figure 2 shows the cable-type winding model; the centerline radius, wire diameter and pitch of the winding are 404.5 mm, 4.37 mm and 26 mm, respectively. The number of collocation points required to achieve the convergence of the pseudo spectral solution was less than $K=120$, however, the ANSYS required about 8000 nodes for the same model. Table 1 describes the forced vibration mode frequencies of free-fixed boundary condition for 20 turns winding, which is compared with the results of ANSYS program. The computed results are in fairly good agreement with the simulated data of ANSYS. The methods presented in this study may serve as one of the useful tools in the electromagnetic force analysis of the transformer winding behavior as well as vibration forces under the short-circuit condition for design of the structure.

Coupled three phase inductors for interleaved inverter switching.

A. Knight, J. Ewanchuk, J. C. Salmon

Electrical and Computer Eng, University of Alberta, Edmonton, AB, Canada

It can be shown that placing coupled inductors between switches in the output legs of three-phase inverters, as shown in Figure 1, can offer significant advantages in the output waveforms of the inverters. This topology is intended to produce multi-level PWM output voltage waveforms with each leg switching at 0 , $V_{dc}/2$ and V_{dc} . Hence PWM voltage harmonics are lowered by 50% while the load sees output current ripple at twice the switching frequency. In the case with ideally coupled inductors, operating the upper and lower switches with complementary modulating signals results in interleaved switching such that the output current divides into complementary ac inductor coil currents in each leg, with magnitudes equal to half the output current. An additional steady dc offset current also flows in both coils in a leg, with magnitude equal to half the peak output ac current. Considering the flux in each coil of a leg, $\psi_1 = L_{l1}i_1 + L_{l2}i_2 + L_l i$ and $\psi_2 = L_{l2}i_1 + L_{l1}i_2 + L_l i$. It can be seen that if the ac components of the coil currents in each leg are equal and opposite, the output ac current will effectively see half the leakage inductance of each coil. Conversely, DC offset current and high frequency switching current is common to both coils and these see effective inductance equal to four times the magnetizing inductance of each coil. A desirable set of coupled inductances for each leg have the following characteristics: (1) low leakage inductance; (2) high magnetizing inductance; (3) self inductance exactly equal to mutual inductance between coupled coils on the same core. This desirable performance may be achieved using three independent toroidal coupled inductors. This approach had been implemented in on a 6 switch inverter similar to that shown in Figure 1 and results in a 5-level output voltage, with very low current ripple, as shown in the experimental plots in Figure 2.

Use of three toroidal inductors requires an offset flux in each core. This creates some disadvantages: the core must be sized such that the sum of the dc flux and high frequency ripple does not drive the core into saturation; losses increase losses due to the higher total flux density; there is no flux reversal, increasing the risk of the core being driven into saturation. A preferred approach is to use a single three-limb core. The three-limb core eliminates the dc flux, but also introduces the risk of increased di/dt and switch damage. Let i_{au} , i_{al} , i_{bu} , i_{bl} be the currents in the upper and lower coils of leg a, i_{ao} the fundamental output currents, i_{ahf} the high frequency coil ripple. One may assume that $i_{au} = i_{dc} + i_{ao}/2 + i_{ahf}$, $i_{al} = i_{dc} - i_{ao}/2 + i_{ahf}$. If one assumes that the coils are closely coupled and that all three legs have equal impedances, then the total mmf, M in each limb of the core may be written as $M_a = 2N(i_{dc} + i_{ahf})$, $M_b = 2N(i_{dc} + i_{bhf})$, $M_c = 2N(i_{dc} + i_{chf})$. Considering a simplified magnetic equivalent circuit for a three-limb core, it can be shown that the DC mmf components cancel and only high frequency fluxes are present in the core. It also becomes clear that if the high frequency currents are common in all three legs, the high frequency fluxes also cancel. This may become a critical mode of operation; cancellation of flux results in a collapse in the magnetizing inductance of an inverter leg, leading to shoot through and catastrophic device failure. In reality, this mode is only likely if all switches are on simultaneously (common if sinusoidal PWM is used). Use of an alternate modulation scheme, such as discrete PWM will alleviate this issue. Results of operation DPWM modulation of an inverter with a 3-limb core feeding an RL load are presented in Figure 3. The 5 level output voltage can clearly be seen. The coupled inductors with interleaved switching offer significant advantages over traditional filter inductors.

A novel approach to extending the linearity range of displacement inductive sensor.

M. S. Damnjanovic, L. Zivanov, L. Nagy, S. Djuric, B. Biberdzic
Department of Electronics, Faculty of Technical Sciences, Novi Sad, Serbia

This paper presents a meander type displacement inductive sensor, usable for detection of small displacement in the plane (less than 0.5mm). Planar, low cost PCB technology was chosen for our prototype.

Previously we have reported measured characteristics of displacement inductive sensor consisting of two sensor elements, each having a pair of meander coils, faced one another [1]. In each pair, one of the coils is fixed (coil A) and between its terminals the input inductance L_{IN} was measured. Other coil (coil B in each pair) is short-circuited. Moving coil B above the coil A, in directions of x- and z-axes, coupling between coils will change, as well as input inductance, serving as a measure of displacement.

The first pair of coils, insensitive to displacement in x-direction, has width of conductive segments of coil A $w_A=1.52\text{mm}$ and coil B $w_B=0.51\text{mm}$ (Fig. 1). Near $x=0$, inductance variation for small displacement in x-direction is less than a few nH. This pair of coils is used for determination of distance between coils, i.e. z-coordinate. In order to achieve less x-sensitivity, gap g is inserted in the middle of each conductive segment of coil A. For sets of such sensor elements were made, with gaps 0, 0.25mm, 0.51mm and 0.76mm.

The second pair of coils consists of two equal width coils, $w_A=w_B=0.51\text{mm}$. If the coil B is arranged relative to coil A by one quarter of pitch p (near $x=0.44\text{mm}$), the slope of the input inductance L_{IN} has its maximum. It depends nearly linearly on displacement in the x-axis direction. Information about z-coordinate from the first pair of coils, in combination with the information from the second pair, will help us to determine the displacement in the x-z plane.

In this paper, we present an extended equivalent circuit model of inductive sensor (Fig. 2), as well as a calculation method based on the partial inductance method and comparison with measurement. Using this model, we have developed new simulation tool in MATLAB for evaluation of the input impedance of the sensor. This calculation method is previously verified in [2].

All sensors were tested using Impedance Analyzer HP4194A. Results of simulation and measurement are presented in Fig. 3 and Fig. 4. If the gap $g=0.25\text{mm}$ is inserted, the linearity range is approximately 3 times wider than linearity range of structure without gap (Fig. 3).

The advantage of this displacement sensor is that the B-coils are short-circuited (so the sensor has one port, only). A possible application of such sensors is in robotics. Miniature version of such sensors could be incorporated into soft-covered fingertips of a robotic gripper. So, normal and tangential components of fingertips' deformation could be measured and corresponding forces could be calculated.

A New Technique for Measuring Ferrite Core Loss under DC Bias Conditions.

C. Baguley¹, U. K. Madawala¹, B. Carsten²

1. ECE, University of Auckland, Auckland, New Zealand; 2. Power Conversion Consulting and Research, Corvallis, OR

Introduction: Despite knowledge of the highly non-linear nature of ferrite core losses under DC bias conditions [1] there is a lack of comprehensive data on the phenomenon. This can largely be attributed to the difficulty of measuring core losses under DC bias conditions due to the very poor power factor, pf, of highly inductive core loss measurement circuits [1], [2]. The contribution of this paper is to propose a ferrite core loss measurement technique which overcomes this difficulty and which, to the authors knowledge, has not previously been used for the measurement of core losses under DC bias conditions.

The Measurement Technique: The proposed technique improves the pf of the core loss measurement circuit by neutralizing the mutual inductance of the core under test, CUT, using two coupled air cored windings. The improved pf reduces the ratio of excitation VA to core losses and thereby allows core losses to be accurately measured at high frequencies through the multiplication of the excitation current, I_{excite} , and winding emf, V_{sense} , waveforms. Fig. 1(a) shows the core loss measurement circuit, and Fig. 1(b) shows the resulting power factor for various ratios of equivalent core loss resistance, R_c , to CUT mutual reactance, X_{m_cut} . However the design and construction of the coupled air cored windings is difficult as it requires the “impurity” [3] of the mutual inductance between the windings to be minimized. The impurity causes the phase angle between the open circuit secondary winding emf and primary exciting current waveforms of the coupled air cored windings to deviate from quadrature, and therefore results in a significant core loss measurement error if it is not minimized. The impurity of two coupled air cored windings with a common connection point has been defined as [3]:

$$\sigma = \omega^2 [C_1 R_1 M_0 - C_{12} (R_1 (L_2 - M_0) + R_2 (L_1 - M_0))] \quad (1)$$

where C_1 , C_2 , and C_{12} are coil 1 and 2 self and inter-capacitances, R_1 and R_2 are the winding resistances, L_1 and L_2 are the winding inductances, ω is the excitation frequency, and M_0 is the true (or geometric) inductance between the coils. To minimize impurity it is apparent from (1) that the self and inter-capacitances between the coupled air cored windings must be minimized, as well as the winding resistances and thus the winding eddy current losses at high frequencies. To meet this requirement the coupled air cored windings are constructed using stranded wire, and two primary coils are used to sandwich the secondary to improve the coil coupling, with all coils being placed end to end to minimize inter-coil capacitance.

To measure core losses in the presence of a DC bias the measurement circuit is modified to that shown in Fig. 2. In this circuit I_{excite} and V_{sense} are measured and multiplied together to measure the total core losses of two ferrite CUTs at the same time. Two CUTs are used in order to allow DC bias windings to be placed on each with polarities such that, when connected in series, the DC bias windings are effectively decoupled from the AC windings in the circuit. Decoupling is necessary in order for the DC bias to be exact [1].

In the paper the results of core loss measurements made using the proposed measurement circuit are presented showing the effects of frequency, core shape, and temperature on ferrite core losses under DC bias conditions. Measurements are made with a Clarke and Hess model 2335 high frequency wattmeter at controlled core temperatures. An analysis of the impurity of the coupled air cored mutual windings is also presented.

Spin-torque oscillator in the presence of thermal noise.

A. N. Slavin¹, J. Kim², V. Tiberkevich¹

The passage of a spin-polarized current through a magnetic multilayer can lead to self-sustained magnetization precession [1]. This effect is interesting due to the potential applications in tunable nano-scale microwave auto-oscillators. Thermal noise plays an important role in the dynamics of nano-sized spin-torque oscillators (STO) in which the characteristic energy of oscillations is comparable with the thermal energy kT . In such nano-oscillators the presence of thermal noise not only determines the generation linewidth, but, also, blurs the threshold between the regime of sub-critical noise-induced damped oscillations and the regime of super-critical auto-oscillations. Also, in contrast with conventional quasi-linear oscillators, in STO the generated frequency demonstrates a strong shift with power, the sign of which depends on the orientation of the bias magnetic field [2]. The theory of a strongly nonlinear STO in the presence of thermal noise developed in this work is based on the nonlinear oscillator equation for the complex amplitude $c(t)$ of a spin wave excited by spin-polarized current [2]

$$dc/dt + i(\omega_0 + N|c|^2)c + \Gamma_0(1 + Q|c|^2)c - \sigma I(1 - |c|^2)c = f(t), \quad (1)$$

where ω_0 is the linear frequency of the excited spin wave mode, N is the nonlinear frequency shift coefficient, Γ_0 is the linear relaxation rate, Q is the dimensionless parameter describing the increase of damping with the increase of the spin wave power $|c|^2$, σ is the spin-polarization efficiency parameter defined in [2], I is the charge current passing through the magnetic layer, and $f(t)$ describes the influence of the thermal noise. The function $f(t)$ is a stochastic Gaussian process with the correlator $\langle f(t)f^*(t') \rangle = 2\Gamma_0 n_T \delta(t - t')$, where n_T is the mean spin wave power in the state of thermal equilibrium (i.e., at $I = 0$).

In the framework of this theory the solution of the nonlinear stochastic equation (1) driven by the thermal noise is reduced to the solution of a corresponding linear and deterministic Fokker-Plank problem (FPP) for the probability density function describing the auto-oscillation process. Both stationary and non-stationary solutions of the FPP are obtained. It is demonstrated that the nonlinearity of the auto-oscillation frequency leads to the renormalization of the intensity of phase-noise and to a significant broadening of the auto-oscillator linewidth [3].

In substantially supercritical regime ($\zeta = \sigma I / \Gamma_0 \geq 1.2$) the main contribution to the linewidth of generation comes from the phase fluctuations of the spin wave amplitude $c(t)$. Analyzing Eq. (1) in this regime, we derived the following expression for the linewidth of the spin-torque-induced oscillations:

$$\Delta\omega = \Gamma_0 (n_T/n_0) (1 + (N/\Gamma_0(\zeta + Q))^2), \quad (2)$$

where $n_0 = |c_0|^2 = (\zeta - 1)/(\zeta + Q)$ is the mean dimensionless power of the auto-oscillation. Equation (2) clearly shows that the equilibrium relaxation rate of the excited mode Γ_0 determines the overall scale of the possible linewidth variations. Then, it demonstrates that the linewidth $\Delta\omega$ is proportional to the noise level (n_T/n_0) , which is determined by the ratio of the population of thermal spin waves n_T to the population of driven spin waves n_0 . Finally, Eq. (2) shows that the nonlinear frequency shift parameter N gives a measure of the contribution of the amplitude fluctuations to the phase noise far above threshold.

Fig. 1 demonstrates that the dependence of the spin-torque oscillator linewidth on the magnetization angle θ calculated from (2) for $Q = 3$ has a minimum at the angle $\theta \approx 80$ degrees, at

which the nonlinear frequency shift coefficient N changes its sign. This result is in good quantitative agreement with the experiment [4].

The nonlinearity of STO is, also, responsible for the asymmetry, broadening, and non-Lorentzian shape of the generation line near the auto-oscillation threshold [5]. In addition, the Fokker-Plank formalism makes possible the calculation of the generation power in both sub-critical and super-critical regime, and provides a simple method for the experimental determination of the auto-oscillation threshold [6].

Frequency Pulling and Locking in RF Assisted Spin-Torque Switching.

S. H. Florez, J. A. Katine, M. Carey, O. Ozatay, L. Folks
Hitachi Global Storage Technologies, San Jose, CA

We demonstrate, at low temperature, that rf currents can dramatically alter the dc driven free layer magnetization reversal dynamics, as well as the dc switching level of current-perpendicular-to-plane spin valves. These effects are observed when the frequency of the rf current, f_{ext} , is tuned to be within a range around the dc driven magnetization precession frequencies, f_0^{dc} . For these frequencies, interactions between the dc driven dynamic excitations and the injected rf induce frequency locking and frequency pulling effects that lead to a measurable dependence of the critical switching current on the frequency of the injected rf.

Spin transfer torque (STT) can excite a broad variety of magnetization dynamics, including reversal and steady-state precessional states [1, 2]. While there has been much interest in the precessional dynamics appearing in the non-hysteretic regime, it has also been recognized that similar dynamics can exist in the hysteretic regime [3-7]. These pre-switching (PS) precessional modes play a key role in determining the spin-torque induced reversal mechanisms. Accordingly, our experiments focus on the unexplored PS dynamical regime as well as on the effects of additional rf current injection on the pre-switching and switching modes.

Figure 1a shows an (I^{dc} , f_{ext}) phase diagram measured at 4.2 K, where the grayscale represents the dc resistance. The figure reveals the dependence of the direct critical switching current, I_c on f_{ext} . These data correspond to a 50 nm x 100 nm hexagonal pillar comprising an IrMn pinned antiparallel (AP) coupled bilayer $Co_{50}Fe_{50}$ (25 Å)/Ru(8 Å)/ $Co_{50}Fe_{50}$ (25 Å), a 40 Å Cu spacer, and 35 Å $Ni_{92}Fe_8$ as the free layer (FL). Measurements of the dc-only driven PS modes reveal that for currents increasing toward I_c , the resonance frequencies drop to a minimum $(f_0^{dc})^{min}$. For this sample the threshold is near 4.2 GHz, as marked on figure 1a. The locations of the dc-only driven peak frequencies, for $I^{dc} < I_c$ are also shown on this figure as white squares. For f_{ext} in this range, additional measurements (not shown here) show frequency locking between the dc driven resonance and the external rf. The region where this occurs is shaded and labeled in the diagram. From figure 1a we see that when this effect occurs near the switching boundary there is an increase in I_c . In contrast, for f_{ext} in the range below 4.2 GHz, there is a steady drop in I_c as the frequency of the external rf increases.

We have performed macrospin simulations based on the Landau-Lifshitz-Gilbert equation using Slonczewski STT [2], including combined dc and rf currents. Strictly speaking such a calculation is over-simplified since it does not take into account micromagnetic details such as non-ideal edge-effects, however, as shown in figure 1b, the model qualitatively captures the underlying physics for the reduction in I_c observed for f_{ext} below $(f_0^{dc})^{min}$ (also obtained through simulation) and the increase in I_c for $f_{ext} \approx f_0^{dc}$, as well as the frequency-locking boundary.

In figure 2 (a) we plot M_y , M_z orbits at a fixed dc current of 1 mA and increasing f_{ext} . Each plot shows three orbits and the arrow indicates the direction of increasing f_{ext} . The labels indicate their corresponding location on the phase diagram in figure 1(b). The Fourier spectra of the M_y components corresponding to the orbits shown in figure 2(a) are shown in figure 2(b). An important conclusion we extract from

the macrospin simulations is that the precessional frequency and orbit are correlated such that small (large) orbits correspond to high (low) frequencies (which is also the case for dc-only driven PS precession). Therefore, when rf currents with $f_{ext} \approx f_0^{dc}$ are applied such that frequency pulling or frequency locking occur, effects on the magnetization precessional orbits also

appear. Through this type of analysis we explore the nature of the dynamic excitations resulting from the interaction between the external rf and the dc driven precession and explain the origin of the effects of the rf on the critical switching boundary.

Spin transfer torque [1, 2] applied to a nanomagnet can either switch its magnetization between static magnetic states or induce steady-state magnetization precession. The primary experimental technique used for studies of spin-torque-driven magnetization dynamics is measurements of the spectra of persistent resistance oscillations excited by direct spin-polarized current. These frequency-domain measurements [3-6] yield ample information on quasi-periodic dynamics but give little insight into non-periodic dynamical processes. We have developed several new experimental approaches [7, 8] that employ time-domain electrical measurements (both stroboscopic and real-time) to probe the transient dynamics of spin-transfer-driven magnetic switching and persistent but non-periodic current-driven processes. We employ these techniques for detailed characterization of current-driven dynamics in Ir20Mn80/ Ni80Fe20/ Cu/ Ni80Fe20 elliptical nanopillar spin valves with misaligned magnetic moments of the free and the pinned layer. Our measurements provide new understanding of strongly nonlinear regimes of magnetization dynamics driven by spin transfer torque that cannot be obtained by conventional frequency-domain measurements.

In the current-induced switching regime, we observe GHz-range resistance oscillations prior to magnetization reversal and a step-wise dependence of the magnetization reversal time on the magnitude of an external magnetic field. These observations reveal a precessional character of current-driven switching in our samples. To understand the origin of the precessional reversal, we make micromagnetic simulation of the reversal process [9]. Our simulations demonstrate that the key factor determining the mechanism of magnetization reversal is the equilibrium angle between magnetizations of the free and pinned layers. We find that in the case of collinear magnetizations of the pinned and free layers, current-induced reversal proceeds via a vortex nucleation process. However, even relatively small misalignments of magnetizations of the pinned and free layers (> 5 degrees) lead to a dramatic change of the reversal mechanism, giving a coherent precessional reversal. Micromagnetic simulations of current induced switching in our samples are in good agreement with our experimental data as shown in Fig. 1.

Near the phase boundaries of the current-field phase diagram that separate different static and dynamic states of magnetization, our measurements reveal that the magnetization dynamics can become stochastic. In particular, close to the phase boundary between persistent oscillatory dynamics and current-driven switching, we find that the resistance signals due to the persistent dynamics evolve as a function of increasing current from a periodic sinusoidal oscillation to brief, randomly-timed, non-sinusoidal, large-amplitude swings in resistance as shown in Fig. 2. Simultaneously, the average frequency of the oscillations approaches zero. These measurements suggest that the magnetization dynamics are affected by thermal fluctuations in the neighborhood of the shallow local minimum of the magnetic energy landscape that exists near the static-dynamic phase boundary for a very large precession angle [7].

Our time-domain measurements also demonstrate that magnetization motion at boundaries of the dynamical phase diagram separating different modes of persistent oscillation can have a stochastic

character [10], and can be described as random switching between two dynamical modes with different frequencies [7]. This switching can occur on a time scale of nanoseconds and it is the dominant mechanism limiting the linewidths of the dc-driven persistent oscillations near these phase boundaries.

Current-driven vortex oscillations in metallic nanocontacts.

Q. Mistral¹, M. van Kampen², G. Hrkac³, J. Kim¹, T. Devolder¹, P. Crozat¹, C. Chappert¹, L. Lagae²

1. Institut d'Electronique Fondamentale, CNRS / Univ. Paris Sud, Orsay, France; 2. IMEC, Leuven, Belgium; 3. Department of Engineering Materials, University of Sheffield, Sheffield, United Kingdom

Lateral confinement in magnetic nanostructures leads to the appearance of complex magnetic states. One important example concerns the magnetic vortex, which arises in patterned structures from competing exchange and dipolar interactions. The dynamics of such vortices is largely governed by the confining potential which defines them. Recent experiments have shown resonance phenomena to be possible with such vortices, including sub-GHz excitations, below the usual ferromagnetic resonance frequency, which involve the spiralling motion of the vortex core about its equilibrium position.

More recently, it has also been shown experimentally that magnetic vortices can be brought into a self-oscillatory state [1]. This is made possible with the spin-transfer effect, whereby spin-angular momentum is transferred between a spin-polarized current and magnetization in a multilayer. It is well-known that spin-transfer leads to an additional torque on magnetization, and it has been demonstrated that this effect can lead to steady-state vortex oscillations in nanopillars [1]. In this talk, we describe how current-driven vortex oscillations can also occur in the absence of any structural confining potential. We demonstrate that spin-polarized currents applied through metallic point-contacts on a continuous magnetic multilayer stack can also lead to vortex oscillations. Here, the Oersted field generated by the applied current provides an effective potential in which a magnetic vortex can oscillate.

The experimental system we study has the multilayer composition Ta/Cu/Ta/NiFe/IrMn/CoFe/Cu/NiFe/Pt, which is a sputter-grown laterally extended stack on which a Cu nanocontact (200 nm in diameter) is deposited. We have measured the electrical high-frequency power spectra through the point contact for external magnetic fields applied perpendicular to the film plane with a direct current flowing through the contact. An example of low-frequency power spectra obtained, for a field of $H = 2.1$ kOe, is presented in Fig. 1. These modes are consistent with vortex oscillations, as the peak frequencies are much lower than the ferromagnetic resonance frequency expected at these fields, hysteresis with applied currents is associated with the existence of these modes [2], and a frequency blueshift is observed with applied currents despite the large in-plane component of magnetization [3].

We have performed full micromagnetics simulations to study the sub-gigahertz oscillations in detail. We take into account the spatially inhomogeneous current distribution flowing through the magnetic free layer and consequently use the Oersted field generated by this current for the magnetization dynamics. The simulations reveal that the observed oscillations correspond to a large-amplitude translational motion of a magnetic vortex. In contrast to nanopillars in which the vortex core precesses within the spin-transfer region, the dynamics reported here corresponds to an orbital motion *outside* the contact region. This is a novel feature brought to light by our experiments. The simulated frequencies give a good quantitative agreement with the measured values, as shown in Fig. 2a. Furthermore, we have derived a modified form of the Thiele equation that includes spin-transfer, and we show that a rigid-vortex approximation can account for the observed variation in the frequency with applied field and currents, as shown in Fig. 2b.

Self-Torque Induced by Local Spin-Transfer Effect and Lateral Spin Diffusion in Magnetic Layers with Inhomogeneous Magnetization.

K. Lee

Korea University, Seoul, South Korea

Initial spin torque theories derived the spin torque term within the macrospin assumption [1]. However, micromagnetic studies [2] and time-resolved imaging experiment [3], have revealed that the spin torque most often generates incoherent spin-waves and thus non-uniformities in the magnetization. Therefore it is essential to consider a possible feedback mechanism between the inhomogeneous magnetization and the spin-transfer torque.

Several authors proposed that the lateral diffusion of spin-dependent reflected electrons at a NM/FM interface (NM=non-magnetic metal, FM=ferromagnetic metal), can induce a stabilizing or destabilizing effect on the local magnetization of the F layer depending on the direction of the current due to local spin-transfer effects [4]. This effect can be named *self-torque* since it allows a single FM layer with inhomogeneous magnetization to exert spin transfer effects on itself.

In order to quantitatively study this phenomenon, we developed a 3-dimensional numerical model to *self-consistently* solve both Landau-Lifshitz-Gilbert and time-dependent spin transport equations. The study was carried out on 3-dimensional structure of Cu (10 nm) / Co (t nm) / Cu (80 nm) patterned to nanopillar of $60 \times 30 \text{ nm}^2$ where t varies from 2 to 8 nm. The patterned part of Cu lead was also included in the numerical study. Magnetic excitation in this single ferromagnet has been calculated as a function of out-of-plane external field ($H_z = 0 \sim 5 \text{ T}$) and injected current ($-15 \sim +15 \text{ mA}$). As in the experiment [5], magnetic excitations were observed only at negative currents (electrons from thick to thin Cu). The critical current for the excitation linearly depends on the out-of-plane field (Fig. 1(a)). Even when $H_z > 4\pi \text{ Ms}$ we observed high frequency precession motions of magnetizations at negatively large currents instead of the out-of-plane saturation. Thickness-dependent slope of $H_{\text{crit}}/I_{\text{crit}}$ is in good agreement with the experimental results especially for a thin Co layer (Fig. 1(b)).

Our result confirms the existence of *self-torque* effects and allows investigating the interplay between the lateral spin diffusion currents and the magnetic excitations in the FM. Numerical studies on spin-valve structures were also performed. The *self-torque* significantly changes the current-induced dynamic modes and more strikingly, can reduce the linewidth of microwave power spectrum. It indicates that the *self-torque* can serve an effective cooling of spin system by suppressing the magnon excitation. In the presentation, the current-induced magnetization dynamics affected by the *self-torque* will be presented in detail.

The observation of steady magnetization excitations induced by spin transfer torque has been reported by many groups in magnetic nanostructures traversed by a spin-polarized current of sufficient density. Here we show that far below this precessional critical current density, spin torque impacts also magnetization thermal fluctuations: in particular, we observed that the noise spectrum of TMR read-heads strongly depends on the direction and amplitude of the applied DC-current.

The electrical noise of 300 nm diameter TMR read-heads with alumina barrier was measured in a range of 1 to 10 GHz as a function of magnetic field, DC current bias and temperature. Measurements were performed both in the parallel and anti-parallel states. We observed several peaks in the noise spectra that shift with the applied DC field and DC current bias. These peaks are attributed to several modes of thermally activated ferromagnetic resonance excitations (FMR) in the free layer, each peak frequency following the Kittel law.

The most interesting feature of the noise spectra is a pronounced asymmetry with the sign of the current[1]. For positive current the normalized noise peak grows, while for negative currents the normalized peak amplitude is reduced. Finally for opposite magnetic field values, the effects of positive and negative currents are exchanged. In other words, symmetric points in the H-I phase diagram exhibit the same behavior. This observation indicates that spin transfer torque reduces or enhances the thermal fluctuations as a function of the DC-current direction, depending on whether it tends to favor or disfavor the equilibrium magnetic configuration.

The influence of spin-torque on magnetic fluctuations is modeled using the macrospin approximation in the framework of linear response theory[2], modified to take into account spin-torque effect. Magnetization dynamics is assumed to follow the Landau-Lifschitz-Gilbert equation modified with the two spin transfer terms: the Slonczewski torque and the inter-layer exchange coupling torque that we hereafter call the “field-like term”. The fundamental FMR mode is analytically calculated using the fluctuation-dissipation theorem. Our model shows that the evolution of the peak line width with the applied current is directly related to the amplitude of the Slonczewski torque while the shift of the resonance frequency is sensitive to the field-like term.

The experimental data are successfully compared with our model. The experimental spectra were first corrected from the noise induced by the experimental set-up itself and from the transfer function of the transmission line between the nanostructure and the spectrum analyzer. The noise spectra were carefully analyzed to take into account the variation with the applied current of both the conductance and the magneto-resistance ratio of the MTJ. From these measurements it was possible to extract the current dependence of the two spin-torque terms. In particular, we have shown that it is possible to extract the Slonczewski spin-torque term from the resonance peak line width in the near-equilibrium regime. Concerning the field-like term extracted from the resonance frequency variation, we must however stress that it is subjected to uncertainties due to the high sensitivity of the resonance frequency to magnetic field, Joule heating and thermo-electric effects.

A significant advantage of these measurements performed below the critical current is the possibility to extract the spin-torque amplitude for both current directions i.e. when the spin-torque tends to destabilize the magnetization equilibrium position as well as when it stabilizes it. Moreover the observed reduction of thermal fluctuations by spin transfer torque could lead to potential applica-

tions. Taking advantage of this effect could help to reduce the electrical noise in hard-disk read-heads especially when the multilayer structure is specifically designed.

In summary, we have studied power spectral density of the voltage noise of magnetic tunnel junctions with alumina barrier in the GHz frequency range and observed that thermal magnetic fluctuations are either reduced or enhanced by the DC-current bias depending on its sign. We ascribe this effect to the influence of spin transfer torque on ferromagnetic resonance excitations depending on whether it favors or disfavors the equilibrium magnetic configuration. Potential use of this effect to control electrical noise in read-heads is conceivable.

Design considerations of tubular flux-switching permanent magnet machines.

J. Wang, W. Wang, K. Atallah, D. Howe

Electronic and Electrical Engineering, University of Sheffield, Sheffield, United Kingdom

This paper describes a tubular, 3-phase, flux-switching permanent magnet (PM) machine, as shown in Fig. 1, which combines salient features from switched reluctance with simple and robust mover structure and high force capability of permanent magnet machines with no end-windings and zero net radial force, and has the potential for low cost manufacture. Further, since the armature reaction field is essentially perpendicular to the axis of magnetisation, the risk of irreversibly demagnetising the magnets is low. This enables a high peak electric loading, and, hence, a high peak power density and force capability. The machine is, therefore, eminently suitable for a variety of applications which requires great mechanical robustness and the ability to operate in harsh environment, such as free-piston energy converters and active vehicle suspensions.

The paper derives feasible pole-slot number combinations applicable to both rotary and linear flux-switching PM machines, Table I, where N_s is the number of stator slots(modules) and N_p is the number of active mover poles(teeth), and examines an alternative winding configuration which is unique to tubular machine topology. It is shown that various feasible pole-slot combinations exists for flux-switching machines, and that the alternative winding configuration yields ~10% higher thrust force capability as compared to the conventional design.

In conventional rotary brushless DC or flux-switching PM machines, a coil is usually wrapped around a stator tooth. This winding configuration results in the winding factor for the fundamental being equal to 0.866. For tubular flux-switching machines, however, there is an alternative winding configuration in which the two coils in one slot are connected in series to form a phase winding, as shown in Fig. 2. This gives rise to ~13% increase in fundamental winding factor and hence 13% higher force capability. Furthermore, the phase windings in this configuration are essentially physically, magnetically and thermally isolated from each other. This will lead to a high degree of fault-tolerance. Fig. 3 compares the variation of thrust force of the 12-slot, 10-pole flux switching machines with conventional and alternative winding configurations as functions of current density. Both machines are optimally designed with the same volumetric and thermal constraints for active vehicle suspension applications. As will be seen, the alternative winding configuration yields ~10% higher force capability as compared to the conventional design.

Detailed derivation and performance analysis of the feasible pole-slot number combinations and alternative winding configuration for tubular flux-switching machines together with the procedure for achieving optimal design for applications in active vehicle suspension will be described in the full paper.

Linear induction motors with modular winding primaries and wound rotor secondaries.

J. Eastham¹, T. Cox^{1,2}, J. Proverbs²

1. The University of Bath, Bath, United Kingdom; 2. Force Engineering, Shephed, United Kingdom

Introduction

Linear induction motors commonly use conventional double layer stator windings. These provide an excellent travelling field with little harmonic content. However when applied to linear stators they must use either half empty slots or coils that overlap at the ends of the stack. In addition the end winding at the sides of the machine tends to be bulky.

Modular Windings

It is the objective of this paper to use modular windings [1][2] which have winding groups that are in a plane and do not overlap. This leads to machines that are inexpensive to wind, compact and can be stacked end to end since no overlapping coils or half filled slots are needed. This is a particularly useful feature when long stators for EM launchers or urban transport schemes are considered. Whilst the windings are excellent mechanically they have the drawback of a high harmonic content in the mmf wave. For example a 9 coil winding of coil configuration (R – R R B – B B Y – Y Y) has large 8 and 10 pole mmfs. Fig. 1 illustrates this showing the open circuit flux together with the 8 and 10 pole components. These components travel in opposite directions.

The windings are typically in use for machines with permanent magnet excitation [1]. For this duty either an 8 pole or a 10 pole magnet array can be provided to cooperate with either the 8 or 10 pole mmf wave respectively. If for example an 8 pole array is chosen then net force will result only with the 8 pole mmf. The 10 pole mmf merely produces air-gap flux which gives extra leakage reactance.

The situation is radically different for induction machines. If an inductive plate rotor is used both the 8 and 10 pole fluxes produce secondary eddy currents and force. The 10 pole force opposes the 8 pole and the net force is severely reduced. Fig. 2 illustrates this condition by comparing the response for an 8 pole short plate rotor first to a double layer winding with small harmonic content and secondly to the 9 coil modular winding described previously. It will be seen that the plate rotor performs poorly with a modular wound stator due to the backward going harmonic. These results were obtained using the MEGA package time stepped FE modelling.

New Principle

The situation can be improved by using an 8 pole double layer wound secondary. This, like the permanent magnet secondary, will respond substantially only to the pole number for which it is wound since the winding factor controlling the induced emf is small except for the fundamental. The response as shown in Fig. 2 is excellent; the peak force is closely the same as when a double layer stator and plate rotor is used but the peak is closer to the synchronous speed indicating a much better secondary efficiency (90% compared to 50%).

The new principle [3] of using wound secondaries so that simple modular primary windings may be used has been described with respect to a particular 9 slot 8/10 pole winding, but it will be appreciated that there are a large number of modular windings [1][2] with substantial harmonic content which can also be used.

An Experimental Machine

A test rig has been constructed to prove this principle using 9 slot 8/10 pole stator winding sections. This cooperates with a short wound rotor carrying a fractional slot double layer 8 pole winding designed so that standstill locking forces are small. Tests were performed using the standstill vari-

able frequency principle [4] to estimate the dynamic response of the system and the results are plotted on Fig. 3 for comparison with FE standstill variable frequency results. It will be observed that the correlation is excellent.

Conclusions

Simple modular windings can be used for linear induction motor stators when wound rotors are employed. The new arrangement enables inexpensive stator modules to be used in EM launch and urban transport systems.

Magnetic Actuator Design using Level Set based Topology Optimization.

S. Park¹, S. Min¹, S. Yamasaki², S. Nishiwaki², J. Yoo³

1. Mechanical Engineering, Hanyang University, Seoul, South Korea; 2. Aeronautics and Astronautics, Kyoto University, Kyoto, Japan; 3. Mechanical Engineering, Yonsei University, Seoul, South Korea

Topology optimization which determines optimal distribution of material has been widely applied to design magnetic devices since the work by Dyck and Lowther[1]. The element based topology optimization method has resulted in mesh dependent boundaries and gray scale elements due to numerical instabilities[2]. These features have great influence on the performance of magnetic devices due to discontinuity of magnetic flux. Level set based topology optimization has emerged recently as an attractive alternative to overcome shortcomings of the conventional method. Level set method is a numerical technique for tracking interfaces and shapes using the implicit function, so called level set function[3]. Sethian and Wiegmann[4] firstly introduced level set method to topology optimization in order to represent material boundaries, and could design a cantilever beam with distinct boundaries free from mesh dependency and gray scale elements. Thus, the goal of research is to develop a novel design methodology for optimum structural design of magnetic actuators using a level set based structural optimization method where the level set method can represent the precise boundary shape of a structure and also deal with complex topological changes during the optimization process.

In this work, we focus on designing a yoke of magnetic actuators using level set based topology optimization in order to improve magnetic force on armature while reducing its weight. Level set method is introduced to represent material boundaries between a ferromagnetic material domain and another domain filled with air where level set function $\phi(x)$ is defined as shown Fig. 1. The magnetic quantities are calculated by linear magneto-static finite element analysis under the assumption that the material property has linear relationship between magnetic field intensity and flux density. To represent the distribution of ferromagnetic material, the magnetic reluctivity of each element can be defined using level set function as follows:

$$v(\phi(x)) = v_0 (v_{\text{air}} + (v_{\text{mat}} - v_{\text{air}})H(\phi(x)))$$

where v_0 is magnetic reluctivity in free space and $H(x)$ is Heaviside function which has zero or one according to x . To formulate the optimization problem the objective function is set to maximize the magnetic energy in a domain between a yoke and an armature since the magnetic force on an armature becomes larger as it increases, and the amount of material used in the domain is constrained to limit its weight. The movement of the implicit moving boundaries of the structure is driven by a transformation of the objective and the constraint into speed functions that govern the level set propagation. The normal velocity is derived from optimality and convergence conditions of level set equation and calculated using sensitivities of the objective function and the constraint where the adjoint variable method is employed since the objective function has implicit dependency with level set function.

The proposed method is applied to design a yoke of magnetic coupler shown in Fig. 2(a) which enables the transmission of mechanical energy through a magnetic field interaction. In order to maximize the magnetic force on the positioner, the design domain is considered as yokes and the positioner and the magnetic energy is calculated in an air gap domain. Fig. 2(b) shows the optimal layout of ferromagnetic material that has clear-cut boundaries and the exact shape extraction of the optimal design can be easily integrated with CAD/CAE systems. It is summarized in Table. 1 that

the optimal design provides 10% higher magnetic force and 30% less material usage than the initial design.

Comparison of numerical and analytical simulation of saturated zig-zag flux in induction machines.

A. Binder, T. Knopik, R. Hagen

Institute for Electrical Energy Conversion, Technische Universität Darmstadt, Darmstadt, Germany

Iron saturation in induction machines (IM) is determined by (i) the main flux saturation k_h , which is excited by the magnetizing current and is dominant at no-load, being clearly visible in the no-load characteristic, and decreases with increasing slip (Fig. 1a, b), and by (ii) the load dependent air gap zig-zag flux saturation k_{zk} , which increases with increasing slip and dominates the iron saturation at stall, being clearly visible in the voltage-current-characteristic at unity slip $s = 1$ (Fig. 1c, d). Whereas the main flux saturates the iron teeth at full length and the iron back, the zig-zag flux along with the slot leakage flux saturates the tooth tips. The analytical calculation of the main flux saturation is well known and found in good coincidence with numerical solutions. The analytical non-linear calculation of the zig-zag flux still is matter of investigation. Here, the basic work of Wepppler, Schetelig and Taegen is revisited and combined. It proves to be a very useful approach to calculate the saturated zig-zag flux and the corresponding tooth flux pulsation under load, along with the induced rotor cage harmonic currents. Hence it allows a satisfactory analytical prediction of the saturated stalled voltage-current characteristic and the stray load losses.

Fig. 1: Saturation in IM: a) Main flux path, b) No-load characteristic, c) Zig-zag leakage paths at $s = 1$, d) Locked rotor characteristic.

Wepppler combined for induction machines the well-known main flux saturation factor k_h with the rotor skew, leading to increased saturation due to the different superposition of the stator and rotor fundamental field in different radial machine cross sections. Further he introduced a method for calculating the air-gap zig-zag flux, which is not based on the conventional summing of stator and rotor field harmonics to arrive at a harmonic leakage inductance. He directly calculates the flux from simple lumped parameter magnetic circuits, defining the coefficients k_{zk} for the zig-zag flux saturation in the tooth tip and k_{sl1-2} for the stator and rotor slot leakage flux saturation. Schetelig improved this method by considering also the saturation in the stator tooth tip, which is caused by the slot harmonics of the rotor m.m.f. and the rotor slot fields, which amplify the slot harmonic field amplitudes due to the rotor slot openings, with the help of conformal mapping. For closed rotor slots a special iterative method for saturation of the tooth tips is used.

Taegen pointed out by careful measurement with tooth and yoke coils, that there is a different saturation for harmonic components of the zig-zag flux with low and high ordinal number. The saturation of harmonic field waves with small wave lengths in the range of a stator/rotor slot pitch is determined by tooth-tip saturation k_{zk} . Harmonic fields with long wave lengths (so-called slot difference harmonics), hence with low ordinal numbers, magnetize in parallel to the main flux via the iron back, resulting in another higher saturation. Adding this effect to the Wepppler-Schetelig theory, the harmonic leakage inductance, corresponding to the zig-zag flux, is determined for an equivalent magnetic circuit, which allows the calculation of the saturated locked voltage-current characteristic without any correction factors. Further, the sum of all field harmonics for a certain value $g \neq 0$ cause a pulsation in the stator tooth.

Considering the harmonic content of leakage flux up to certain maximum ordinal number yields the time function of the flux pulsation in the stator teeth, and in a similar way, in the rotor teeth, along with the calculation of the cage harmonic currents, which are damping the flux pulsations considerably.

The above described methods were applied to several 4-pole, skewed aluminium cage induction machines with 36 stator slots and 28 rotor slots. The analytically calculated no-load and locked voltage-current-characteristics were compared with measurements (Fig. 2a). With the 2D FEM program package FLUX2D non-linear time stepping simulations for unskewed machines were performed and compared to the analytical results (Fig. 2b, Fig. 3).

The FEM and analytical result fit very well, showing a by ca. 10% bigger current in comparison to the skewed rotor due to the lack of skew leakage inductance.

As an example, for the same rated motor data of Fig. 2 the analytically calculated tooth flux density in the middle tooth is shown in Fig. 3a at no-load and in Fig. 3a at rated slip for an unskewed rotor. The increase of the tooth flux pulsation amplitude with increasing slip due to the increasing zig-zag flux is clearly visible and in good coincidence with the FEM result, which for clarity is shifted in Fig. 3a.

In the full paper the numerical solutions and further experimental work is given in more detail along with a description of the analytical calculation method.

Newly structured double excited 2-DOF motor for security camera.

J. Lee¹, D. Kim², S. Baek¹, B. Kwon¹

1. Hanyang University, Ansan, South Korea; 2. Korea Electronics Technology Institute, Gwangju, South Korea

Introduction

Recently, the research of multiple degrees of freedom (DOF) motor has been extensively conducted without a dynamic transfer device [1-2]. The Multiple-DOF motor with only one joint is not necessary to use additional gears and links parts. Therefore, The Multiple-DOF motor can eliminate the combined effects of inertia, backlash, non-linear friction, and elastic deformation of gears. But it has a complicated control algorithm and difficult manufacture due to the spherical shape. Thus, it has not been put to practical use. However, the 2-DOF motor has the advantage of the 3-DOF Spherical motor in terms of practical use.

A few researchers have been concerned to develop 2-DOF motor. Hirata has suggested 2-DOF motor which consist permanent magnet rotor and 'E' type, 'C' type stator segment for linear/rotate motion [3]. Yano has suggested 2-DOF motor which consist inner sub-motor and outer sub-motor for horizon/vertical motion [4]. It is not suitable for a security camera application with pan-tilt motion. This paper has proposed the novel designed 2-DOF motor with pan-tilt motion to use in a security camera and also analyzed its performance by 3D FEM.

Design of a Double Excited 2-DOF

Fig. 1 and 2 show the proposed structure of 2-DOF motor and the operation principle. The proposed 2-DOF motor consists of the rotor and the stator. The Stator is designed as 'C' type to form closed loop to tilt direction. 'C' type stator is placed to 12 stator segments. Also Stator is placed to 90 degrees interval by 3 phases so that it react both main pole and auxiliary pole. Rotor is designed to form flux loop of symmetry via tilt rotating axis so that flux is not overlapped. The Rotor is placed to auxiliary pole, because it does not pan direction driving by only main pole. Tilt positioning is decided by main pole in 2-phase conduction. And pan positioning is decided by stator current excitation. The proposed model is following advantage. First, lamination is possible structure. Because two-dimensional core that is not third dimension processing was divided by several, processing is easy. Second, Encoder or hall sensor is not required. Third, it is not required for complex axis conversion and is available for independent control.

Result and Discussion

Fig. 3 shows torque simulation results which do tilt-pan direction by 3D-FEM. According to excite in each phase, the torque converges in position that is '0' by pan-tilt torque simulation. As a result, it can drive -33~+33 degree tilt to 5 degrees interval and 360 degree pan. Micro position drive is impossible by shortcoming of proposed 2-DOF motor. However, it is not required for security camera application which can be reserved visual field in some degree. Therefore, it is noted that the proposed 2-DOF motor is suitable for security camera application. The experimental results will be performed in future.

3-D Finite Element Analysis of Magnetic Forces Exerted on Stator End-windings of an Induction Motor.

R. Lin, A. Arkkio

Helsinki University of Technology, Espoo, Finland

I. INTRODUCTION

This paper studies the forces on the end-windings of a 1250-kW induction motor by 3-D finite element analysis.

II. MODEL AND METHODS

A. Model

The stator winding consists of two-layer chorded coils. The coil group of phase A is studied. The coil end is divided into 29 segments, as marked in Fig. 1.

B. Methods

A time-harmonic analysis is used. The equation to be solved is:

$$\nabla \times [\nu(\nabla \times \mathbf{A})] + j\omega \sigma \mathbf{A} = \mathbf{J}. \quad (1)$$

C. Magnetic Forces

The force \mathbf{F} is calculated by

$$\mathbf{F} = \int \mathbf{J} \times \mathbf{B} dV. \quad (2)$$

The force consists of a constant time-average component and a periodic sinusoidal component with double frequency. Here, the time-average component is studied.

III. RESULTS

Figs. 2-4 and 5-7 plot the distribution of average volume density of forces at no-load and rated-load.

IV. CONCLUSIONS

At both no-load and rated-load, in the coil ends which are close to iron core, inner layer coils have larger radial force density than outer layer coils, as shown in Figs. 2 and 5. In the inner layer, coil 1 has stronger peripheral and axial force densities, but in the outer layer, those in coil 4 are stronger, as shown in Figs. 3, 4, 6 and 7. Besides, all the forces tend to enlarge the coil outward.

Fig. 1. The index of segments of one coil for forces.

Magnetoelastic Characteristics of the Multilayered Magnetostrictive Thin Film with Polyimide Substrate for Micro Actuator.

H. Lee, C. Cho

Mechanical Engineering, Inha University, Incheon, South Korea

Magnetostrictive materials have been studied for sensors and actuators using Joule effect, Villari effect, Wiedemann effect etc.¹⁻⁴ They introduced rod and thin film type designs and fabrication techniques for the applications.⁵⁻⁷ Among them, thin film structures can be applicants for micro scale devices for their thin film characteristics and high magnetic-mechanical responses should be produced under the low magnetic field to be a micro actuator. During ten years, most magnetostrictive thin films for actuators were based on Si substrates of high brittle property, so it could not be used in impact or bent environment. The development of micro actuators based on magnetoelastic response requires highly magnetostrictive thin films with flexible substrates.

In this paper, we have suggested a TbFe/Ni/TbFe layered magnetostrictive film type actuator and investigated to the magnetoelastic characteristics of the actuator for micro application.

The schematic diagram of a multi body structure is illustrated in Fig. 1, which consists of array type cantilevers thickness of 127 μ m as polyimide substrate (Kapton, Dupont Corp.) with frame (size of a: 1.5mm, b: 1mm, c: 1.5mm). The back side of each cantilever is deposited with multilayer of TbFe/Ni/TbFe film thickness of 0.2/0.1/0.2 μ m and 0.2/0.1/0 μ m using selective DC magnetron sputtering.

When the magnetic field is applied to the film deposited structure along with longitudinal direction as Fig. 1, magnetic field creates magnetic moment and it leads to magnetization of the structure, and the magnetization in the deposited film that causes magnetostriction. As a result of the movement of the multi body structure, it can be used as a position drive actuator.

To fabricate a suggested thin film actuator design, the micromachining process and selective DC magnetron sputter techniques are combined.

The fabricated film thicknesses are measured by X-ray diffractometer (XRD). From XRD results, the film thicknesses can be calculated as follows:

$$\Lambda = I\lambda / 2(\sin^2\theta - 2\delta)^{1/2}$$

Where I is the intensity of the upper peak point at each 2θ , λ is the wave length of the deposited film, Λ is the film thickness and δ is the real part of the refractive index and has a value of 10^{-5} .

The magnetic moments and the magnetostrictions are also measured to characterize the magneto-mechanical properties of the TbFe/Ni/TbFe films at each deposited film thickness. The magnetic moment is observed using vibrating sample magnetometer. 0.2/0.1/0.2 μ m has higher hysteresis and coercive force of 0.01T.

The magnetostrictions of each film are determined by measuring the differences of the curvature of the coated silicon substrates using the optical cantilever method. The curvatures of the length and width directions of the film due to external magnetic fields by the electromagnet are measured by detecting deflected the laser signals through a position sensitive detector. The calculated magnetostrictions can be expressed as deflections. The measured deflection results at each thickness are shown in Fig. 2.

In summary, polyimide substrate based TbFe/Ni/TbFe layered actuators are fabricated using micro-machining process with selective DC magnetron sputtering technique. The actuator has cantilever arrays and its back side is deposited with magnetostrictive thin films at the thicknesses of 0.2/0.1/0.2 μ m and 0.2/0.1/0 μ m. The thickness is evaluated using XRD. Characterized results show the magnetic moments at the two kinds of substrate size. TbFe/Ni/TbFe of 0.2/0.1/0.2 μ m shows

higher magnitude of magnetic moment, coercive force and hysteresis. Maximum deflection is about 60 μ m under 0.5T for 0.2/0.1/0.2 μ m as a micro-device application.

Analysis of the force produced by speed-induced eddy currents in an xy-actuator.

A. F. Flores Filho¹, N. F. Baggio Filho¹, M. A. da Silveira²

1. Post-graduate Programme in Electrical Engineering, Federal University of Rio Grande do Sul, Porto Alegre, Brazil; 2. Post-graduate Programme in Engineering – Environment, Energy and Materials, Lutheran University of Brazil, Canoas, Brazil

The xy-actuator employs a slotless ferromagnetic slab as armature core and orthogonal planar windings with multiple phases, Fig. 1. Its mover comprehends a set of two permanent magnets, a back iron and a guiding system. The actuator presents a 3d distribution of the magnetic flux density throughout its magnetic structure[1][2]. The movement of the actuator can be established when the coils of the armature phases located under the permanent magnets are properly fed with currents. Induced currents will appear in the armature core due to the velocity of the mover and to the switched currents in the coils. This work will focus on the effect of the velocity only. That will produce a magnetic braking force that act on the mover. To reduce it and let the actuator benefit from the 3d distribution of magnetic field, the armature core should be made of a ferromagnetic material with magnetic isotropy and also high resistivity. Hence, the use of a magnetically isotropic and particle-insulated soft magnetic composite called Somaloy 500 [3] was considered. For comparison, two armature cores were employed: one is a slab of AISI 1020 steel; the other is a set of pieces of Somaloy 500 put together to resemble a solid slab. The electrical resistivity of the Somaloy 500 is much higher than that of AISI 1020 steel. But Somaloy 500 presents a lower maximum permeability than the AISI 1020. Yet, the 12-mm large air gap between the armature core and the mover of the actuator sets the operation point of the permanent magnets. A 3d finite element model allowed a dynamic simulation. That made possible to verify the distribution of the velocity-induced current density J in the armature core. Table 1 shows the velocity-induced current as a result. The analysis provided the current through a cross section of the armature core defined in between the projected center of the permanent magnets over that core and along the thickness of that core. The magnetic braking force was obtained by means of the displacement of the mover over the plane of the armature core at a velocity v . A standard weight attached to the mover by means of a string pulled it by a force F , Fig. 2. That induced currents in the armature core, and they react by producing a braking force on the mover. Its dynamic relation to the system can be given by Eq. (1), $F_f = -kv = F_b + F_{mf}$ (1), where F_f is the total friction force, F_b is the braking force produced by the velocity-induced current, F_{mf} is the mechanical friction force, m is the mass of the mover and k is an overall friction coefficient. As it takes into account mechanical friction and the magnetic braking forces, k is related to both effects. When Somaloy 500 was employed, $k = 0.382235$ Ns/m, while $k = 1.86564$ Ns/m when an AISI 1020 core is used. With the figures obtained for k in each case, the magnetic braking force produced by the velocity-induced current was computed, Fig. 3. The numerical results and experimental ones point to the differences between the use of both materials and, at the same time, favours a soft magnetic composite core to diminish the velocity-induced eddy currents and their effects.

An Extension to Multiple Coupled Circuits Modeling of Induction Machines to Include Variable Degrees of Saturation Effects.

M. Ojaghi, J. Faiz

Department of Electrical and Computer Engineering, University of Tehran, Tehran, Iran

Multiple Coupled Circuit Modeling (MCCM) of Induction Machine (IM) [1], using winding function theory and its extension[2], has gained a broad application in the analysis of IM, mainly because of its ability to analyze faulty machines. However, neglecting magnetic saturation effects is a great weak-point of this model. Nandi took valuable steps on adding saturation effects to it[3] using a theory presented in[4], where the reluctance increasing effect of saturation is substituted by a proportional increase in the Air-Gap (AG) length as eq.1 where ϕ is the angle in the stator frame, ϕ_r is the angle of the peak value of the AG flux density(B_m), P is machine's pole pairs, g , ρ and g_s are the mean value of AG length, the peak value of its fluctuation and the AG function respectively in the presence of saturation(see Table 1 for equations). Our contribution in this paper has the following advantages:

1.No approximation encountered in evaluating the inverse AG function P_s (see eq.2).

2.Introducing the saturation factor (K_{sat}) as a variable in the model:

K_{sat} is the ratio of fundamental components of the AG voltage for saturated and unsaturated conditions [4], so it obviously varies by varying the load. Thus introducing K_{sat} to the model as a variable is necessary. Using some definitions given in [4] we obtain eqs.3 where g_0 is the normal AG length of unsaturated machine.

3.Introducing a simple but precise technique to evaluate the angular position of B_m :

When simulating an IM using MCCM, flux-linkages of rotor meshes are evaluated. It is obvious that any time, B_m is within the arc of a mesh which has the most flux-linkage. Using flux-linkages of this mesh and the two adjacent meshes and a linear function, ϕ_r can be obtained precisely by eq.4 where θ_r is the angle of rotor in stator frame, θ_i is the angle of center of mesh i who has the most flux-linkage in rotor frame, λ_i is the flux linkage of mesh i and n is the number of rotor bars. In [3] the angle of time derivative of stator flux linkage space vector has been taken instead of $2P\phi_r + \pi/2$. Fig.1 represents these two angles on a simulated IM, where their high difference is notable.

4.Establishing analytical equations to calculate inductances and their derivatives:

MCCM needs all self and mutual inductances of stator phases and rotor meshes and their derivatives versus θ_r to be available [1]. The introduction of the AG function as eq.1 causes all of these inductances and derivatives to be time variant, so they must be updated by progress of the simulation. All users of MCCM till now have introduced look-up tables or approximate functions to update them, but in this paper, we established precise analytical functions. For this purpose we first determined the indefinite integral of P_s function (eq.2) with respect to ϕ as eq.5, then using winding function theory and its extension, we obtained simple equation for inductances and derivatives. Fig.2 represents the variation of self inductance of rotor mesh 1 and its derivative. When $K_{sat} = 1$, L_{11} is constant and its derivative is zero. By increasing K_{sat} , L_{11} and its derivative fluctuate largely.

Using these equations, an 11kW, 380V, 50Hz, 4 poles, Δ connected IM was simulated using MCCM. Also experiments were done on IM while its currents and voltages sampled and saved on PC using PCI-1710HG card made by ADVANTECH. Using an estimation technique, we estimated the stator inductance (L_s) from simulation and experimental data(Fig.3a). As seen adding saturation effect to MCCM causes an oscillation of about 300Hz in the estimated inductance which is in accordance with experiments, although the amplitude of oscillations are different. This difference is partly due to some inherent abnormalities such as eccentricity in motor structure and part-

ly due to dependency of (3) to core material. Fig.3b shows the normalized power spectral density of motor line current. As expected, saturation caused odd harmonic components to be present in the simulation results which are in accordance with experiment results.

Switched Reluctance Motor with External Rotor for Fan in Air-condition.

H. Chen

College of Information and Electrical Engineering, China University of Mining & Technology,
Xuzhou, China

Switched Reluctance external rotor motor had been developed to drive fan in air-condition directly. The electromagnetic design of the external rotor motor is implemented based on the Switched Reluctance internal rotor motor with the two dimensions finite element electromagnetic field calculation. The method is described with some examples, such as the electromagnetic design of the Switched Reluctance 3-phase 6/8 external rotor motor with six internal stator poles and eight external rotor poles could be implemented based on the Switched Reluctance 4-phase 8/6 internal rotor motor with eight external stator poles and six internal rotor poles, but the calculated period of the external rotor motor is 45 degree, and the calculated period of the internal rotor motor is 60 degree. The electromagnetic design of the Switched Reluctance 4-phase 8/12 external rotor motor with eight internal stator poles and twelve external rotor poles could be implemented based on the Switched Reluctance 3-phase 12/8 internal rotor motor with twelve external stator poles and eight internal rotor poles, but the calculated period of the external rotor motor is 30 degree, and the calculated period of the internal rotor motor is 45 degree.

Those had got three Chinese invention patent rights, such as Chinese Invention Patent 200710019552.7, Chinese Invention Patent 200710019638.X, Chinese Invention Patent 200710019705.8.

The design results of the Switched Reluctance 3-phase 6/8 external rotor motor were given, which is compared with that of the Switched Reluctance 4-phase 8/6 internal rotor motor.

1. The University of Bath, Bath, United Kingdom; 2. Force Engineering, Shephed, United Kingdom

Introduction

The common method [1] for calculating end turn reactance involves removing the machine core from the problem and forming air-cored coils from the two end regions of the machine coils. The results of this calculation can vary considerably from experimental values due to the presence of the core iron. Lawrenson developed approximate methods for modifying the inductance to allow for the iron in the case of a turbogenerator [2]. It is the objective of this paper to use 3D & 2D finite element modelling to calculate the leakage inductance of concentrated and modular windings, including the presence of the core. These windings are in use for permanent magnet machines [3] and are proposed for special linear induction motors [4].

3D Finite Element Modelling Methods

The first finite element method using the MEGA package involved the use of several full 3D stator models of varying core widths [5]. For convenience these were linear in form. The stator reactance measured from the terminals comprises several parts including end turn, slot and magnetising reactance components. Whereas all other reactance components are directly proportional to core width, end turn reactance is constant. Therefore, if the terminal reactances of several otherwise identical machines of varying core width are plotted, referring this plot to zero core width will yield a value for end turn reactance of the machine Fig. 1.

This method and its results have been validated experimentally, by constructing 3 otherwise identical machines of reducing core width, and referring to zero core width. These results are also plotted on Fig. 1 for comparison with the FE values. It will be observed that the correlation between the results is excellent.

A simpler method has also been developed. A 3D FE model can accurately model all aspects of a stator. A 2D FE model can accurately model per metre depth all stator characteristics whose parameters can be described in two dimensions, and thus is able to account for all reactance effects except end turn reactance. Therefore, if both 2D and 3D FE models are produced based on the same machine, the difference in reactance between the two must be due mainly to end turn leakage reactance, and can therefore be calculated. This method gave a value within 10% of the 3 core experimental and full 3D results with significant saving in computation.

Differences

The main reason for the differences between experimental and FE results and the simple analytical method [1] is the presence of Iron [2]. The analytical method makes no allowances for the presence of iron, where this has been shown experimentally to have a significant effect on the measured end turn reactance. The three machines of varying core width have been tested experimentally with and without iron cores, and their reactance referenced back to zero Fig. 1. This shows an obvious and significant difference due to the presence of an iron core.

Analytical Parameterised Modelling Method

A new method of modelling end turn reactance of iron cored concentrated coils was now developed. The 2D and 3D comparison method used above was used to find values of end turn reactance over a useful range of coil depths & widths. These values were then used to develop the parameterised equation[6] for 12mm coil protrusion Fig. 2.

This equation is able to predict the end turn leakage inductance of a machine within 10%.

Conclusions

Simple analytical methods of end turn leakage reactance modelling have been found to be inexact when modelling concentrated iron cored coils. The equation developed is a fast and accurate method of calculating end turn reactance. The correlation between experimental results and 2D finite element results using this method of calculating end turn reactance is excellent.

Instituto de Química-Física Rocasolano, CSIC, Madrid, Spain; 4. Centro de Microanálisis de Materiales, Universidad Autónoma de Madrid, Madrid, Spain; 5. Berkeley National Laboratory, Berkeley, CA; 6. Livermore National Laboratories, Livermore, CA

Thin-film ferromagnetic materials are still a source of surprises. For example, consider the easy axis of magnetization, a property crucial for technological applications. Recently, spin-polarized low-energy electron microscopy [1] revealed that ultra-thin cobalt islands and films on ruthenium present consecutive spin-reorientation transitions: mono-atomic (ML) films present an in-plane easy-axis of magnetization, bilayer islands or films have an out-of-plane easy-axis, while thicker films have an in-plane easy-axis again. Furthermore, additional deposition of silver [2] produces also a magnetic easy-axis reorientation -at selected Co coverages- as a function of the silver coverage, again with atomic scale abruptness: depositing Ag on an in-plane magnetized 3 ML thick cobalt film produces an out-of-plane easy-axis, depositing additional Ag layers switches the easy-axis in-plane again.

To understand, and even predict the observed magnetic behavior, separating those different contributions becomes essential. Magnetic, structural and electronic measurements from uniform film regions with precisely known properties (such as structure and thickness) are needed. Such measurements are challenging in systems such as cobalt on ruthenium, where the film wants to form three-dimensional islands rather than remain flat. Here we use the imaging capability of photoemission microscopy coupled to a synchrotron radiation source (ELLETRA, Italy) to measure the properties of a few layers thick uniform cobalt regions on ruthenium. Photoemission microscopy performed by a low energy electron microscope with energy filtering -Spectroscopic Photoemission and Low Energy Electron Microscope, SPELEEM [3]- is a versatile technique capable of obtaining both spatially resolved X-ray absorption data -by imaging the secondary electrons emitted by the sample upon X-ray illumination-, or spatially resolved and angle-resolved photoemission data in normal incidence.

In the last mode we have performed valence band measurements of Ag films of several thicknesses, both directly on the ruthenium substrate as well as on 3 ML thick Co films in order to clarify the contribution that dominates the magnetic behaviour. We report on the surprising observation of a strong valence-band dichroism in the Ag-related d-bands of the films grown on 3 ML Co. Ab-initio calculations of the band structure to explain the experimental results are under way.

By using circularly polarized X-rays, the L-level dichroism from regions as small as a single Co island is detected, providing a direct image of the local structure's magnetization. We have also measured the dichroic difference between the L3 and L2 Co levels. In particular we have imaged both Co islands and films 3 ML thick using L-level dichroism (see Figures). The islands have a triangular shape with a common orientation, aligned along the high symmetry directions of the substrate[5]. After the application and removal of an external magnetic field prior to our photoemission microscopy observations, we detected that large islands (around one micrometer in size) present the same magnetization pattern which includes vortex-like structures, while smaller islands were observed to be single domain in remanence. Based of micromagnetic simulations based on the

OOMMF code [4], we suggest that our observations can be explained by the interplay of in-plane shape anisotropy of the triangular islands coupled to the applied magnetic field direction.

We report on the effect of magnetostatic interactions on the emergent magnetization pattern in artificial two-phase magnets, which are a model system for the study of collective effects in magnetic arrays. The structures consist of patterned hard magnetic CoPt squares with out of plane anisotropy embedded in a soft magnetic Permalloy (Py) matrix. In previous work [1] we have shown that the patterning introduces a long-range ordered symmetry breaking domain pattern in the matrix if the distance between the CoPt squares is equal to their size. At smaller distances the magnetostatic interaction between neighboring squares results in a correlated nucleation of reversal domains at opposing edges of the hard magnetic squares [1]. In this paper we address the following new aspects: (i) Long-range order in small arrays with only a few CoPt squares and in arrays with larger distances d between neighboring CoPt squares. (ii) The role of the matrix in the correlated nucleation of reversal domains in adjacent hard magnetic squares.

The arrays were fabricated as described in [1]. The CoPt squares and the matrix have a thickness of 50 nm and the size of the squares is $5 \times 5 \mu\text{m}^2$. Magnetic force microscopy (MFM) is used to image the structures.

Figure 1 shows MFM images of 1×1 , 1×3 , and 3×3 arrays for a distance d between adjacent CoPt squares of $5 \mu\text{m}$. We find that single squares as well as one dimensional arrangements of squares influence the domain pattern in their proximity, but do not cause a breaking of the symmetry. Yet, in arrays with only 3×3 squares a symmetry breaking pattern appears. Here, in the area between four squares the magnetization of the Py is reorganized and the domain walls form large rhombs. One of these rhombs is marked by dotted lines. These large domains have diagonal magnetization, as previously observed in larger 7×10 arrays [1]. Both for 3×3 and 7×10 arrays, all of the rhombs are aligned over the whole array, i.e., they show long-range ordering. Moreover, this magnetization pattern is found to be very stable. Even though it disappears at a perpendicular field of 400 mT, for which the magnetization of the Py aligns with the field, the pattern reappears once the field is turned off. Our results indicate that the long-range ordered rhomb-shaped domain pattern is the ground state of two-dimensional arrays with d being equal to the square size. If the distance between the squares is doubled, $d = 10 \mu\text{m}$, the domain pattern in the matrix becomes less regular and the rhomb shaped domains decompose into smaller domains, see figure (1d).

In order to obtain additional insight in the correlation of reversal domains in adjacent hard magnetic squares,

we analyze the interaction between the CoPt and the matrix close to the CoPt/Py interface. Figure (2a) shows a corner of a CoPt square. The CoPt square is in a multi domain state. The domains which are located directly at the edge of the square produce a stray field which, in turn, generates an out of plane component of the matrix magnetization opposite to the magnetization of the CoPt domains. Since the CoPt is in a multi domain state, the magnetization of the matrix is modulated along the square edge in the proximity of the interface, as can be seen from the line profile. The modulation in the matrix decays within several hundred nanometers (data not shown). If the distance between the squares is reduced to the decay length of the modulation of the matrix, the CoPt squares begin to interact via the Py matrix. An image of the matrix between two neighboring squares spaced by the distance $d = 1 \mu\text{m}$ is shown in figure (2b). At this short distance correlation

of domains in the hard magnetic squares is found. Figure (2b) indicates that this correlation is strongly affected by the domain pattern in the matrix.

Most studies concerning the micromagnetic properties of nanostructures are performed on single ferromagnetic layers. However, spintronics applications generally require structures with several magnetic layers, separated by a non-magnetic spacers. In these structures, magnetic couplings may appear between the ferromagnetic layers. This is emphasised in nanostructures having in-plan magnetizations for which an antiferromagnetic dipolar coupling originates from the stray fields at the nanostructure edges. An antiparallel alignment of the two layers can thus be observed in micron and submicron tunnel junctions and spin valves. We have used the chemical selectivity and the high spatial resolution of the X-ray photo-emission electron microscopy technique (X-PEEM) to study the influence of the dipolar coupling taking place between a FeNi (Py, soft layer) and a Co (hard layer) layer when inserted in an elliptical shaped magnetic tunnel junction (MTJ). The comparison of our experimental results to micromagnetic calculations sheds light on the previous observations of 360° domain walls (DW), on their formation conditions and on their statistics of occurrence (1). The MTJ multilayer stack has been grown by sputtering. $1 \times 3 \mu\text{m}^2$ ellipses have been patterned by electron beam lithography. To determine the onset of the magnetic structure within each layer of the MTJ, the samples were imaged using X-PEEM. Figure 1 shows images taken at zero field recorded at the Co and Ni edges after saturation with a 1 kOe field applied parallel to the ellipses long axis. Here, the observed contrast is due to the magnetization component parallel to the long axis. The Co magnetization is uniform and oriented along the saturating field (white contrast in Fig 1 a). Regarding the Py layer, some elements show a single domain state magnetized in the opposite direction. Other ellipses present an inhomogeneous Py layer magnetization. More insight in this domain structure is gained after a 90° rotation of the sample. Then, the magnetic contrast arises mostly from the magnetization component along the ellipses short axis. Figure 2 shows images recorded at the Ni edge for two ellipses exhibiting a non-uniform state. Black/white or white/black contrasts are signatures of clockwise (CW) and counter clockwise (CCW) 360° DW. Understanding the presence/absence of these 360° DWs requires a study of the Py magnetization reversal dynamics. Therefore, we have modeled our MTJs using the 3D OOMMF code. In silico experiences show that the dipolar field originating from the Co layer activates the nucleation and propagation of two domains at each extremity. They also reveals that the nucleation of the two domains by opposite curling direction is a mandatory condition to the formation of a 360° DW. Figure 2 c. shows a simulated DW. All the ellipses do not exhibit the same magnetic state at zero field. The statistic of DWs formation has then be studied. We observed that 82% have always the same magnetic configuration (DW or not). These ellipses are composed of three subgroups: 50% have a single domain state, 27% stabilize a CW DW, and 23% a CCW DW. As the presence of a DW is linked to the initial direction of curling, these statistics prove that for a majority of elements, the curling direction is determined uniquely for each ellipses extremity. Furthermore it appears that each curling direction is equally probable on the observed array. Local anisotropy sources related to the local structure of the ellipses and to their topology, can influence the curling direction and each ellipse extremity may have a specific anisotropy direction. Those local anisotropy sources (shape and/or magnetocrystalline) break the symmetry of the system. For the 82% of the elements exhibiting

always the same magnetic configuration, the initial curling direction determines the zero field state and the observed magnetic configurations are induced by the local magnetic anisotropy at the ellipses extremities. A significant number of ellipses (18% of ellipses) presents either a 360° DW or a single domain state. In this case, the curling direction is not uniquely determined by the local magnetic anisotropy at one ellipses extremity: the magnetization curling direction could be driven by a stochastic effect as thermal fluctuations. In conclusion, we show that the formation of 360° DWs in our system is mainly influenced by the local magnetic anisotropies existing at each extremity of the elements. Controlling the nucleation/propagation of such DWs is essential for magneto-transport measurements or for devices based on the switching of the two layers of a magnetic tunnel junction.

In this paper we report studies of the behavior of magnetic vortex structures in single layer Permalloy or CoFe ferromagnetic (FM) disks and in disks exchange-biased to an adjacent IrMn antiferromagnetic (AF) layer. 1 μm diameter disks were fabricated by electron lithography and lift-off, on 50 nm thick SiN windows set into a 300 μm -thick Si wafer frame. Four different configurations were sputter-deposited: Ta/Ni₈₀Fe₂₀/Cr (Py); Cr/Co₉₀Fe₁₀/Cr (CF); Ta/Ni₈₀Fe₂₀/IrMn/Cr (Py/IrMn); Cr/Co₉₀Fe₁₀/IrMn/Cr (CF/IrMn). $t_{\text{Py}}=12\text{nm}$ and $t_{\text{CF}}=10\text{nm}$. An exchange-bias (EB) was imprinted in a vortex geometry in some of the bilayer disks by zero field cooling (ZFC) through the Néel temperature of IrMn from 240°C, as described previously by Sort et al. [1]. MOKE magnetometry data was used to confirm the vortex geometry of the EB. Images of the magnetization reversal process of the FM layer were obtained using Lorentz transmission electron microscopy (LTEM). Vortices were swept out of the disks and renucleated by changing the intensity of a magnetic field applied in-situ in the microscope, by tilting the sample around the holder axis and weakly exciting the objective lens. The Py and Py/IrMn disks spontaneously formed vortices at remanence, whereas the CF and CF/IrMn disks formed either vortices or domain walls but could all be set in a vortex state by an in-situ demagnetization procedure.

For the micromagnetic simulations the grain structure was simulated by seeding random nucleation sites which grew until their boundaries met, with an average grain size of 20 nm. This grain structure was propagated conformally through the film thickness. The exchange-bias coupling was modeled using an interfacial energy density ϵ_{eb} at the FM/AF interface, leading to an effective field H_{eb} . The FM magnetization was relaxed into an equilibrium vortex state, and the direction of H_{eb} in each AF grain was taken as an average of the direction of the magnetization in the adjacent FM grain. A random, in-plane uniaxial magnetocrystalline anisotropy was added to the CF grains.

The displacement of the vortex from the disk center as a function of the in situ applied field is plotted in Fig. 1 for Py and ZFC Py/IrMn and in Fig. 2 for CF, CF/IrMn and ZFC CF/IrMn disks. Filled data points indicate experimental data and empty data points indicate simulations. The simulations show that increasing the EB produces a flatter displacement vs field curve, such that a larger field is necessary for a given displacement of the vortex. Linear fits through the initial vortex displacement curve for the experimental data show a decrease in slope from 1.77 for the Py disks to 1.67 for the ZFC Py/IrMn disks. The simulated curve with an interfacial coupling energy $\epsilon_{\text{eb}}=0.1\text{ erg/cm}^2$ gives the best fit to the experimental curve for the ZFC Py/IrMn disks.

In-situ magnetizing experiments show that for the Py disks the vortex nucleation occurs with random chirality, whereas in ZFC Py/IrMn disks the initial chirality in the FM layer is preserved throughout the magnetizing experiments indicating an EB vortex configuration. This is confirmed by the fact that the vortex nucleation field (H_n) and annihilation field (H_a) are insensitive to the applied field direction. H_n and H_a increase for the ZFC Py/IrMn disks with respect to the Py disks, indicating that the circular exchange bias increases the stability of the vortex state.

CF and CF/IrMn disks reverse by a mechanism involving domain walls at remanence that collapse into a vortex at higher fields. In ZFC CF/IrMn disks the reversal follows a regular pattern whereas in CF and CF/IrMn disks the reversal is randomized by microstructural pinning. By comparison

between the experimental data and simulations, we conclude that the value of EB for ZFC CF/IrMn disks is larger than that for ZFC Py/IrMn disks (0.3 vs. 0.1 erg/cm^2 from best fitting simulation). In addition, pinning effects originating from nonzero magnetocrystalline anisotropy cause the vortex to move in a zig-zag motion about the ideal trajectory (in the absence of pinning).

Due to the high demand on new magneto electronic devices, there is a steady search for new magnetic materials and preparation methods (1-3). Recently, to tailor exchange biased thin films properties, ion beam assisted patterning gains importance. As associated disadvantage, this method inherits sputter effects and may lead to an alteration of the magnetization saturation of the implanted area (4). As an alternative, we used local oxidation of the antiferromagnetic layer to prepare extended NiFe/IrMn films with laterally modulated unidirectional anisotropy.

The films were structured into 2-d arrays of alternating stripes with (NiFe/IrMn) and without unidirectional anisotropy K_{ud} (NiFe/IrMnO). Thereby, the stripes were either aligned parallel or perpendicular to the preset K_{ud} . The role of interfacial contributions between the magnetically different areas was addressed by varying the stripe dimension from 20 μm down to 2 μm .

Measuring the macroscopic properties, different reversal mechanisms for the two different stripe orientations have been detected. Stripes aligned parallel to the unidirectional anisotropy exhibit a two step hysteresis (Fig. 1a) similar to spin valves, those aligned perpendicular show a shifted but single step hysteresis loop (Fig. 1b). Microscopic Kerr observations revealed for the parallel alignment separate switching of the two different stripe magnetizations (comp. Fig. 1a, 2a)). For the perpendicular stripe orientation the free and biased stripes reverse simultaneously along the forward and recoil branch of the loop (Fig. 1b, 2b)). Reducing the stripe width down to 2 μm both structure types exhibit quasi-domains (Fig. 2c, d)). Those quasi-domains appear as correlated reversal of a broad range of neighboring stripes.

The magnetic features are discussed in terms of lateral direct exchange coupling at the stripe interface and Néel wall interactions.

To investigate the dynamic behavior, pulsed inductive microwave magnetometry (5) was employed. Different to the quasi-static behavior, the parallel aligned stripes (Fig. 3a) above 10 μm show two resonant frequencies f_{res} originating from the bimodal magnetic properties. Below 10 μm the resonance frequencies merge to one intermediate frequency at about 1.5 GHz. The perpendicularly arranged stripes (Fig. 3b) maintain a dynamic behavior similar to the extended reference samples throughout the whole range of 2 μm to 20 μm . In addition, a third f_{res} similar to the merged frequency of the parallel stripes is observed. In both cases, the increasing f_{res} for all stripe dimensions below 10 μm are due to increased NiFe-IrMn contribution caused by the offset of the stripe width. The different dynamic performance for the two alignments is ascribed to the introduction of additional quasi-magneto-static coupling for the parallel stripes.

The presented observations demonstrate that by combination of different magnetic properties anisotropic magnetization reversal behavior and different dynamic properties can be created which are due to the direct exchange coupling of the magnetization at the stripe interfaces.

Dynamic splitting of azimuthal spin wave modes in circular magnetic dot in vortex ground state.

K. Y. Guslienko¹, A. N. Slavin², V. Tyberkevych², S. K. Kim¹

1. Research Center for Spin Dynamics and Spin-Wave Devices and Nanospintronics Laboratory, Seoul National University, Seoul, South Korea; 2. Department of Physics, Oakland University, Rochester, MI

Spectrum of spin wave excitations of circular magnetic dots in a vortex ground state consists of low-frequency gyrotropic (or translational) mode, that describes motion of the vortex core, and high-frequency spin wave modes, which describe excitations of the main part (far from the vortex core) of the dot [1]. It was shown both experimentally [2, 3] and numerically [2] that high-frequency spin waves with azimuthal indices $m = +1$ and $m = -1$ (i.e., the modes that propagate in opposite directions) demonstrate significant frequency splitting of the order of 1 GHz for typical dot parameters. It is clear, that the frequency splitting is caused by the spin wave interaction with magnetic core, since it vanishes after removing of small central “core” region of the dot [3]. This fact can also be proven rigorously by symmetry considerations, since magnetic dot without a core (“ring” magnetic structure) has an additional symmetry – reflection about the plane of the dot.

An attempt [4] to explain frequency splitting by spin wave interaction with the static dipolar field of the core (which breaks reflection symmetry of the system) produced frequency splitting that is several times smaller than experimentally observed one [2, 3]. Thus, at the present time the reason of significant frequency splitting of $|m| = 1$ modes remains unclear. It is also unclear, why other azimuthal modes with $|m| \neq 1$ have much smaller splitting.

In this work we develop a simple theoretical explanation of the splitting of $|m| = 1$ modes that quantitatively agrees with experimental data. The splitting is explained as a result of *dynamic hybridization* of $|m| = 1$ azimuthal modes with the gyrotropic mode. The gyrotropic mode can be considered as a mode with azimuthal index $m = 1$. Due to the same azimuthal behavior, this mode can hybridize with high-frequency $|m| = 1$ modes and shift their frequencies. As a result of hybridization, profile of the azimuthal mode \mathbf{m}_v in the vortex ground state can be approximately written as $\mathbf{m}_v = \mathbf{m}_R + i\eta\mathbf{m}_G$, where \mathbf{m}_R is the normalized profile of the azimuthal mode in a “ring” structure and \mathbf{m}_G is the normalized spatial profile of the gyrotropic mode. The coupling constant η is determined by the condition of orthogonality of \mathbf{m}_v and \mathbf{m}_G :

$$\eta = \int \mathbf{M}(\mathbf{r}) (\mathbf{m}_G^* \times \mathbf{m}_R) d\mathbf{r}, \quad (1)$$

where $\mathbf{M}(\mathbf{r})$ is the spatially-inhomogeneous equilibrium orientation of magnetization vector and integration is performed over the area of the dot.

It is clear from Eq. (1) that, for spin wave modes with other azimuthal dependence ($|m| \neq 1$), $\eta = 0$ (no hybridization with gyrotropic mode) and their splitting is caused solely by the interaction with a static dipolar field of the core, which is weak far from the vortex core.

The spin wave frequencies in the vortex ground state can be calculated as matrix elements of the spin wave Hamiltonian (that includes contributions from the magnetodipolar interaction and inhomogeneous exchange) with orthogonalized profile \mathbf{m}_v . Using the fact that both \mathbf{m}_R and \mathbf{m}_G are eigen-modes of the “ring” and “vortex” structures and neglecting influence of the static core field, one can derive simple expression for the frequency ω_v of the azimuthal mode, shifted by the hybridization with the gyrotropic mode: $\omega_v = (\omega_R - |\eta|^2 \omega_G) / (1 - |\eta|^2)$, where ω_R is the unshifted frequency of the azimuthal mode (without the hybridization) and ω_G is the gyrotropic frequency.

For typical experimental parameters, the coupling constant $|\eta|^2$ is small and proportional to $\omega_G/\omega_R \sim \sqrt{L/R}$, where L and R are thickness and radius of the dot, respectively. Then, the frequency split-

ting $\Delta\omega = |\omega_v^{(+1)}| - |\omega_v^{(-1)}|$ between the $m = +1$ and $m = -1$ modes than can be written approximately as

$$\Delta\omega \approx 2|\eta|^2 \omega_R. \quad (2)$$

Fig. 1 shows the dependence of the frequency splitting Eq. (2) on the dot aspect ratio L/R . One can see, that the developed here simple analytical theory of splitting of azimuthal modes gives a reasonable description of experimental data [2].

Enhancement of superconductive vortex pinning through formation of magnetic vortices.

A. Hoffmann^{1,2}, L. Fumagalli³, N. Jahedi³, J. C. Sautner³, J. E. Pearson¹, G. Mihajlović¹, V. Metlushko³

1. Materials Science Division, Argonne National Laboratory, Argonne, IL; 2. Center for Nanoscale Materials, Argonne National Laboratory, Argonne, IL; 3. Electrical and Computer Engineering, University of Illinois at Chicago, Chicago, IL

The pinning of superconducting vortices in type-II superconductors has been studied for a long time due to the wide variety of unusual flux flow phenomena and, more importantly, for its relevance in applications, since vortex pinning is one of the essential parameters controlling the enhancement of critical currents. A case of particular interest is the use of artificial magnetic pinning centers, since they can be fabricated to match well the characteristic length scales relevant for superconductivity and their magnetization offers another degree of freedom to influence the pinning properties. To this end, a lot of work has been focused on periodic arrays of magnetic structures, which give rise to commensurate pinning of superconducting vortices in adjacent superconducting films.

In our current work, we compare the pinning effects in Nb films due to magnetic permalloy dots with either single domain or vortex magnetization configuration. Magnetic vortices occur in small circular magnetic structures when magnetostatic energies become dominant. This may give rise to hysteresis loops characterized by two critical fields for the nucleation and annihilation of the magnetic vortices. The formation of a magnetic vortex minimizes the overall magnetic stray fields from the dot. However, at the center of the vortex, the so-called vortex core, there is a singularity, where the magnetization points out-of-plane resulting in a strong, but very localized magnetic field penetrating the superconductor.

We observe a clear correlation between the magnetoresistance in the superconductor [see Fig. 1(a)] and the magnetization configuration of the magnetic dots [see Fig. 1(b)]. Namely, while the magnetic dot is quasi-saturated (i.e., positive fields for the decreasing field branch) the resistance minimum due to the coherent pinning is higher than for the magnetic vortex state (i.e., negative fields of decreasing field branch). This indicates that the pinning of the superconducting vortices is strongly enhanced for the magnetic vortex state. The origin of this enhanced pinning is the presence of locally larger magnetic stray fields produced by the magnetic vortex cores. Furthermore, measurements of minor loops, where the vortex core polarity is constant, do not show any asymmetry between positive and negative applied magnetic fields. This absence of an asymmetry for parallel and anti-parallel orientation between the superconducting vortex flux and the magnetic vortex cores suggests that the enhanced pinning is not due to the magnetostatic interactions, but is rather due to the local suppression of superconductivity by highly localized, large perpendicular stray magnetic fields generated by the magnetic vortex cores. Thus this work shows that a careful tuning of the magnetic properties allows for a controlled manipulation of the superconducting vortex pinning.

This work was supported by the Office of Basic Energy Sciences, U.S. Department of Energy, under Contract No. DE-AC02-06CH1357.

Beams of spin waves guided by permalloy micro-strips.

V. E. Demidov¹, S. O. Demokritov¹, K. Rott², P. Krzysteczko², G. Reiss²

1. Institute for Applied Physics, University of Muenster, Muenster, Germany; 2. Department of Physics, Bielefeld University, Bielefeld, Germany

Since the first observations of spin-wave quantization effects in magnetic micro-strips [1] the interest to the high-frequency magnetization dynamics in confined ferromagnetic structures with sub-micrometer lateral dimensions has been continuously growing. Such investigations are of importance for the deep understanding of basic physics of magnetic phenomena on the microscopic scale, as well as for technical applications of magnetic nanostructures for high-speed signal processing and information storage technologies.

In this work we study propagation of spin waves in permalloy micro-strips by means of a micro-focus Brillouin light scattering (BLS) technique [2] with the spatial resolution of 250 nm, which allows the direct space-resolved mapping of magnetization dynamics on the sub-micrometer scale. The experimental samples are 300 μm long micro-strips with the widths $w=2.1$, 5.1, and 10.2 μm patterned from a 20 nm thick permalloy (Ni80Fe20) film deposited onto a glass substrate. At the top of the stripes 300 nm thick and 1 μm wide Au stripe antennae were manufactured. The antennae were oriented perpendicularly to the axes of the permalloy micro-strips and were used for the excitation of spin waves by a microwave-frequency current. The samples were placed into a static magnetic field of $H=300$ -2000 Oe oriented in the plane of the stripe perpendicular or parallel to its axis.

We experimentally show that the shape of the spin-wave beam propagating in micro-stripe waveguides significantly depends on the orientation of the static magnetic field H . In particular, if H is oriented along the stripe axis, the spin-wave intensity distribution in the transverse section of the stripe is nearly uniform and independent of the propagation coordinate. As a result, the spin-wave beam occupies nearly the entire cross-section of the stripe and is characterized by a constant width. These facts are illustrated by Fig. 1, where the intensity map is shown recorded in 2.1 μm wide stripe. The map was obtained for $H=930$ Oe and excitation frequency $f=9.4$ GHz. The scanned area has dimensions of 2.2 μm * 3.5 μm . Note that for the given propagation geometry the shape of the spin-wave beam is practically independent of the stripe width and the excitation frequency.

In the case of H oriented perpendicularly to the stripe axis, the spin-wave propagation was found to have completely different character. In contrast to the previous case, the transverse distribution of the spin-wave intensity changes periodically with the propagation coordinate, which is equivalent to a periodic modulation of the width of the spin-wave beam. This results in a periodic self-focusing of the spin-wave energy at the stripe axis appearing at the points, where the width of the beam has its minima. An example of the spin-wave intensity maps recorded in transversally magnetized permalloy stripe with $w=2.1$ μm is presented in Fig. 2. The map has dimensions of 2.2 μm * 7 μm . It clearly shows a periodic local increase of the intensity on the middle line. Further measurements have shown that the period of this focusing pattern depends strongly on the stripe width and the excitation frequency and can vary from several micrometers to fractions of a micrometer. In our talk we will present further experimental data characterizing the above two types of spin-wave propagation in micro-strips. We will also discuss a theoretical model explaining the experimental findings and allowing calculations of the self-focusing spatial period. As illustrated by Fig. 3, the results of the calculation using the model show very good agreement with the experimental data.

We believe that our findings can be of especial interest for the design and optimization of microscopic waveguides to be used for efficient transmission of spin waves and microwave-frequency signal processing in microelectronic magnetic circuits.

At room temperature, atomically ordered $\text{Fe}_{1-x}\text{Al}_x$ alloys are paramagnetic for Al atomic contents, x , larger than 0.32. However, between $x = 0.32$ and $x = 0.5$, these alloys become ferromagnetic when being atomically disordered [1]. This effect has been systematically studied in ball milled powders [2] and can be used to generate arrays of ferromagnetic dots at the surface of a paramagnetic $\text{Fe}_{60}\text{Al}_{40}$ sheet by local deformation techniques, such as nanoindentation [3].

In this presentation we will show that a similar magnetic patterning, scaled down to the sub-100 nm regime, can be achieved by ion irradiation through lithographed poly(methyl methacrylate), PMMA, masks (90 nm thick) or porous alumina templates. Irradiation has the advantage over nanoindentation that, due to the low doses used, it does not induce any surface corrugation, avoiding eventual tribological problems. Moreover, the induced ferromagnetism is confined into the locally disordered regions, rendering isolated magnetic dots surrounded by a paramagnetic matrix, thus virtually free from the detrimental effects of interdot exchange interactions. Furthermore, contrary to nanoindentation or other types of irradiation (like focused ion beam), all magnetic nanostructures are obtained simultaneously (i.e., in an in-parallel process). Patterning of magnetic structures with several geometries can be performed in very large areas (several cm^2) and in a few seconds. Contrary to the PMMA masks, the use of alumina templates does not require sophisticated equipment for their fabrication and the membranes can actually be reutilized. However, in this case one is restricted to hexagonal arrays and the limited long-range order of this type of masks.

The fabricated entities exhibit a range of magnetic properties, depending on their size and shape. Hysteresis loops, recorded by magneto-optic Kerr effect, reveal magnetization reversal by coherent rotation (single domain states) for sizes smaller than 100 nm. Flux closure states (e.g. magnetic vortices) form at larger sizes in square or circular dots. The local character of the induced ferromagnetism and the magnetization reversal mechanisms were examined by magnetic force microscopy. As an example, shown in Figure 1 is the magnetic force microscopy image of a hexagonal array of circular dots (300 nm in diameter) obtained by ion irradiation through an alumina membrane. The corresponding hysteresis loop shows a central constriction, evidencing that magnetization reversal occurs via formation of a vortex state.

Remarkably, the structural effects induced by the irradiation (i.e., atomic disorder) are fully reversible. That is, by annealing the disordered (ferromagnetic) FeAl phase at 750 K, the ordered (non-magnetic) FeAl structure is completely recovered. Consequently, FeAl sheets can be re-pat-

terned indefinitely. Contrarily, most of the other patterning methods, e.g. those based on intermixing, can only be patterned once.

Furthermore, it should be noted that the described procedures can be easily extrapolated to a variety of other systems, such as CoZr, CoAl, CoGa, CoV, NiSn, FeGe, FePt_3 and FeV intermetallics or even austenitic stainless steel, where local deformation causes a martensitic phase transformation [4].

The control of the domain configurations in lithographically defined magnetic elements with sub-micron lateral dimensions (nanomagnets) is of great current interest for a range of spintronic devices for both storage and logic applications. Most reported work to date has been focused on nanomagnets patterned from polycrystalline films, which typically display a magnetization reversal dominated by shape anisotropy. In the present work, we show that arrays of Nickel wires with sub-micron widths, patterned from epitaxial Cu (3nm)/Ni (4-15 nm)/Cu (100 nm) films, display transverse easy magnetization direction instead of the longitudinal easy axis expected from the increased shape anisotropy. On patterning the Cu/Ni/Cu stacks into nanowires, the strain in the film releases transversally to the long axis of the wires introducing a magnetoelastic anisotropy which is sufficient to overcome shape anisotropy and generate an easy axis magnetization direction transverse to the nanowires long axis.

Large area (~ cm²) arrays of Nickel nanowires were made using a subtractive fabrication approach combining interference lithography and ion-milling. Epitaxial Cu (3nm)/Ni (4-15 nm)/Cu (100 nm) were grown on Si(001) wafers at room temperature by e-beam evaporation in a chamber with a base pressure below 2×10^{-10} Torr. The nickel films exhibit out of plane magnetization for Nickel thicknesses between about 1.5 and 10 nm [1]. Arrays of Ta nanowires were first defined over the films using templates created by interference lithography (see Figs. 1a-b) and liftoff processing. Pattern transfer was achieved using Ne ion milling. Arrays of wires with widths from 200 nm and periods of 400 nm and above were investigated using AGM, VSM and MFM. For structures patterned from 4 nm-thick Ni films (see Fig. 1c), the magnetization lays out-of-plane for both the nanowires and the films, although the coercive force is larger for the nanowire arrays (290 Oe) than for the unpatterned film (215 Oe), and the magnetization reversal appears to include magnetization rotations. For structures made from 9nm, 10nm and 15 nm- thick Ni films, the magnetization for both the arrays and the films lays in-plane (see Figs. 1d - f). Most significantly, hysteresis loops applying magnetic fields transversally to the long axis of the wires saturate at lower fields than those measured on applying fields parallel to the wires.

We also observe that, compared with the film, become magnetically easier (\perp lines) or harder (\parallel lines) magnetize the structure after the patterning process (see in Figs. 1e for $t_{\text{Ni}} = 10$ nm); regarding the out-of plane anisotropy observed in the Ni films, we observe that for $t_{\text{Ni}} = 9$ nm the perpendicular to the plane direction is no longer easier than the in-plane transversal direction to the lines, although the difference in the magnetization process is small between both directions.

That kind of loops appear to agree with MFM images shown in figs 2a and d, taken at remanence after applying a field of 1 kOe perpendicular to the plane. The magnetic image has the same periodicity than the nanowire arrays, with maximum signal located at the borders and the center of the wires (Fig 2c), that contrast may be due to the in-plane components of the magnetization; while the remanence observed in the 9nm-thick film could be ascribed to the domain structure that can be observed on top of the periodic structure (see Fig 2d).

The reported behavior could be explained including an in-plane anisotropic magnetoelastic contribution in the magnetic anisotropy energy, due to an anisotropic relaxation of the strain [2] In this way, our finite element modeling indicates that the transverse line strain relief is largely a function of cross-section aspect ratio. The outer 1-1.5 thickness units of a given cross section relax their strain completely, while the center regions retain their biaxial strain state.

Manipulation of magnetic domain walls (DWs) in nanostructures has recently become the focus of intense research due to its great potential for application to spintronics. Magnetic nanorings are particularly apt geometry to such investigations [1]. If the magnetocrystalline anisotropy is negligible, only the geometry of the ring determines the microscopic spin structure of the magnetic states. The effects of geometrical constrictions, such as notches and corners, on DWs in nanorings have been intensively investigated [2].

In an earlier work we have studied the magnetization reversal in Permalloy (Py) triangular rings and we observed that head-to-head DWs can be positioned at selected corners and moved between corners by applying a magnetic field [3]. In this contribution we present the results of a combined experimental and numerical study with which we determined the details of the pinning of domain walls in isolated and interacting Py triangular rings (side 2 μm , width 250 nm and thickness 25 nm). In the former case the rings form a square lattice with a period of $\sim 4.2 \mu\text{m}$ so that inter-element interactions are negligible; in the second sample the rings are arranged in chains with a corner tip of each triangle in proximity of the edge centre of the triangle above with inter-element spacing of 50 nm. Using the longitudinal and diffraction magneto-optics Kerr effect (L- and D-MOKE, respectively [4,5]), magnetic force microscopy (MFM), and micromagnetic simulations [6] we determined the field dependence of the spin structure in the rings. The results show that magnetization reverses from an onion state to the reversed state via the formation of a vortex. Each onion state is characterized by DWs (one head-to-head and the other tail-to-tail) geometrically pinned at two corners of the ring [see MFM image in Fig. 1 panel (a)]. We prepared each sample in a well defined onion state (monitored with D-MOKE) and determined the DW motion and pinning potentials recording the L-MOKE loops obtained by sweeping the wall with a field H_1 applied along a branch of the ring. We studied this process as a function of a second fixed field H_2 applied perpendicularly to the branch of the ring along with the DW is swept to prevent oblique segments from switching, as sketched in panel (b) of Fig. 1 for the chains of rings. In the case of isolated rings a DW moves freely between the geometric pinning potential wells determined by adjacent corners as the external field H_1 reaches a critical value H_d and a single transition is observed in the loops at any value of H_2 [solid line in Fig. 1 panel (c)]. For interacting rings, when the wall is swept in the branch closer to the corner tip of the nearest neighbor ring, the loops show an intermediate step for H_2 above a certain value caused by the pinning of the wall by the magnetostatic dipolar field emanating from the corner of the nearest ring neighbor [see open symbols in Fig. 1 panel (c)]. Quite interestingly, the depinning of the DW from the starting corner is always (viz. at any value of H_2) anticipated in the chains with respect to isolated rings [compare open dots (H_d) and open triangles (H_{d1}) in Fig. 1 panel (d)], due to the presence of the potential well created by the magnetostatic interaction. We observed that H_2 affects appreciably only the depinning field H_{d1} from the corner but not the depinning field H_{d2} from the potential well due to the magnetostatic interaction [com-

pare open and solid triangles in Fig. 1 panel (d)]. Qualitatively, the process can be modeled as a domain wall in a triple potential well landscape with the depth of the two wells at the adjacent corners delimiting the branch, function of the vertical applied field H_2 . Micromagnetic simulations reproduce the behavior observed and provide additional details on the DW spin structure during its motion.

The development of new magnetic recording technologies based on patterned media requires a deep understanding of the magnetic dynamics of laterally confined structures on a submicron length scale. We report results from experimental and theoretical investigation of spin-wave spectra of one-dimensional periodic arrays of interacting Permalloy ($\text{Ni}_{80}\text{Fe}_{20}$) stripes. Samples with different type of translational symmetry were fabricated on a silicon substrate using deep ultraviolet lithography with 248 nm exposure wavelength followed by a lift-off technique. Brillouin light scattering (BLS) technique was used to measure spin wave spectra as a function of the transferred wave vector, with the magnetic field applied along length and width of the stripes in a wide range of fields, as well as during hysteresis cycles.

Our previous theory [1] shows that propagating collective spin wave modes are formed due to magnetostatic interaction which couples the dynamical magnetization of adjacent stripes resonating into individual stationary states. Several discrete collective modes were obtained from light scattered within the plane normal to the major (longest) axes of the stripes ($\phi=90^\circ$), while experimentally studying wavevectors across several Brillouin zones of the periodic array. Different types of collective modes were identified for different geometries and at different applied fields.

In-plane angle resolved measurements were made by changing the relative orientation (ϕ) between the magnetic field (applied along the stripes length) and the scattering plane with a constant incidence angle of light $\theta=30^\circ$, corresponding to a value of transferred wavevector of $1.81 \times 10^5 \text{ rad/cm}$. (Sample parameters: width is 350 nm, thickness is 30 nm; and edge-to-edge spacing is 55 nm.) We found that with the increase in the in-plane angle ϕ , the mode frequencies increased (Fig. 1, dots). We understand this as due to a change in group velocity of the collective modes with the change in ϕ . For $\phi=0$ (propagation along the major stripes axis y) the modes represent *collective* backward volume magnetostatic spin wave excitations with negative group velocity. For larger angles (rotation towards the axis x) they transform into Damon-Eshbach surface wave *collective* excitations with positive group velocity.

To explain dependence of the spin wave eigenfrequencies on the wave number we constructed a theory of collective spin wave modes propagating at an arbitrary angle ϕ with the array major stripes axis. Our theory is based on the Bloch wave approach for collective modes developed in Refs. [1] and the Green's function of dipole field of guided spin waves with continuous wavevectors along the y axis [2]. The one-dimensional calculation of Ref. [1] was overcome here by the use of a two-dimensional Green's function which allows one to rigorously account for eventual nonuniformity of the out-of-plane profile of the dynamic magnetization. The lines in Fig. 1 show the results of our calculation. One sees a good agreement with the experimental data. To produce these results we used the following magnetic parameters of permalloy: saturation magnetization $4\pi M_0=10100 \text{ G}$, gyromagnetic ratio $|\gamma|=2.82 \text{ MHz/Oe}$, and exchange constant $A=9 \cdot 10^7 \text{ erg/cm}$. To obtain this good fit we had to assume that the coherence length of the Bloch waves is finite and equals to two structure periods.

To achieve a better understanding of the band structure of the one dimensional magnonic crystal under investigation, we performed a calculation of the full two-dimensional eigenspectrum of col-

lective modes $\omega(k_x, k_y)$, shown in Fig. 2. This calculation was done for a value of the applied field $H=0.5 \text{ kOe}$ in order to compare the results of calculation with the experiments performed as a function of k_y for $\phi=0^\circ$ and as a function of k_x for $\phi=90^\circ$. One sees a set of surfaces which do not cross each other. It is noticeable, however, that the spectrum does not show full stop bands: the stop bands existing for a fixed value of either k_y or k_x overlap with the permitted frequencies for other values of the two parameters, thus one concludes that the frequency gaps in this structure are partial.

Head-to-SUL spacing reduction with a magnetic seed and the effect on perpendicular recording characteristics.

G. Choe, M. Minardi, K. Zhang, M. Mirzamaani
Hitachi GST, 5600 Cottle Road, San Jose, CA

In narrow track perpendicular recording system designs, reduction of write head-to-media SUL spacing has become a primary way to enhance media writeability. However, the crystallography of the Co-alloy recording layer was reported to degrade at reduced Ru underlayer thickness due to an increase in Ru (0002) c-axis dispersion[1]. Although many attempts using different seed layers such as Ta, Ti, Ni-alloys and AlN were made to improve Co c-axis orientation at reduced Ru underlayer thickness, it is difficult to retain good anisotropy of well-isolated Co grains when the Ru underlayer thickness varies. In this study, recording characteristics were investigated for a new underlayer structure using a magnetic seed used to reduce the recording layer-to-SUL (RTS) spacing without degrading the Co c-axis orientation.

The reference non-magnetic multi-underlayers consist of FCC(111) Ni-alloy (9nm)/BCC(110) Cr(9nm)/HCP(0002) Ru(11nm). The RTS spacing is varied by partially replacing the non-magnetic FCC Ni-alloy layer with a magnetic CoNiFe layer that acts as a part of the underlying SUL through magnetic exchange coupling. Fig.1 shows the change in the Ru and Co (0004) c-axis dispersion($\Delta\theta_{50}$) as a function of the CoNiFe-to-non-magnetic Ni-alloy thickness ratio at constant total thickness ~ 9 nm. The $\Delta\theta_{50}$ values of Ru and Co decrease with increasing CoNiFe thickness, indicating that the Co c-axis orientation is further improved at lower RTS. As shown in cross sectional TEM image of the layered structure (Fig. 2), both magnetic CoNiFe and non-magnetic Ni-alloy have predominant FCC (111) planes growing in the perpendicular direction, which promotes epitaxial growth of the subsequent Cr BCC (110) and Ru HCP (111) layers.

In this study, we characterized the media magnetic performances using heads with trailing-shield (TS) and wrap-around shield (WAS) writer designs. For both heads, the magnetic write width (MWW) increases with decreasing RTS, indicating that the write field becomes stronger with lower RTS. However, the influence of side fringing fields on the nearest adjacent track erasure was highly dependent on the head type at different RTS spacing. As shown in Fig. 3-a, for the TS head, the erase band(EB) representing the magnitude of side fringing field erasure linearly decreases with decreasing RTS spacing, indicating that the side fringing field is better confined to on-track pole at lower head-to-SUL spacing. The WAS head, with a side shield to reduce the side fringing field, shows narrower EB than the TS head for a wide range of RTS spacing, and the EB is less sensitive to RTS spacing. Besides the head writeability, the change in RTS spacing also affects the read-back response, particularly at different linear densities. The track average amplitude (TAA) at low linear density is significantly higher at lower RTS, while the TAA at high linear density is similar for all the RTS ranges within 8 nm. Fig. 3-b shows the signal-to-media noise (SNRm) dependence on linear density for media with different RTS spacing. At low linear density(250 KFCI), SNRm is improved regardless of the amount of RTS reduction. By replacing the non-magnetic Ni-alloy layer with 4nm thick CoNiFe layer, the SNRm is enhanced at every liner density. However, as RTS spacing is further reduced, the SNRm begins to degrade and the decrease is more significant at higher KFCI conditions. This suggests that even though the magnetic seed containing FCC/BCC/HCP multi-underlayer enables RTS spacing reduction with enhanced Co c-axis orientation, it is also important to optimize the amount of spacing reduction and the head media integration to improve overall system performance.

Reduction of transition layer thickness showing incoherent switching behavior in single CoCrPt-SiO₂ perpendicular media.

H. Jung, M. Kuo, S. Malhotra, G. Bertero
Western Digital Media Inc., San Jose, CA

Perpendicular magnetic recording technology recently demonstrated high areal density of 520 Gb/in² [1]. For further improvement of media performance, advanced media structures with the concept of exchange-coupled composite [2] and exchange spring [3] media are currently in development. We recently reported the existence of highly exchange-coupled initial thin layer on top of Ru layer in CoCrPt-SiO₂ films [4], which should be removed ideally. This non-uniform microstructure caused significant incoherent switching behavior and high magnetic activation volume (V_{act}). The hard magnetic layer is particularly sensitive to microstructure of intermediate layer (IL). Good epitaxial growth of CoCrPtB films on top of Ta/RuCr IL with narrower crystallographic c-axis orientation ($\Delta\theta_{50}$) of 2 - 3° was reported. [5]. In this paper, the effect of two different types of Ta/Ru₁/Ru₂ (IL1) and Ta/RuCr/Ru₂ (IL2) on magnetic switching behavior and magnetic cluster volume in single CoCrPt-SiO₂ media is investigated. Here Ru₁ and Ru₂ indicate the Ru layer deposited at low and high pressure of Ar, respectively.

Fig. 1 shows the effect of t_{MAG} on coercivity (H_c) and coercivity squareness (S^*) of the CoCrPt-SiO₂ films with two different IL types. Replacement of Ru₁ with RuCr provides superior $\Delta\theta_{50}$ of < 2.3°. As t_{MAG} in IL1 varies from 2 to 27 nm, H_c linearly increases, reaches a plateau, and then decreases. It reaches maximum value of $H_c = 6.6$ kOe at $t_{MAG} = 18$ nm. The use of IL2 achieves higher H_c at thinner t_{MAG} , $H_c = 7.3$ kOe at $t_{MAG} = 12$ nm. The H_c trend is similar to that in IL1. S^* significantly decreases from 0.59 to 0.41 at $t_{MAG} \leq 8$ nm and become constant at $t_{MAG} > 8$ nm for IL1 while they continuously decrease from 0.61 to 0.40 with increasing t_{MAG} to 30 nm for IL2. Overall IL2 provides higher S^* than IL1.

The short time switching field (H_o) and thermal stability ($K_u V/k_B T$) at room temperature are estimated by fitting time-dependent H_{cr} to Sharrock's equation using the attempt frequency = 1 GHz and $n = 1/2$. The plot of H_{cr}/H_o versus t_{MAG} is fitted with Sharrock's equation as used in Ref 6. Curve fitting is good at certain ranges, indicating that they follow coherent switching behavior. There exist incoherent switching behaviors at thin and thicker layers: $t_{MAG} \leq 6$ nm and $t_{MAG} > 21$ nm for IL1 and $t_{MAG} > 12$ nm for IL2. The critical thickness exhibiting superparamagnetic state decreases from 3.4 nm for IL1 to 1.6 nm for IL2. A similar incoherent switching behavior was reported in CoPt-O layers with $t_{MAG} > 21$ nm and the critical thickness was ~6 nm. [6]

Values of H_{cr} at 45° normalized by H_{cr} at 0° ($H_{cr,45}/H_{cr,0}$) in films with two IL types show similar trends in Fig. 2. The 4 nm-thick film with IL1 clearly exhibits that $H_{cr,45}/H_{cr,0}$ continuously increases with increasing the angle of the easy axis and applied field direction, close to domain wall switching behavior. Initial high values of $H_{cr,45}/H_{cr,0}$ significantly decrease with increasing t_{MAG} and then increase again. Interestingly, the value of t_{MAG} showing minimum $H_{cr,45}/H_{cr,0}$ decreases from 15 nm for IL1 to 9 nm for IL2. Compared to IL1, IL2 enhances coherent switching behavior at $t_{MAG} \leq 9$ nm but also increases incoherent switching behavior at $t_{MAG} > 9$ nm. The increase in incoherent switching behavior and the decrease in H_c at thicker layers with IL1 were understood by both lower K_u , caused by formation of sub-grains and higher stacking faults density, and stronger magnetoelastic effect at the top region containing higher oxide contents. [7] They will provide broader magnetic c-axis orientation. Values of V_{act} decrease with increasing t_{MAG} . IL2 provides considerably higher V_{act} than IL1.

It is concluded that IL2 achieves higher H_c at thinner t_{MAG} by both reduction of transition layer thickness showing incoherent switching behavior and the increase in V_{act} . Reduction of V_{act} by using a proper IL will further improve magnetic properties in the hard layer while maintaining higher H_c at thinner t_{MAG} .

Compositional structure and magnetic properties of CoCrPt-SiO_x Perpendicular Recording Medium.

M. Futamoto¹, T. Handa¹, Y. Takahashi²

1. Faculty of Science and Engineering, Chuo University, Tokyo, Japan; 2. Central Research Laboratory, Hitachi, Ltd., Tokyo, Japan

INTRODUCTION For high density perpendicular magnetic recording, CoCrPt-SiO_x recording layer with isolated crystal grain structure is widely employed. Magnetic properties and the thermal stability depend on grain diameter, the crystal grain composition as well as the grain boundary composition [1]. In the present study, we investigated the distribution of grain diameter and the composition focusing on individual crystal grains by using a transmission electron microscope (TEM) equipped with an energy dispersive X-ray spectrometer (EDX). The grain boundary composition was also estimated from the average film composition including the boundary region and the average grain compositions. The K_u values of individual crystal grains were estimated from the grain compositions.

EXPERIMENTAL A perpendicular recording medium with a structure of protective-layer/[CoCrPt-SiO_x (12 nm)]/Ru/underlayer/glass substrate was used for TEM analysis. In the EDX measurement, an electron beam of about 2 nm in diameter was focused at the center of a crystal grain to measure the grain composition. Wider electron beam was used to measure the average film composition including the grain boundaries. Two types of crystal grain, with uniform TEM contrast and with irregular contrast, were recognized in the plan-view TEM image as shown in Fig. 1(b) and (c). We measured the grain compositions by classifying the two types of grain.

RESULT AND DISCUSSION Fig. 2(a) shows the dependence of composition on crystal grain diameter measured for uniform contrast crystal grains. The composition of individual grain depends little on the grain diameter. However, Co and Pt compositions slightly increases, while Si slightly decreases with increasing the grain diameter. Fig. 2(b) shows the relationship between grain diameter and K_u value estimated by citing the reference [2]. The K_u values increases slightly with increasing the grain diameter. Table I summarizes the compositions determined for the average film layer including the grain boundaries, the uniform contrast grains, the irregular contrast grains, and the grain boundaries. The grain boundary composition is calculated from the average film composition and the two types of crystal grains by referring the respective volume ratios estimated from the plan-view TEM observation. When the average composition is compared between two types of grain, the Co and Pt contents are decreased while that of Si is increased for the irregular contrast grain. The result suggests that oxides like SiO_x are incorporated within the crystal grain, which might be the reason for the brighter contrast in the TEM image. It is not possible to directly measure the grain boundary composition because the width is approximately 1.1 nm which is smaller than the electron beam diameter of 2 nm. The composition of the grain boundary estimated in the present study clearly indicates that the grain boundary includes a lot of Si atoms and not a small amount of Co, Cr, and Pt elements. Although Si and possibly other elements are expected to exist in the form of oxides, the oxygen content could not be determined in the present study due to a lack of sensitivity of the EDX analysis.

Exactly Lattice Matched Novel Under Layers (LML) in Perpendicular Media.

A. Ajan, T. Sugimoto, T. Uzumaki
Magnetic Media Laboratory, Fujitsu Laboratories Ltd., 10-1 Morinosato-Wakamiya, Atsugi,
Japan

Introduction: In order to enhance the perpendicular media [1] performance, good c-axis orientation of magnetic CoPt grains, lower grain size and smaller size distribution are necessary. Ruthenium (single or double layer) or its alloys stand out to be the best candidate as intermediate layer, which impart a good epitaxial growth, grain size control and high nucleation field for the CoCrPt-SiO₂ type magnetic layer [1,2]. Since the seed layers (NiCr, NiFeCr or Ta)[2] have a lattice mismatch of >7% with Ru(0002), a thick Ru layer (~25-40nm) was needed. This reduces the writing capability and increases the cost of the media. Thus it is necessary to develop new seed layer materials, which has near perfect lattice match with Ru(0002), thereby reducing the Ru thickness (~5-10 nm). Here we describe the structural properties of the newly developed materials (alloys) with face centered cubic (fcc) structure, whose (111) textured plane can controllably be varied to make an exact lattice match with Ru(0002) plane.<p>

Experimental:

The materials for LML are chosen from a combination of one of Ni, Cu, Pt, Pd, Al such as NiPt, NiPd, PdCu etc.. In order to illustrate the LML concept, we have made the following structure on 2.5" glass substrates; Ta(3nm)/(Ni+Pt)(10nm)/C(3nm). The Ni and Pt (or other alloy combinations) are co-sputtered in various power ratios in order to obtain different alloy compositions. ICP analysis indicated that the expected and obtained atomic ratios are within the range of ± 1 at%. For the SNR evaluation, the following media structures were made; Anti-parallel soft under layer(APS_SUL)/PdNi(LML)/Double Ru layer (5-30 nm)/Magnetic recording layers(CoCrPt-SiO₂/CoCrPtB)/protective layer(C). Media were studied using various techniques such as X-ray diffraction (XRD), TEM, SQUID magnetometer, Kerr magnetometer, Guzik spin-stand and UDT tester.<p>

Results and Discussion :

Figure 1A shows the X-ray diffraction (XRD) spectrum for various PtNi(x) composition in Glass/Ta/PtNi/C structure. The data indicates that for the entire composition range, the film contain grains which are fcc structured. The peak position of PtNi(x)(111) shift systematically towards the higher angle side as the Ni percentage increases from 0 to 100 at%. Fig. 1B shows the calculated lattice spacing of the alloy in the (111) plane. As the Ni content in the film increases, a continuous variation of lattice spacing is observed, which nearly follows the Vegards law [3]. The lattice mismatch of (111) plane with Ru(0002), is also shown in the same figure. The lattice matching of PtNi with Ru(0002) is nearly perfect when Pt content is ~60 at%. Similar variation of lattice spacing is observed with other LML layers such as PdNi, PdCu etc.. Moreover, the transverse TEM image of the interface between LML and Ru indicated a smooth interface and lattice packing across the thickness of the film. <p>

For studying the Ru (0002) growth, we have sputter deposited APS_SUL (FeCo alloy(25 nm)/Ru(0.5 nm)/FeCo alloy(25 nm))/Ta(3 nm)/PdNi or PtNi(5 nm)/Ru(8-26 nm))/C(4 nm) on glass substrates. The $\Delta\theta_{50}$ of Ru(0002), which is a measure of the distribution of c-axis orientation from the film normal, is estimated from the XRD rocking curve measurement. For comparison purposes, media with a conventional NiFeCr alloy seed layer of 5 nm thickness is used. It is clear from the Fig.2 that for obtaining the same $\Delta\theta_{50}$ of c-axis, a 15 nm thinner Ru could be used with PtNi or PdNi alloy than that of NiFeCr alloy. <p>

The SNR of the media with various Ru thickness were evaluated at a writing frequency of 990 kBPI. The results indicated that the SNR level (from a standard media) could be maintained until ~10 nm of Ru thickness (Fig. 3). For NiFeCr underlayer media, SNR decreases by more than 1dB at Ru thickness of 15nm in comparison to the media with Ru thickness of 25nm. This large difference of SNR variation with Ru thickness is attributed to the better lattice matched growth for the Ru layer on LML. <p>

LML alloys may also be used for the lattice match growth for CoPt layers. Since the lattice spacing of CoPt grain depends strongly on the Pt content, LML provide an ideal choice as an under layer. Further discussion on the structural, magnetic and SNR evaluation of media along with the performance of media with thinner Ru thickness will given in the detailed paper.

Magnetic and Recording Characteristics of CoCrPt-Oxide Media with a Mixture of SiO₂ and TiO₂.

I. Tamai, R. Araki, K. Tanahashi

Central Research Laboratory, Hitachi, Ltd., Odawara-shi, Kanagawa-ken, Japan

CoCrPt-oxide granular films have been widely used as a recording layer in perpendicular recording media. The granular films have a well-isolated structure with oxide grain-boundaries, thereby leading to low noise properties. To further improve media performance in higher areal densities, we need smaller grains with narrower size distribution while maintaining the well-isolated structure. However, an increase in oxide content tends to hinder film growth with high quality, resulting in poor media performance. Various oxides such as Cr-O, Si-O, Ta-O, and Ti-O have been studied as a segregant to de-couple Co-alloy grains [1-3], but it is still unclear which oxide additive is suitable for use with future media with small grains. In this study, we prepared CoCrPt-oxide media with SiO₂, TiO₂, or a mixture of SiO₂ and TiO₂, and we investigated the capability of dual oxide by comparing the magnetic and recording characteristics of three types of media.

The media were deposited onto glass disk substrates using an Anelva C3010 sputtering system. Anti-parallel coupled FeTaCoZr layers through thin Ru were used as a soft magnetic underlayer (SUL), and Ru was used as an intermediate layer. The granular layer was deposited by reactive sputtering of CoCrPt alloy targets doped with SiO₂, TiO₂, or a mixture of SiO₂ and TiO₂. The O₂ partial pressure (PO₂) was varied by adjusting the flow rate of Ar-10%O₂ gas. A CoCrPtB cap layer was deposited onto the granular layer, and its thickness was varied from 3 to 5 nm as a way of controlling media write-ability.

Figure 1 shows the magnetic properties of the CoCrPt-oxide granular films as a function of PO₂. For the media with SiO₂ (CCPS), coercivity (H_c) and nucleation field (-H_n) increase as PO₂ increases up to 2.3 Pa, while for media with TiO₂ (CCPT), H_c and -H_n increase up to a PO₂ of 1.7 Pa, and then decrease as PO₂ increases further. CCPS media have a higher achievable H_c than that of CCPT media. Media with a mixture of SiO₂ and TiO₂ (CCPST) have a higher H_c especially at a low PO₂ than that of the CCPS or CCPT media. The recording characteristics of the three types of media with various PO₂ and cap layer thicknesses were evaluated with a wrap-around-shield head. The recording performance for a PO₂ of 1.3 Pa was optimum for the CCPT and CCPST media, and the performance for a PO₂ of 1.7 Pa was optimum for the CCPS media. These optimal PO₂ values are slightly lower than the PO₂ values at which the highest H_c was obtained. Figure 2 shows the recording characteristics at the optimal PO₂ as a function of cap layer thickness. For all the media, the magnetic core width (MCW) increases as the cap layer thickness increases, and it is correlated with the change in H_c. The CCPST and CCPS media exhibit a higher SNR than the CCPT media. Considering that the high SNR of the CCPST media is obtained on narrower MCW conditions than the CCPS media, we believe that the CCPST media have greater potential for areal density growth than the CCPS media. We clarified the reason for the difference in recording characteristics by conducting TEM analysis. As shown in Fig. 3, the CCPS granular film has well isolated grains, while the CCPT granular film has non-uniformly separated grains. In addition, many sub-grains, which are consistent with the lower H_c, were observed. The degraded performance of the CCPT can be attributed to the inhomogeneous microstructures. The CCPST granular film appears to have narrower and more uniform grain boundaries than the CCPS and CCPT films. These microstructures would lead to higher packing density, which is one possible reason for the improved performance of the CCPST media. To further explain the recording results, we will present a detailed compositional analysis of grain cores and grain boundaries.

I. INTRODUCTION

Oxide composite perpendicular media has been shown to produce fine grains that are decoupled by oxide at the grain boundaries, leading to low noise performance in disk drive media. However, too large an increase in oxide content to decouple the grains can result in an interconnected or isolated network of magnetic volumes, rather than segregating completely to boundaries of columnar grains. In this work, we present an overview of our recent work on producing fine granular mixtures of magnetic media (either Co alloy or L10) and an oxide which acts to isolate the grains. Low and high mobility sputter conditions, which correspond to two very different regimes in Thornton's well-known film growth model [1], were investigated. High Ar pressure during deposition of recording layer was selected to achieve a well-separated film microstructure in the low mobility conditions whereas bias sputtering was utilized to modify a film microstructure in high mobility sputter conditions.

II. LOW MOBILITY SPUTTER CONDITIONS

In Fig. 1, a notable contrast in film morphology for different argon gas pressure is seen from the TEM micrographs of CoCrPt-SiO₂ media. A similar visual grain size of about 7 nm, however, much better defined SiO₂ on the thicker boundary was observed at higher Ar pressure. The magnetic measurements show that there is an optimum Ar pressure in order to have high squareness and negative nucleation (see Fig. 2). The CoCrPt-SiO₂ media fabricated with a high Ar pressure of 60 mT showed reduced squareness and positive nucleation field.

III. HIGH MOBILITY SPUTTER CONDITIONS

Another approach to enhancing this grain separation is to utilize bias sputtering [2]. One example (FePt-MgO) of bias-sputtered films where biasing aids in achieving decoupling is shown in Fig. 2. For unbiased FePt-MgO deposited at room temperature (RT), the length scale for the precipitation of oxide is 1-2 nm, and an interconnected network is seen, which is likely to produce a large switching volume. On the other hand, well-defined grains with boundaries are in evidence with biasing. See Fig. 3(b). There is no significant grain growth or coalescence in the biased films even at elevated temperatures of 400°C. Average grain size is 5 nm.

For CoCrPt-SiO₂ films, the grain size can be achieved by appropriate choices of sputtering pressure and substrate bias. The enhanced mobility of the adatoms by bias sputtering controlled the growth of the columnar structure of the composite structure. The films were sputter-deposited at room temperature.

High-Resolution TEM Analysis Of Perpendicular CoCrPt-SiO₂ Media.

R. Araki¹, Y. Takahashi¹, I. Takekuma², S. Narishige²

1. Central Research Laboratory, Hitachi Ltd., 1-280 Higashi-koigakubo Kokubunji-shi, Tokyo, Japan; 2. Central Research Laboratory, Hitachi Ltd., 2880 Kozu, Odawara, Kanagawa, Japan

Introduction For high-density perpendicular magnetic recording media, not only the grain size in a magnetic recording layer should be small, but also the grain boundary should be uniformly wide to reduce the medium noise [1]. As width of the grain boundary plays an important role in the exchange decoupling, it should be finely controlled. In this study, we have analyzed the relationship among the boundary width, the grain size, and the in-plane crystallographic orientation of grain in a CoCrPt-SiO₂ magnetic layer.

Experimental The media sample was analyzed and sputtered on a glass substrate at a room temperature was composed of the following layers: a CoTaZr soft magnetic one, seed ones, a Ru intermediate one, a CoCrPt-SiO₂ granular magnetic one and a protective one. The size structures and the crystal lattice directions of CoCrPt-SiO₂ grains were measured with a Hitachi HF-2000 high-resolution transmission electron microscope (TEM). The grain size was defined as the length of the dark contrast region on the line connecting between centroids of neighboring grains and the width of grain boundary was defined as the length of the bright contrast region. About 100 grains in a CoCrPt-SiO₂ layer were used to obtain the average values of grain size and of the grain boundary width. Although the grain size defined in this study was different from the diameter of a grain, we confirmed that the average and the dispersion of the grain size distribution was equivalent to the value defined by the conventional method. To analyze the correlation between the boundary width and the crystallographic orientation, the a-axis direction of each neighboring grain was measured.

Results and discussion A plan-view high-resolution TEM image of a CoCrPt-SiO₂ layer is shown in Fig. 1. The average grain size and its dispersion were 7.5 nm and 18 %, respectively. The average width of the grain boundary was 0.68 nm. The dependency of the grain boundary width on the grain size in a CoCrPt-SiO₂ layer is shown in Fig. 2. We found that the grain boundary width increased with the grain size. This fact suggests that the inter-grain exchange coupling depends on the grain size. The a-axis direction is shown by a triangle-mark on each grain in Fig. 1. We defined the crystal grain cluster as a group of grains with an a-axis direction that ranged from 0 to 1 degree. A frequency histogram of the number of grains in a cluster is shown in Fig. 3. The dependency of the average width of grain boundaries on number of grain in a cluster (cluster size) is shown in Fig. 4. The grain boundary width tended to decrease as the cluster size increased. The dotted line shows the average of grain boundary width surrounding non-clustered grain. We also found that the grain size in a cluster decreased as the cluster size increased. These results suggest that the controlling of the size of a crystal grain cluster is a way to control the grain boundary width. To achieve a wider grain boundary for exchange decoupling, we need to reduce the size of the crystal grain cluster.

Epitaxially grown FCC/BCC/HCP multi-underlayers for high performance perpendicular recording media.

G. Choe, X. Xu, K. Tang, X. Bian
Hitachi GST, San Jose, CA

Fabrication of a magnetically decoupled fine grain structure with high perpendicular anisotropy is necessary to achieve high density perpendicular recording. In a Co-alloy based recording layer that grows epitaxially onto a nonmagnetic underlayer, the nonmagnetic underlayer plays an important role in controlling the c-axis orientation of the Co crystals and the Co grain size and distribution. Ru underlayers with amorphous Ta [1] or crystalline Ni based seed layers [2] were reported to enhance the Ru and Co (0002) crystallography.

In this study, a new epitaxially grown FCC/BCC/HCP multi-underlayer structure is reported as a promising underlayer candidate to obtain well-isolated Co grains with good c-axis orientation. The multi-underlayers, consisting of FCC (111) Ni-alloy, BCC (110) Cr-alloy and HCP (0002) Ru layers, are grown epitaxially, resulting in preferred (0002) texture of Ru and Co grains, smooth surface morphology, excellent magnetic and read/write performance. Fig.1 shows a bright field cross sectional TEM view of a multi-layered media structure and a FFT of each layer component. As indicated by the FFT patterns, each underlayer grows in the perpendicular direction with the atomic plane of closest packing. A highly oriented Ru HCP <0002> c-axis is achieved through epitaxial growth onto the underlying Cr BCC (110) and Ni-alloy FCC (111) planes. The lattice matching of the Ni-alloy/Cr and Cr/Ru was analyzed by obtaining the FFT patterns (Fig.2) of enlarged HRTEM image at the interfaces. The lattice of the Ni-alloy layer matches well to that of Cr layer with ~0.3% lattice misfit ratio, while the lattice misfit ratio between Cr and Ru layers is relatively large at ~11%. The lattice parameter of Cr seemingly expands to the growth direction from 0.278 nm at Ni-alloy/Cr interface to 0.285 nm at the Cr/Ru interface.

The Co (0004) c-axis orientation dispersion was measured by XRD $\Delta\theta_{50}$ for bi-layered CoPtCr-SiO₂/CoPtCrB recording layers deposited onto underlayers with varying thickness of Ni-alloy and Cr layers. The $\Delta\theta_{50}$ value sharply decreases with increasing Ni-alloy thickness for Ni-alloy(x nm)/Cr(9 nm)/Ru(11 nm) and ~3 deg was achieved for Ni-alloy > 4 nm thickness. For Ni-alloy(5 nm)/Cr(x nm)/Ru(11 nm) underlayers, an increase in the Cr layer thickness slightly improves the Co c-axis dispersion. Fig.3 shows the coercivity H_c of the recording layer as a function of Ni-alloy and Cr layer thicknesses. The H_c increases with increasing thickness of either Ni-alloy or Cr and appears to correlate well with the Co c-axis dispersion. Nucleation fields and saturation fields also increase with increasing Ni-alloy thickness and/or Cr thickness. Fig. 4 shows the change in signal-to-media noise ratio measured at two linear densities (457, 685 KFCI) with varying Cr thickness of Ni-alloy(5 nm)/Cr(x nm)/Ru(11 nm) underlayers. The SNR_m continues to increase with increasing Cr thickness and the SNR_m gain at thicker Cr layer is more obvious at higher linear density. The media jitter is significantly reduced with increasing Cr thickness. Improved recording performance is also achieved by optimizing head-to-SUL spacing with variation in each underlayer thickness.

A General Method to Fabricate Exchange Coupled Composite Media with Graded Structure for Energy Assisted Magnetic Recording.

H. Zhao, H. Wang, J. Wang

ECE, University of Minnesota, Minneapolis, MN

Small and uniform grains and exchange-decoupling between grains in magnetic recording media are key requirements for high density magnetic recording. $L1_0$ -FePt has been studied intensively as the future recording material. Unlike the current CoCrPt-type perpendicular recording media, preparation of $L1_0$ -FePt media need either substrate heating or post-annealing to assist the $L1_0$ -FePt phase formation, which is similar to that of the longitudinal recording media, but normally needs higher temperature ($\geq 350^\circ\text{C}$). This difference, together with the intrinsic differences in material properties between FePt and CoPt alloys, demands innovative methods to achieve those key requirements, especially for exchange-coupled composite (ECC) media with graded structure (or so-called graded media).

In this paper, an atomic and nanoscale layer engineering process (capable for media production line) without involving post-annealing was proposed [1] and demonstrated to control grain size and grain isolation and to form the high-anisotropy phase at relatively low substrate temperature. As shown in Figure 1 (a), a particular underlayer that can generates small and uniform grains (e.g. RuAl) is deposited at first, and then followed by the multilayer consisting of alternating thin FePt layer and thin layer of grain boundary material. In this method, the underlayer (RuAl) serves as the template for columnar grain growth and therefore defines the grain size and size distribution of the whole recording media. A proper lattice misfit between (002) RuAl underlayer and the interlayer (e.g. Pt) above it provides a strain energy for the directly formation of $L1_0$ phase FePt at substrate temperature around 350°C or less. Grain isolation is achieved by surface diffusion of grain boundary materials (e.g. Ag, Cu) on top of previous FePt layer. Figure 1 (b) shows the typical structure for a FePt-type anisotropy graded media that can be made using this method. FM-M and FM-S are the ferromagnetic magnetic layers with medium and low anisotropy, respectively. FM-M and FM-S can be made from FePt with reduced process temperature to control the ordering of FePt (equivalently the anisotropy). The graded structure can also be achieved by varying the composition of FePt alloy in FM-M and FM-S layers. The key advantages of our proposed fabrication method for FePt media are: 1) clean interface for exchange-coupling control (especially for direct coupling between soft and hard region) in graded media structure with more than one magnetic region in grain vertically; 2) highly packed grains (in-plane) with narrow grain boundary – crucial for future energy assisted magnetic recording media.

Figure 2 shows the TEM plane-view, XRD spectrum and hysteresis loops of samples made with this method. Sample A shows typical grain size and size distribution, which is similar to that of the RuAl underlayer alone (not shown here). The FePt(001) peak in the XRD spectrum of sample B confirmed the existence of $L1_0$ -FePt phase. Anisotropy graded sample C (Glass/Ta(3nm)/AlO(5nm)/RuAl(20nm)/Pt(7nm)/[FePt(6nm)/Cu(2nm), 370°C] \ [FePt(2nm)/Cu(1nm), 200°C] \ [FePt(2nm)/Cu(1nm), $<150^\circ\text{C}$]) was prepared by reducing the process temperature for the top two FePt layers. Figure 2 (c) shows the hysteresis loops of sample B and C. The coercivity of sample C was reduced significantly as expected. More details will be discussed in the full paper.

Tuning pinning-site size of percolated perpendicular media (PPM) fabricated on pre-patterned substrates.

M. Rahman¹, C. Lai¹, D. Suess²

1. Materials Science and Engineering, National Tsing Hua University, Hsinchu, Taiwan; 2. Solid state physics, Vienna University of Technology, Vienna, Austria

Introduction

Recently, a new class of perpendicular media consisting of exchange coupled grains with non-magnetic pinning sites, termed as percolated perpendicular media (PPM), has been proposed theoretically for recording density of 1Tb/in² and beyond [1, 2]. Few experimental realization of PPM are also shown its promise in high density magnetic recording [3, 4]. However, the ultimate success of PPM is limited by the control of pinning site size and density that is quite challenging. We have already reported the fabrication of PPM with wide range of pinning-site density [3]. Here, we demonstrate a simple method to fabricate pinning sites with a wide range of size from 5-30 nm and its effects on the magnetic properties of the Co/Pt multilayers (MLs). Furthermore, the thermal stability of such media is estimated by micromagnetic simulation.

Experimental procedure

At first, a thin Al film deposited on a Si wafer by sputtering is anodized to get porous alumina (AAO) with a density of $\sim 1 \times 10^{11} \text{ cm}^{-2}$. The pore diameter, d is tuned from 5- 30 nm by controlling the pore widening time at dilute phosphoric acid while the aspect ratio (pore height/diameter) is kept almost same at 5. Then {Co(0.5nm)/Pt(2nm)}₅ MLs are deposited onto the porous AAO/Si by sputtering at room temperature.

Results and discussion

Fig.1 (a) – (d) show plane-view SEM images of Co/Pt MLs deposited on AAO with different pore diameters, d . The pores are clearly visible in all samples. The cross-sectional TEM image {inset of Fig.1 (b)} of sample with d of 10 nm reveals that the magnetic material is deposited mainly on the top of the pores. As a result, the Co/Pt MLs are percolated by columnar defects.

The media exhibit strong perpendicular magnetic anisotropy and negative nucleation fields as shown in Fig. 2 (a). As shown in Fig.2 (b), the out-of-plane coercivity, H_c of (Co/Pt) MLs increases from 140 Oe to 1300 Oe when it is deposited on AAO/Si with d of 5 nm. Then the H_c increases with increase in pore diameter and saturates at 1600 Oe for the d of 10-20 nm followed by a decrease for further increase in d to 30 nm. The variation of H_c as a function of pore diameter is due to the domain-wall pinning at the pores as evidenced by the initial magnetization curve shown in Fig. 2(a). The magnetization of initial curves for the all samples deposited on AAO irrespective of pore diameter, starts to increase when the applied field reaches a critical field to de-pin the domain walls. It can be concluded that the optimum pinning-site size for Co/Pt MLs is about 10-20 nm, which is 1 to 2 times of the domain wall width of the Co/Pt MLs. This result is good in agreement with the theoretically predicted optimum pinning site size for PPM[1].

We also investigate the switching behavior of the fabricated structures as shown in Fig. 2.c (I). Unlike the Stoner-Wohlfarth or domain-wall motion model, the switching fields, H_s of all samples deposited on AAO are quite insensitive to the angular variation from easy axis that may be beneficial to address the problem of adjacent track erasure. Micromagnetic simulation confirms that this kind of switching is due to the domain wall pinning at the pores as shown in Fig.2.c (I). Finally, thermal stability of a written bit in the proposed media with d of 10 nm is investigated using the nudged elastic band method as shown in Fig.2c (II). Fig.2c (II)-top shows the magnetization after applying the external field. After removing the field, the domain wall which separates the bit from

the film moves towards the next pinning centers into a stable state S₁ shown in Fig.2c (II)-bottom. In order to de-pin the domain wall from the weakest pinning center of stable state S₁, an energy barrier of $\Delta E = 69 \text{ kBT}$ has to be overcome. Thus, the investigated sample is thermally stable even though the H_c is small.

Conclusion

We introduced a simple and economic method to control pinning-site size over a wide range for percolated perpendicular media. Though the magnetic properties are shown for Co/Pt MLs, the approach is versatile to any magnetic materials to engineer the optimum pinning effect. Furthermore, the fabricated PPM is thermally stable and the angular insensitivity of H_s may ensure high signal-to-noise ratio.

Effect of carbon cosputtering in the growth of ultra-thin FePt particulate films on oxidized Si substrates.

Granular-type L10 ordered equiatomic FePt alloy thin films are considered as one of the promising candidates for recording media with an areal density of Terabits/in², since the large magnetocrystalline anisotropy (K_u) of this material provides a thermal stability of the FePt particles as small as 3 nm [1]. For such large recording densities, the required lowest coercivity is 12–15 kOe and media thickness is below 5 nm [1]. The use of MgO single crystal substrates to obtain desirable properties in FePt films [2,3] is not suitable for practical applications because of their cost. In this work, we explore an appropriate way to obtain strong perpendicular anisotropy in FePt films using MgO polycrystalline underlayer that was sputter deposited on economically viable substrates such as glass or thermally oxidized Si wafer. To control magnetic isolation of particles, c-axis oriented L10 ordered FePt-C granular films were prepared by cosputtering FePt and carbon. The obtained properties are encouraging and desirable for the application of perpendicular recording. FePt films of 1–10 nm and 3 nm thick FePt-C granular films were fabricated on thermally oxidized Si substrates with 10 nm MgO intermediate layers using sputtering with a base pressure of better than 10^{-7} Pa and the sputtering Ar gas pressure of 10 mTorr. The MgO layer was deposited at a substrate temperature (T_s) of 100 °C by rf sputtering a MgO target. Subsequently, the FePt and FePt-C films were deposited at $T_s=500$ °C by dc sputtering a FePt target with carbon chips. The structure of the films was characterized by X-ray diffraction (XRD) patterns. The plan-view and cross sectional microstructures of the films were examined by Phillips CM200 and FEI Technai F30 transmission electron microscopes (TEM). Room-temperature magnetic properties of the films were investigated by a SQUID magnetometer with an applied field up to 55 kOe.

At first we carried out careful investigation of FePt(x nm)/MgO (10 nm) films with $x=1,2,3,4,5,7$, and 10 nm. The MgO underlayer has a polycrystalline nature with strong (200) texture. The FePt (1 nm) film has an average particle size of 4 nm and well separated from each other, but shows low degree of L10 order. With increasing FePt thickness up to 5 nm, the isolated FePt particles of 30 nm [Fig.1(a)] with a high degree of L10 order (~ 0.75) and large K_u (3.9×10^7 ergs/cc) was fabricated. The coalescence of the particles occurs at larger FePt thicknesses (> 5 nm) and eventually the particles are interconnected to form an island structure. In addition, we observed the development of randomly oriented FePt grains which leads to a rapid increase in in-plane coercivity with increasing FePt thickness. Perpendicular coercivity of the isolated FePt particles is controllable in the range from 15 to 20 kOe.

Fig.1 shows the plane view micrographs of FePt and FePt:C(4 %) films with 10 nm MgO(200) underlayer on oxidized Si substrate. The microstructures are found to be similar particulate structure for both films. However, the XRD results showed that the presence of fine FePt(111) reflection in the FePt film disappeared with carbon addition, indicating that the orientation of the FePt grains is controlled considerably. Room temperature M-H loops show that the remanence ratio increased from 90 % for the FePt film (Fig.2a) to 100 % for the FePt-C film (Fig.2b). Also, the tiny hysteresis loops observed in the in-plane loop is also reduced noticeably. This is because the small carbon addition helps to develop the strong (001) texture. In addition, the perpendicular coercivity increases from 21 kOe to 22.5 kOe for the low amount of carbon addition and decreases to 15 kOe for 30 % carbon content.

In summary, the carbon addition in ultrathin FePt particulate structure enhances the development of (001) texture of the grains. The obtained properties of FePt:C/MgO(10 nm) films deposited on economically viable substrates suggest that this system is promising to accomplish a magnetic recording medium capable of storage density beyond 1 Tb/in², if a better method to obtain a finer monodisperse granular structure can be found.

Effect of carbon mixing on the perpendicular anisotropy of FePt thin film.

S. Lee, M. Kim, J. Park

Materials Science and Engineering, Korea Advanced Institute of Science and Technology, Daejeon, South Korea

The ordered (L10) FePt-based granular thin film has been known as a promising candidate for ultra high density magnetic recording media because of its high magnetocrystalline anisotropy energy. Numerous research efforts have been performed to fabricate FePt-based granular thin film showing a perpendicular magnetization and magnetically decoupled fine grain structure [1-5]. And it was shown that ordered (001) FePt films were, at elevated temperatures, easily growing epitaxially on (200) MgO single crystal substrate [1] to show a good perpendicular magnetization. However, the ordered (001) FePt films are prone to an excessive grain growth during elevated temperature deposition and are also susceptible to a strong magnetic coupling between grains leading to a low coercivity squareness. In order to solve these problems, we have studied the effect of the intercalation of carbon thin layer on the perpendicular magnetization of ordered FePt thin film on (200) MgO single crystal substrate. FePt film was DC-magnetron sputter-deposited on (200) MgO substrate at 600C using Pt chips placed on Fe target. Carbon was added to FePt film in a form of multi-layer of (FePt/C)/4/FePt/MgO. The volume fraction of carbon was altered by varying the thickness of intercalated carbon film layer at a fixed thickness of FePt film layer. The measurement of the magnetic hysteresis curve using vibrating sample magnetometry showed that the FePt:C composite film showed a large perpendicular anisotropy. However, its magnitude was varying with the volume fraction of mixed carbon in FePt alloy (Figure 1), in agreement with the previous reports [2,5]. Unlike a general expectation, the result showed that the perpendicular coercivity was rather increasing with the carbon volume fraction before eventually decreasing at a large volume fraction, exhibiting a maximum at about 20 vol.% of carbon. This result was rather surprising in view of the fact that magnetic crystalline energy K_u was known to be continuously decreasing with the increase of carbon volume fraction [2]. In order to find out its reason, we have measured the variation of (001) FePt texture with carbon content using x-ray diffraction. The result showed that the variation of the intensity of ordered (001) peak was similar to the variation behavior of perpendicular coercivity with the carbon volume fraction, showing a maximum near about 20 vol.%. This was believed to be due to two factors, the enhancement of texturing and the increase of the ordering kinetics. The micromagnetic simulation using OOMMF was carried out to study the effect of texturing on the perpendicular coercivity. The comparison of simulation results on three different textures, (111), random, and perpendicular textures indicated that the perpendicular coercivity can be significantly enhanced as a result of perpendicular texturing. The ordering kinetics was believed to be increased not only because the intensity of (001) ordering peak was increased but also M_s was significantly reduced at 20 vol.% of carbon. The microstructure observation using TEM showed that the size of ordered FePt grains was greatly refined as a result of carbon mixing. More importantly however, the observation (Figure 2) showed that the FePt grains have begun to be completely encircled by amorphous carbon film at the carbon volume fraction of about 20 vol.%. Thus, the FePt grains became isolated from neighboring grains and became free from constraint due to transformation (disordering to ordering) strain. This will lead to a large increase of ordering kinetics. A further increase in the carbon volume fraction would slow down the ordering kinetics because of increasingly higher carbon supersaturation in the disordered phase.

Radio-frequency transverse susceptibility studies of effective magnetic anisotropy in nanoparticle assemblies.

H. Srikanth¹, P. Poddar^{2,1}, M. Morales¹, N. Frey¹

1. Department of Physics, University of South Florida, Tampa, FL; 2. National Chemical Laboratory, Pune, India

Magnetic nanoparticles are considered basic building blocks of next generation spintronic devices as well as high density storage applications. Magnetism in nanoparticle assemblies and clusters is strongly influenced by particle shapes, intrinsic magnetocrystalline anisotropy, surfaces, interfaces and inter-particle dipolar interactions. It is often extremely difficult to decouple many of these effects from conventional experimental methods. Transverse susceptibility is an excellent tool for probing all these effects in nanoparticle assemblies. We use a very sensitive tunnel-diode oscillator (TDO) operating at 12-15MHz to measure the transverse susceptibility in different classes of ferrite nanoparticles. The main advantage of TS over conventional methods is that it uses singular point detection in directly measuring the most important parameters in magnetic materials such as the switching and anisotropy fields in a single experiment. We have established over the past few years that the TS method is very effective in studying anisotropy field distribution, inter-particle interactions and superparamagnetic relaxation that are inherent in nanoparticle aggregates [1-3]. Moreover, TS is versatile and could be applied to various geometries including thin films, multilayers and nanowires that form the basic components of spintronic devices.

Experimentally, in this technique both DC magnetic field H_{DC} (which can be varied) and a small perturbing AC field (H_{AC}) field from kHz to MHz range is applied. TS as a function of H_{DC} show two maxima at $\pm H_K$, which directly correspond to the anisotropy fields and are referred to as the anisotropy peaks. These peaks are highly sensitive to magnetocrystalline nature, particle size and shape distribution, as well as surface environment around particles, inter-particle interactions, and temperature.

An important problem in nanoparticle assemblies is to understand the influence of inter-particle dipolar/exchange interactions on the global magnetization as well as the effective magnetic anisotropy. To study the effect of varying strength of dipolar interaction on TS peaks in a reasonably controlled fashion, we used high quality, chemically synthesized, monodispersed manganese zinc ferrite (MZFO) nanoparticles as a model system and varied their concentration in paraffin wax matrix which is a non-magnetic host. The variation in coercivity, blocking characteristics as observed through DC susceptibility experiments were measured and compared with TS experiments. We were thus able to make a systematic study of the influence of interparticle interactions directly on the anisotropy peaks.

For magnetic property measurements, MZFO particles coated with excess surfactant and suspended in n-propanol were dispersed in varying concentrations in pure paraffin wax to alter the average interaction strength in a reasonably controlled manner with MZFO(conc) being the most concentrated dispersion resulting in the largest interactions. Samples labeled MZFO(50), 100 and 500 correspond to 50 μ l, 100 μ l and 500 μ l volume dispersion of nanoparticles in paraffin wax with MZFO(50) having the least contribution from dipolar interactions. The blocking temperatures for these samples varied from 27K to 32K as the concentration increases. The TS experiments were done using a sensitive RF coil that is part of a tunnel-diode oscillator with a resonant frequency around 12 MHz. The shift in resonant frequency is directly proportional to change in transverse susceptibility which can be monitored at varying fields and temperatures above and below the blocking transition. In the field-dependent TS data, two distinct peaks located at the anisotropy fields can

be seen clearly at low temperatures in the blocked state. As the temperature is increased, when the system becomes superparamagnetic, the two TS peaks merge into a single peak centered at zero field. Our key result from TS studies on all the samples with varying interaction strengths is that the effective anisotropy fields (H_K) increase with increasing interparticle interaction strength. Specifically, the H_K values vary from 100 Oe for the most dilute sample to around 600 Oe for the most concentrated one. This large variation cannot be accounted for by the increase in blocking temperature alone or by taking a distribution of anisotropy fields. While the influence of interactions in nanoparticle assemblies have been investigated through DC and AC susceptibility experiments, our work reported here represents the first transverse susceptibility study that directly probes the influence of interactions on the effective anisotropy. We will also report on using transverse susceptibility as a probe of exchange bias in nanoparticles with enhanced surface spin disorder [4].

Magnetic properties characterization of single IBICVD fabricated magnetic particles.

T. Suzuki, Y. Pogoryelov, A. Htoo

Information Storage Materials Laboratory, Toyota Technological Institute, Nagoya, Japan

Introduction

The research interest in nanoscale magnets is stipulated by their potential application for high-density recording media, so-called patterned media. The method of ion beam induced chemical vapor deposition (IBICVD), which was previously used to fabricate magnetic dot arrays of ferromagnetic (FM) materials [1-3], requires understanding of the physical processes, responsible for the magnetic properties of each low-dimensional particle in such arrays. In this view it is attractive to investigate magnetic behaviors of an isolated single particle fabricated by IBICVD in order to clarify the basic physics associated with size reduction. For these purposes the method based on the measurements of anomalous Hall effect, known for its high sensitivity [4-5], was selected to study magnetic properties of single FM particle (Fe).

Experiment, Results and Discussion

For experiment a 20 nm thick Pt cross electrode structure was fabricated through the specially designed mask in the e-beam deposition system onto glass and Si substrates. Then the intersection of the electrodes was further etched in the focused ion beam (FIB) system to form the electrodes of desired width. In this experiment the width of Pt electrodes was $\sim 2 \mu\text{m}$. A single particle of Fe was deposited by IBICVD to the center of electrodes intersection. An FIB system with liquid Ga ion source and equipped with three deposition nozzles was used for deposition. The base pressure of the deposition chamber was about 2×10^{-5} Pa. Precursors vapor pressure was controlled by heating nozzle during the deposition. All samples studied in this work were annealed at 600°C for 5 hours before measurements. AHE measurements were performed on the improved setup at room temperature and the current I was set at 0.5 mA. Figure 1 shows the Hall loop for a single Fe particle (1.5 μm diameter and 700 nm thickness) for magnetic field applied perpendicular to the surface. The observed decrease of anomalous Hall voltage in the high-field region indicates the increase of the magnetization component along the in-plane direction. The asymmetry of the loop indicates the appearance of the contribution from the planar Hall effect [6]. This is presumably due to a misalignment of a particle structure with respect to the applied magnetic field direction. In order to check the existence of the inplane magnetization component measurements in the in-plane geometry were carried out by utilizing planar Hall effect (PHE). Results are presented in the inset of Fig. 1. The observed asymmetry is probably due to the slight deviation of the field direction from the sample plane. In that case the obtained loop is a combination of two effects – AHE and PHE [7]. These effects have different symmetries regarding to the applied magnetic field H [8]. Besides in order to confirm the effect of suppression of the perpendicular magnetization component by the in-plane one it is possible to utilize the characteristic property of the IBICVD method. The matter concerns the role of high energy Ga ions on the process of formation of a structure of single particle. As a result of the ion collision with the Fe metal-organic molecule the part of the momentum is transferred to the Fe atom after molecule decomposition. These will cause partial intermixing of the deposited Fe with the electrode material (Pt) and formation of some amount of FePt phase at the interface. It was possible to confirm these by studying the similar sample fabricated onto Si substrate. Hall effect studies of a single Fe particle on the sample with Si substrate showed the absence of perpendicular magnetization component (Fig. 2). Only component corresponding to the planar Hall effect was observed. Apparently due to the small thickness of the Pt electrode there also occurs partial implantation of Fe atoms into Si substrate with the formation of Fe-silicide. As it is

known, such Fe-silicide possesses the in-plane magnetization [9], which possibly suppresses the perpendicular component in the detected signal.

The obtained results indicate the predominantly inplane orientation of the magnetization in the Fe particles fabricated by IBICVD. This is apparently determined by the formation of an appropriate material structure. Thus it was shown that the measurement method based on the anomalous Hall effect can be successfully applied for the studies of magnetic properties of single IBICVD fabricated particles and also for the indirect characterization of their structural features.

Ground states in ferromagnetic nanotubes.

P. Landeros, O. Suarez, A. Cuchillo, *P. Vargas*

Departamento de Física, Universidad Técnica Federico Santa María, Valparaiso, Chile

In this paper we present a theory to describe the magnetic ground states in ferromagnetic nanotubes. Our model enables us to investigate the size dependence of the ground states as a function of the tube geometrical parameters, by using a simple form characterizing the magnetic configuration. Geometrically, tubes are characterized by their external and internal radii, R and a respectively, and length L . It is convenient to define the ratio, $\beta=a/R$, so that $\beta=0$ is a solid cylinder and $\beta \rightarrow 1$ corresponds to a narrow tube. We adopt a simplified description of the system in which the discrete distribution of magnetic moments is replaced by a continuous one, defined by a function such that $\mathbf{M}(\mathbf{r})\delta v$ gives the total magnetic moment within the element of volume δv centered at point \mathbf{r} . The total magnetic energy is composed by four contributions which are taken from the well known continuum theory of ferromagnetism. That is $E=E_x+E_d+E_k+E_z$ where E_x is the exchange energy, E_d is the dipolar contribution, E_k is the anisotropy energy and E_z is the Zeeman term. We then proceed to describe the magnetization of the mixed state which allow us to calculate the total energy of the system. The arrangement of magnetic moments in a tube [1-3] can be seen as a uniform state in the middle region of the tube, but with two deviations of the magnetization, like a incomplete vortex domain walls, located at the tube ends (see Fig. 1). We adopt a trial function for the magnetization with four minimizable parameters, where d and λ are the dimensions of the regions where the magnetization deviate from the z -axis. θ_0 and θ_L correspond to angles of the magnetization with the z -axis, evaluated at the tube ends. This set of model parameters enable us to investigate in detail the magnetic properties as a function of the geometrical parameters (R , β and L). The model parameters are such that they minimize the total energy for each set of geometrical parameters. It is worth to mention that the variational problem with four parameters can be simplified considerably if the tube is symmetric, that is, if there is no difference between both tube ends. Therefore, in some special cases, the four parameters model is reduced to a two parameters model, when $d=\lambda$ and $\theta_0=\theta_L$. If we know the magnetization vector and the geometry of the ferromagnetic body, we can obtain the total energy, E , of a magnetic nanotube in the mixed state. With the energy expression it is easy to demonstrate that the uniform magnetization state is achieved when the cylinder radius is small enough, and that the mixed state configuration dominates for a wide selection of geometrical parameters. On the other hand the d parameter, half width of the domain wall, increases up to its maximum value $d=L/2$ when the vortex state is the ground state configuration. These results are shown in Figure 2.

If we only consider the Uniform (F) and Vortex (V) states, it has been shown recently [3] that the phase diagram depends on the topological form factor β . The critical line ($E^F = E^V$) that separates magnetic phases Ferro and Vortex (F and V) follows a very simple equation. Thus, to the left (right) of this curve we have $E^F < E^V$ ($E^F > E^V$) [3]. However, if we evaluate the energy of the mixed state in the symmetric case ($d=\lambda$ and $\theta_0=\theta_L$) we find that the mixed states have lower energy than the two main states (F and V) over a wide range of geometrical parameters.

The phase diagram in the R - L plane contains three regions corresponding to the three ground states, as shown in Figure 3.

A study of the magnetic behavior of Ni/Cu multilayer nanowire arrays, using FORC diagrams.

F. Beron, L. Carignan, D. Menard, A. Yelon

Génie physique, École Polytechnique de Montréal, Montréal, QC, Canada

Multilayer nanowire arrays (alternation of ferromagnetic (FM) and non-ferromagnetic (NF) discs along a nanowire) are promising nanostructures, especially for the use of giant magnetoresistance (GMR) with current perpendicular to the plane (CPP). Their magnetic behavior depends upon a number of factors: nanowire diameter, length and interwire distance, disc thickness, ferromagnetic material, etc. The first-order reversal curve (FORC) method is an effective way to study and distinguish their magnetic behavior. With a standard magnetometer, it allows us to obtain information about the magnetization reversal of the magnetic entities.

A set of first-order reversal curves consists of several minor hysteresis curves beginning at different reversal fields H_r , the FORC distribution ρ is then calculated by applying a second-order mixed derivative of magnetization.¹ Using extrapolated FORC diagrams permits us to obtain only the signal coming from irreversible processes, while the reversibility percentage can be calculated from the slope of the first-order reversal curves at H_r .² The position of the peak of the distribution on the H_c axis (H_c^{FORC}) is related to the coercive field of the nanodiscs.³

Arrays of Ni/Cu multilayer nanowires were fabricated by electrodeposition into an alumina template (diameter = 175 nm), with Ni disc thickness between 20 and 50 nm, and Cu thickness between 10 and 35 nm.⁴ Vector major hysteresis loops were measured both with out-of-plane (along the nanowire axis) and in-plane (perpendicular to the nanowire axis) applied field. During the magnetization reversal, we observed no net component of transverse magnetization (M_y), perpendicular to the applied field H_x . Extrapolated FORC diagrams were measured out-of-plane (Fig. 1) and in-plane (Fig. 2). While the major hysteresis loops of all arrays have similar shapes, their FORC diagrams reveal distinct patterns, suggesting different magnetic behavior.

In the out-of-plane direction, H_c^{FORC} values from multilayer nanowires (between 200 and 250 Oe) are considerably lower than the theoretical coercive field of an isolated nanodisc and the reversibility percentage increases with the thickness of Cu. We assume that this is caused by a small rotation followed by a spin flip magnetization reversal in the nanodiscs. This behavior is favored by the in-plane component of the interaction field due to the dipolar interactions between the discs in a nanowire. From the null M_y component of the vector plots, it is not possible to discriminate between a reversal by spin flip only, and an alternative rotation toward y-direction from disc to disc before the flip. The high H_c “tail” of the FORC distributions (Figs 1 b-c) is assumed to derive from some nanodiscs not subject to any in-plane field, such as those located at the extremities of the sample and the nanowires.

The interaction field in the nanowire axis direction depends predominantly on the FM thickness. We can see on the FORC diagrams that when the Ni thickness decreases, the elongation along the H_u axis, as well as the flatness of the H_u cross-section top, also decreases. These features are related to the maximum value and the distribution of interaction fields felt by the nanodiscs.³ The central peak in the FORC distribution represents nanodiscs that are not subject to an out-of-plane interaction field.

In the in-plane direction, the FORC diagram shape can be explained by the creation and annihilation of vortices in the nanodiscs, which is theoretically predicted to be the predominant magnetic behavior for an isolated disc, especially when the disc thickness is large. We assume that the nanodisc distributions of thickness and diameter in the nanowire arrays disperse and widen the char-

acteristic FORC distribution of the creation and annihilation of a vortex (i.e. two sharp peaks located at (H_c, H_u) and $(H_c, -H_u)$, and a broad one around $(H_c + H_u, 0)$). We believe that the single peak visible on the experimental FORC diagrams (Fig. 2) is due to the small H_u values, which favor the convolution of these peaks in the numerical calculation. The presence of vortices in the nanodiscs is consistent with no M_y signal in the vector plots, because the magnetization perpendicular to the vortices in one direction is compensated by the vortices in the opposite direction.

The FORC diagrams of nanowire arrays with small spacer thicknesses exhibit some “wings” around the peak (Figs 2 a,c). They are thought to come from the antiparallel interaction field created by the dipolar interaction of a nanodisc with its neighbors along the nanowire.⁴

Magnetic properties of metal/silicon nanocomposites tailored by specific metal precipitation.

P. Granitzer, K. Rumpf, H. Krenn
Institute of Physics, Karl Franzens University Graz, Graz, Austria

Summary:

Porous silicon (PS) is used as template for electrochemical deposition of distinct metals. The precipitation of different ferromagnetic metals (e.g. Ni, Co) under various process parameters leads to nanocomposites consisting of 3-D arrays of metal-structures embedded in the PS-templates. These arrays are tunable in their structure by the electrochemical parameters and due to the fact that the magnetic characteristics depend on the geometry and distribution of the incorporated metal it is possible to fabricate desired ferromagnetic nanocomposites with specific characteristics like coercivity, squareness or magnetic anisotropy.

Experiments and discussion:

PS-templates of different morphologies (pore-diameter adjustable between 30 nm and 100 nm, length up to 50 μm) are filled by a pulsed galvanic process with Ni or Co. The geometry (spheres, ellipsoids, wires) of the embedded metal-structures and their spatial distribution within the pores is tunable by the fabrication parameters (deposition current density, pulse duration). Thus samples with specific magnetic characteristics (coercivity, squareness, magnetic anisotropy) can be prepared. In case of Ni the magnetocrystalline anisotropy is small (anisotropy constant $K = -0.005 \text{ MJ/m}^3$) and moreover the precipitations exhibit random orientation leading to a cancellation of the crystal orientations resulting in a dominance of the shape anisotropy. The coercivity H_C is always smaller for PS-membranes with a high amount of embedded Ni-wires than for those with preferentially deposited particles shown in fig. 1 for various temperatures. In both cases (wires, particles) H_C shows a temperature dependence which follows an exponential law contradictory to some literature [1] where a linear relation is assumed.

Considering ZFC/FC (zero field/field cooled) measurements the broadness of the ZFC-curve of a sample containing mainly ellipsoidal Ni-particles (< 200 nm) depends on the size distribution as well as on the density of the spatial distribution of the particles which means on their interaction (fig 2a). Samples with metal wires (length of a few micrometers) show a gently increasing ZFC-magnetization and a flat FC-curve (fig 2b). Both indicate a strong dipolar coupling of the embedded nanostructures.

At typical pore-diameters of 60 nm Co tends more to precipitate as particles than Ni does and up to now the maximum length of the Co precipitations is 200 nm (Ni up to a few micrometers). Therefore Co-filled PS-membranes offer less magnetic anisotropy (below 10%) between easy axis and hard axis magnetization mainly due to the shape of the spherical and ellipsoidal particles (the greater magnetocrystalline anisotropy of Co: $K = 0.53 \text{ MJ/m}^3$ does not effect because it is averaged out due to random orientation of the precipitations). In contrast to Ni-particles the temperature dependence of the coercivity of Co-particles do not show a continuous exponential curve. Between 4.2 K ($H_C = 500 \text{ Oe}$) and 100 K ($H_C = 470 \text{ Oe}$) the coercivity H_C is nearly constant, whereas from 100 K to 250 K ($H_C = 260 \text{ Oe}$) the coercive field reduces almost of 50%.

Conclusion:

The fabrication of PS-templates with desired pore-arrangements and subsequent metal filling (Ni, Co) of the channels by a galvanic process leading to tailored precipitations yields to ferro-magnetic nanocomposites with tunable magnetic characteristics. The use of silicon as base material is of interest not only due to the capability of applications in today's micro and nanotechnology but also

because of the biodegradability of porous silicon in the human body which offers potential in medical and biological applications like destroying of tumor cells (hyperthermia).

Polymer nanocomposites with embedded Cobalt nanoparticles.

S. N. Kale¹, S. H. Hatamie¹, S. D. Kulkarni²

1. *Department of Electronics-Science, Fergusson College, Pune, India;* 2. *Centre for Materials Characterization, National Chemical Laboratory, Pune, India*

In the last decade, one of the most interesting categories of materials which have been explored in their nanodomain are the magnetic materials. This is because of their potential applications in nanotechnology, typically in memory devices, nanomedicine, medical instrumentation and also in the novel area of Spintronics. A more focused area of magnetic nanomaterials is the polymer-embedded magnetic nanoparticles. Such configurations find applications as magnetic fillers (nanocomposite materials), electromagnetic device applications like electromagnetic interference suppression and in biomedicine as MRI contrast agents. Magnetic nanoparticles embedded in the polymer matrices are also providing a lot of new information about critical phenomena in the underlying structures [1-2]. In addition, such materials have made important contributions to fundamental studies in nanoscale physics such as quantum tunneling of magnetization, spin reversal mechanisms in single-domain particles and quantum size effects [3-4].

Out of many magnetic systems, including Fe-oxides, perovskite manganites, Nickel, Manganese, Cobalt is one interesting material which can be harnessed for variety of applications mentioned above [5]. Though Co exhibits ferromagnetism at room temperature, it has been less explored in nanoregime due to its rapid oxide formation, which is rather easy during the coating mechanism. The key requirement here is to develop a processing technique based on the idea of the encapsulation of the Co nanoparticles in an inert atmosphere to form a non-agglomerated and stable coating layer.

In this context we have synthesized Cobalt nanoparticles using wet chemistry route. Whole procedure is done in vacuum to ensure that there is no oxide formation. Using a combination of ultrasonication and vacuum drying Co nanoparticles were embedded in a matrix of Poly-Vinyl Alcohol (PVA). The processing conditions were optimized to achieve good uniform dispersion of the nanoparticles in the polymer matrix. The concentration and dispersion of nanoparticles were varied in a controlled way to yield self-supporting, flexible films. The films have been characterized and compared with bare nanoparticles using X-Ray Diffraction (XRD) technique, Vibrating Sample Magnetometry (VSM) and Transmission Electron Microscopy (TEM). Typical Co nanostructures show particle size ~ 20 nm using XRD and TEM data. VSM analysis show increased coercivity of the films (260 Oe) as compared to Co nanoparticles (120 Oe) at room temperature. As is known, magnetic nanoparticles precipitated from solution tend to aggregate thereby exhibiting larger cluster size. However, in the polymer matrix, inter-particle separation was seen to improve, which is also reflected in VSM results. In isolation these particles are envisaged to be single domain, thereby showing increased coercivity. The results have been understood on the basis of dipolar interactions and their influence on magnetic properties. Overall, the excellent dispersion coupled with reasonable control over magnetic properties achieved in our experiments is promising for electromagnetic applications of these materials.

Single domain nanoparticles are of prominent interest for biomedical and data storage applications, as well as a means to directly probe the magnetization dynamics of interparticle correlations. Our samples are polycrystals of ferromagnetic monodisperse 7 nm diameter magnetite nanoparticles with an average edge-to-edge separation of 2.5 nm. They have blocking temperature below room temperature and strong interparticle magnetic correlations. Preparation techniques are described elsewhere [1]. Using small angle neutron scattering (SANS) we have examined these nanoparticles in order to determine the temperature dependence of their magnetic interparticle correlations. SANS is a technique well suited for nanoparticles because it covers length scales from single particles up to long-range correlations and probes a whole ensemble at once. Both of these features are absent when using local probes such as TEM.

While a typical magnetic SANS experiment observes the convolution of nuclear and magnetic scattering terms which cannot be uniquely resolved, we have used polarization analysis in order to provide an unambiguous separation and independent measurement of magnetic and nuclear contributions. An FeSi supermirror array was used to polarize the incident neutrons, while a polarized 3He cell was used as a spin analyzer with coverage over the entire angular range of the scattered beam. Polarization efficiencies range from 0.75 to 0.88. Using the formalism of Moon, Riste, and Koehler [2] we have implemented and further developed an algorithm to extract all four polarization-corrected spin scattering cross-sections (i.e. $\uparrow\uparrow, \uparrow\downarrow, \downarrow\downarrow$, and $\downarrow\uparrow$). The polarization analysis was conducted on a pixel-by-pixel basis from position sensitive detector scans, and it reproduces the corrected spin dependent scattering in 2D. Additionally, the 3He polarization decays during the period of data collection so we have also explicitly included its time dependence within our algorithm. Using a transmission geometry, the direction of the incident beam is denoted the x-axis, while the z-axis corresponds to the perpendicular neutron polarization axis. Here $\uparrow\uparrow$ and $\downarrow\downarrow$ (non-spin flip) corrected cross-sections along Qz provide nuclear information, while $\uparrow\downarrow$ and $\downarrow\uparrow$ (spin flip) cross-sections also along Qz yield information about pure magnetic moments oriented along the x and y axes. $\uparrow\downarrow$ and $\downarrow\uparrow$ cross-sections along Qy, however, give information about magnetism oriented along only the x-axis. Finally, magnetic scattering along the third direction, z-axis, may be obtained from $(\uparrow\uparrow+\downarrow\downarrow)_{Qy} - (\uparrow\uparrow+\downarrow\downarrow)_{Qz}$. Assuming that magnetic scattering is nearly isotropic in the absence of an applied magnetic field, the scattering from the combined x and y directions should be twice as much from either the x direction or the z direction. This is observed experimentally and displayed in Figure 1 at 50 K (same trends also observed for 100, 200, and 300 K). The inset taken at 300 K shows a pronounced peak at 0.085 inverse angstroms consistent with the interparticle spacing.

Within the framework outlined above, we can isolate and probe directly the magnetic evolution of interparticle correlations with temperature. Figure 2 illustrates that the magnetic correlation lengths change not only at the bulk magnetic blocking temperature of 65 K, but substantially vary up to 300 K. The curling over feature near low Q indicates a loss of long range magnetic correlations with increasing temperature. The inset shows that the corresponding nuclear scattering does not significantly vary, as expected. Additionally, at all temperatures saturation from an applied field of 1.3

Tesla (not shown) shifts the magnetic scattering to longer length scales and lower Q than was observable in our current set-up.

Unpolarized SANS (not shown) shows a similar temperature dependent reduction in the low Q combined nuclear plus magnetic scattering. As with the polarized data, this demonstrates a decrease in the long-range magnetic correlations with increasing temperature. Further decrease upon application of a saturating magnetic field indicates that even at the highest temperature (300 K) long range magnetic correlations are non-negligible. While the polarized and unpolarized data are in agreement, the interpretation of polarized SANS is more straightforward.

First-order Magnetic Phase Transition in Manganese Phosphide Nanorods.

R. Booth, S. Majetich

Physics Department, Carnegie Mellon University, Pittsburgh, PA

Manganese phosphide is an interesting material to investigate in nanoparticle form because it has a Curie point near room temperature. In most of the commonly studied nanoparticle materials, such as Co, Fe, and iron oxide, the blocking temperature where the particle moments decouple is well below the Curie temperature where the atomic moments disorder. In MnP there is a first order ferromagnetic-to-paramagnetic phase transition near room temperature associated with a concurrent hexagonal to orthorhombic structural phase transition. MnP is also an interesting material for the study of nanoparticle interactions because it has a sizeable saturation magnetization (636 emu/cc at low temperature, greater than that of Ni). The strength of the magnetostatic interactions between nanoparticles can therefore be tuned over a wide range with small changes in the sample temperature.

MnP nanoparticles were synthesized by high temperature solution chemistry methods [1, 2]. Comparison samples of bulk MnP were prepared by arc melting mixtures of elemental powders. Transmission electron microscopy images of the nanorods as-synthesized show a broad and bimodal size distribution (Figure 1). There are large numbers of small nanorods 15 nm in length or shorter, plus larger nanorods with typical dimensions of ~ 60 nm length and ~20 nm width. The large and small nanorod fractions can be separated by size-selective precipitation.

Small, spherical MnP nanoparticles (< 8 nm) have blocking temperatures below 100 K [1], and are therefore become superparamagnetic long before they reach the Curie temperature, which is 291 K for the bulk alloy. In contrast, the field-cooled magnetization of nanorod samples shows an abrupt drop in the magnetization just below room temperature (Figure 2). The zero field-cooled (ZFC) magnetization is sharply peaked at this temperature. With a blocking transition the ZFC peak is usually much broader and varies with particle size. In the MnP nanorods. We associate the peak near 280 K with the Curie temperature of the nanorods. This is confirmed by magnetization curves as a function of the applied field.

Because the MnP nanoparticles have a first-order magnetic phase transition near room temperature, there is a large change in magnetic entropy in this range. Ball-milled MnFePAs [3] showed large values of magnetic entropy due to an analogous phase transition, but this required a large applied field and the behavior was less than optimal due to irreversible magnetic losses. Melt-spun MnFePGe ribbons [4] also show significant irreversible losses. Nanocomposite materials have the advantage of reduced saturation fields, and with good structural order the irreversible losses may be less than those for ball-milled materials. Magnetic entropy and irreversible losses for bulk, large, and small nanorod samples near their Curie temperature.

1. *Spintronics and Nanodevice Laboratory, Department of Electronics, The University of York, York, United Kingdom;* 2. *Department of Physics, University of York, York, United Kingdom*

Self-assembly fabrication techniques such as nanosphere lithography (NSL) have attracted much interest because of their low cost and high throughput. The challenge is to fabricate large area and well defined structures with feature sizes approaching the superparamagnetic limit.

In this paper, we report the fabrication and magnetic properties of FeNi dot arrays with ultrafine, large-area, well-ordered periodic nanostructures fabricated on silicon substrate by nanosphere lithography (NSL). We have achieved well-defined triangular shaped dots with lateral size of about 30nm (as shown in Fig.1) with the thickness of 10nm. The composition of the elements was determined by Nano EDAX. The ordered magnetic dot arrays have a large enough uniform area for magneto-optic Kerr effect (MOKE) measurements.

The hysteresis loop of the triangular shaped Fe₆₄Ni₃₆ dot arrays were achieved at room temperature by focused MOKE, as shown in the figure 2. The MOKE loops from the continuous thin films have also been measured to compare the magnetic properties of both the dot arrays and the thin film. The coercivity H_c of the dot arrays was found to increase to approximately 200Oe while the H_c of continuous thin film is around 50 Oe. This may be due to the fact that in the continuous films the coercivity is controlled by the nucleation and depinning of domain wall, and in the nanoscale structures by magnetization rotation as the exchange energy is too high to form domain wall.

To gain an insight into magnetization reversal process, we have performed micromagnetic calculations using the object-oriented micromagnetic framework (OOMMF). We found that the magnetization process follows two steps, the rotation of the top corner and then a switching of the bottom base

Both these processes show the effect of the local shape anisotropy. The easy-axis of the bottom base of the triangle is along the direction of the applied magnetic field. For the top corner, however, the magnetization reversal might be similar to that of the hard axis. We think that the competition of these two local shape anisotropies lead to the two step reversal process.

These results suggest that the magnetization reversal process in sub-50nm magnetic dots can be controlled by the local shape anisotropies related to the detailed shape of the dots, which should be significant for the development of ultrahigh-density patterned media.

Monodisperse doped iron core-shell nanoclusters: synthesis, transport and magnetic properties.

Y. Qiang, A. Sharma, D. Meyer
Physics, University of Idaho, Moscow, ID

Iron naturally occurs in oxidation states that range from Fe0 (for example, at the core-mantle boundary) to Fe³⁺ (at the Earth's surface). Recently, core-shell structured iron nanoparticles have drawn great attention for potential application in biology, enhanced NMR imaging, information storage, and reduction of carbon dioxide and ground water remediation [1-5]. However, as common as what we have experienced in our daily life on the oxidation of metals, a pristine surface of Fe0 exposed to air or oxygen-including atmosphere will be oxidized instantly, a process normally called initial oxidation. This initial oxidation will lead to an instant formation of an oxide layer on the metal surface. Nanometer-sized iron particles exposed to oxygen including environment show no exclusion to this rule. This leads to the Fe nanoparticles covered by a thin layer of oxide, which was termed as core-shell structured Fe nanoparticles. The typical thickness of this oxide layer is ~ 2-3 nm. Although the core may have the types of quantum effects characteristic of metal nanoparticles, the whole particle will involve the core and properties of the outer shell. Therefore, the properties of the core-shell nanoparticles may significantly depend on details of the shell structure and properties. For example, the biocompatibility of the Fe may be mediated by the oxide layers. It has been observed that cancer cell can absorb a large amount of Fe-iron oxide core-shell structured nanoparticles, thus enhancing the NMR imaging. Reduction of carbon chloride by Fe is also completed through the surface oxide layers. Most recently, it has been suggested that iron nanoparticles may be the next generation clean fuel for engine, incurring the questions of a clear picture on oxidation-reduction of Fe-iron oxide nanoparticle system.

In particular, the behavior of Fe-based alloys has been extensively studied for the scientific interest and potential technological applications such as thermostat, sensors, semiconductors, biomedical and environmental applications [2-5]. We present here synthesis, characteristics, magnetic properties and magnetoresistance (MR) of Cu, Ni, and Pd doped D_xFe_{100-x} (D=Cu, Ni, Pd and x = 2, 5, and 15) core-shell nanoclusters deposited on Si substrate, which are prepared by a third generation sputtering-gas-aggregation cluster source. The average nanocrystallite size of D_xFe_{100-x} nanoclusters is about 12 nm. XRD and TEM observed the presence of dopants and iron in core, Magnetite (Fe₃O₄) in shell. The resistance-temperature curves shows exponential behavior till 70-90 K and proportionality is observed with further increase in temperature. Zero field cooling (ZFC) and field cooling (FC) curves indicate a jump in magnetic moment between 70 and 90 K. These phenomena are similar to Verway type transitions⁶. The shifts in Verway transition observed in resistance, ZFC and FC can be due to interionic coulomb interaction between spinel structures of Fe₃O₄, and dopant oxides such as CuFe₂O₄. Magnetic properties and Verway transitions of the core-shell nanoclusters are doping concentration dependent. Verway transition temperature decreases from 90 K to 70 K when increasing doping concentration. For example of Cu doped iron nanoparticles, the magnetization is from 81 emu/g for x = 2 to 53 emu/g for x = 15. The maximum positive MR observed 1.52 % at 5 K for x = 2 when magnetic field of ±7 T is applied. MR decreases with increasing Cu concentration.

Porous Silicon/Metal Hybrid System with Ferro and Paramagnetic Behaviour.

K. Rumpf, P. Granitzer, H. Krenn

Institute of Physics, Karl Franzens University Graz, Graz, Austria

Summary:

Fabricated ferromagnetic hybrid systems consisting of a porous silicon (PS) matrix with incorporated metal-nanostructures exhibit magnetic properties which can be distinguished in two ranges. A first one is related to magnetic fields below the saturation magnetization of the deposited metal and a second one to higher magnetic fields. Considering the low field region the samples show magnetic characteristics due to the metal-precipitations (geometry, distribution, kind of metal) tunable by the deposition parameters. At higher fields an additional non-saturating term is observed which is dependent on the temperature and differs in strength between Ni and Co. In the frame of this work this additional paramagnetic term is investigated.

Experiments and discussion:

Magnetization measurements performed on the semiconductor/metal nanocomposite have been carried out in a field range between +7 T and -7 T and the temperature has been varied from 4.2 K up to 310 K. Considering a PS-membrane with precipitated Ni-structures at applied fields greater than 1 T the non-saturating term decreases with increasing temperature (figure 1a). This behaviour is independent of the geometry and distribution of the embedded Ni-structures within the channels of the PS-template. The field dependence of the susceptibility shows an exponential decay (figure 1b).

The decay of the magnetization with increasing temperature shows a paramagnetic-like behaviour which follows the Curie-Weiss law very well, illustrated in figure 2a and 2b for an applied magnetic field of 7 T. Considering PS-membranes filled with Co-particles a non saturating behaviour is also observed but is less developed than for Ni-filled samples (not shown here). In this case at a magnetic field of 7 T the enhancement of the magnetization above the saturation of the spin-magnetism is about 20% in contrast to Ni structures where the increase amounts about 130% of the ferromagnetic saturation of the low field behaviour.

Conclusion:

The fabricated semiconductor/metal nanocomposite system offers not only a ferromagnetic behaviour (which is tunable by the deposition parameters) at magnetic fields below the saturation magnetization M_S of the embedded metal but it exhibits also an additional paramagnetic-like term at magnetic fields above M_S , following the Curie-Weiss law. This additional term depends on the kind of metal which is deposited within the template offering a stronger contribution in case of Ni than of Co. For both metals the mentioned high field behaviour is temperature dependent.

Electrical Resistance and Magnetoresistance of Glass Ceramics Containing Magnetite Nanoparticles.

P. Allia¹, F. Celegato², M. Coisson², P. Tiberto², F. Vinai², O. Bretcanu³

1. Politecnico di Torino, Torino, Italy; 2. INRIM, Torino, Italy; 3. Imperial College, London, United Kingdom

Magnetite nanoparticles less than 100 nm in size embedded in bio-compatible glass-ceramic matrix have been considered for specific biomedical applications such as bone cancer therapy [1]. We report on the electrical resistivity and magnetoresistance of three ferrimagnetic glass-ceramics prepared at different melting temperatures (1500 and 1550 °C), both as-cast and annealed ($T_{\text{ann}} = 600$ °C for 14 hours). The electrical resistivity was measured between 60 K and room temperature by means of the 4-point method. Isothermal magnetoresistance (MR) curves were measured in the same temperature interval and up to a maximum field of 70 kOe. In our glass-ceramics, magnetite nanoparticles give rise to a percolating network [2].

The electrical resistivity of all samples is dominated by activated processes; the Verwey transition separating the activation regime from the variable-range hopping regime occurs around 110 K. The transition has been independently observed by measuring the sample magnetization as a function of temperature under constant field. A magnetization jump is observed at exactly the same temperature where the resistance vs. T curve exhibits a change in slope. The Verwey-transition temperature T_v is lower than the standard value observed in bulk magnetite (about 120 K) and could be related to either imperfect stoichiometry or to frozen-in stresses. A negative, unsaturating MR is observed in all samples up to 70 kOe. When the temperature is decreased from RT down to T_v , $MR_{\text{max}} = [R(H=70 \text{ kOe}) - R(0)]/R(0)$ is observed to increase; below T_v , MR_{max} is increasingly and markedly reduced.

The effect is interpreted as follows: the MR observed at high fields mostly arises from spin disorder at magnetite grain-grain interfaces. The electrical current is carried through hopping processes within the percolating magnetite network. The hopping range is much less than the average grain size, even in the variable-range hopping regime. Both intra-grain and inter-grain hopping processes exist. At large fields, intra-grain hopping does not contribute to the MR because the magnetization at the atomic sites involved in the hopping process is substantially aligned by the field, and therefore is almost the same. Therefore, the MR effect is dominated by inter-grain hopping, which occurs between atomic sites whose magnetization can be substantially misaligned even at high fields. It is well known that the magnetization of magnetite grains is highly disordered at grain-grain boundaries [3]. Such a disorder is not suppressed by an applied field as high as 70 kOe. Above T_v , the hopping is short-ranged and all electrons do probe the surface magnetic disorder; in the variable-range hopping regime below T_v , the fraction of electrons hopping between sites located deeper in each grain increases. These electrons do not appreciably contribute to the MR signal, because they involve sites exhibiting the same magnetization direction. Therefore, the overall MR is increasingly reduced below T_v .

Switching field distribution reduction and effective write gradient enhancement in domain wall assisted media.

A. Y. Dobin
Seagate Technology LLC, Fremont, CA

Domain Wall Assisted Magnetic Recording has been extensively studied as a means to overcome the super-paramagnetic limit of the magnetic recording. In previous work [1-3], the main benefit of the DWAMR was attributed to the increase of the energy barrier without increasing the switching field. Then the grain diameter can be reduced without sacrificing thermal stability or write-ability, which allows to increase the areal density. In this work we will demonstrate that in optimized domain wall assisted media, in addition to the aforesaid effect, the switching field distribution is reduced and the effective write gradient is enhanced.

For simulations below we use a hard/soft composite media structure with 8nm-thick soft and hard layers, saturation magnetization 1000emu/cc, exchange stiffness 1microerg/cm. The field is applied at 10deg off the easy axis. For large enough soft layer anisotropy the dependence of the switching field on hard layer anisotropy (Fig. 1) becomes flat, which leads to a significant reduction of the switching field distribution (SFD) caused by the fluctuations of the hard layer anisotropy. In Fig. 2, the relative SFD normalized to relative hard layer anisotropy distribution is shown. Note, that for coherent “Stoner-Wohlfarth” switching this normalized SFD is equal to 1. We can see that for optimum values of soft and hard layer anisotropies the normalized SFD for domain wall assisted switching can be reduced by a factor of 10.

Next we studied the domain wall assisted switching under realistic write fields, using FEM write head fields.

The maximum anisotropy of a coherent (Stoner-Wohlfarth) particle that can be written with this head is ~18kOe. The gradient of the maximum switchable anisotropy (“effective write gradient”) reaches 0.25 kOe/nm. Maximum switchable anisotropy of the hard layer in the 8/8nm hard/soft layer structure, calculated using the 1D micromagnetics [3], is shown in Fig. 3. Optimizing soft layer anisotropy allows switching hard layers with extremely high anisotropy of ~55kOe, 3-fold increase with respect to the single layer media. The “effective write gradient” (Fig. 4), reaches 8kOe/nm for the composite media. To compare the effective write gradient with that of the single layer media, it has to be normalized with the maximum switchable anisotropy. At optimum soft layer anisotropy, the normalized gradient is enhanced by a factor of ~10 compared to that of the single layer media, which will result in sharpening of the transitions, reduction of the transition jitter, and hence significant media SNR improvement. We will also present the full micromagnetic recording simulations which confirm our findings, and discuss the underlying physics of the SFD reduction.

A Simple Model for Optimal Read Width due to Finite Write Width and Off-track Interference.

Z. Jin¹, H. N. Bertram^{1,2}

1. Hitachi GST, San Jose, CA; 2. CMRR, UCSD, La Jolla, CA

For a written track of infinite width a wider reader is always preferred because the signal to noise ratio (SNR) varies as the square root of the read width [1]. However, with current areal densities in the range of 300-500Gb/in² [2], extremely narrow written track widths are needed. Because the reader reads beyond the geometric read width, for finite written track width, an optimal read width will occur. Here, in order to estimate the optimal read width, a simple model is used that includes the effect of the finite widths of both the reader and the written track. In addition the effect of off-track interference is included in the SNR estimate.

A reader microtrack profile is assumed of the form $h(z) = \exp(-c_0 z^2)$, where z is the cross track direction. $c_0 = 8 \ln 2 / WR^2$, WR is the read width defined by the half height locations of $h(z)$. Assuming uniform writing over a write width WW , the SNR including off-track interference is given by:

$$\left(\int_{-WW/2}^{WW/2} h(z-z_0) dz \right)^2 / \left(\alpha \int_{-WW/2}^{WW/2} h^2(z-z_0) dz + 2 \int_{WW/2}^{\infty} h(z-z_0) dz \right) \quad (1)$$

In (1), the reader is centered at position z_0 and α is the media noise scale factor independent of the read width. The effect of off-track interference is estimated from a tail integral of the signal profile.

In Fig. 1, the on-track ($z_0 = 0$) SNR is plotted versus WR/WW with and without the adjacent track interference term. Also included is a dashed curve of the simple “basic” variation of the SNR with read width WR (assuming uniform reading only over a finite read width). The vertical axis is calibrated from a measurement at $WR/WW = 0.73$ that yields $\alpha = 3.2$ for an on-track SNR (2T) of 18.8dB. For low values of WR/WW and all cases, the SNR varies as the square root of the read width WR . The simple case of a uniform reader exhibits an SNR reduced by 1dB due to the specific form of $h(z)$. At higher values of WR/WW , the SNR saturates due to the finite write width without the adjacent track term and maximizes including the adjacent track term. With the adjacent track interference term a maximum occurs: for a value of $\alpha = 3.2$, this maximum occurs at $WR/WW \sim 0.7$ with a SNR of 18.9dB. Note that near the maximum, the SNR is approximately independent of read width (within a 10% WR/WW variation). Even without including the off-track interference term the noise variation with read width is significantly reduced from the simple form (dashed).

Equation (1) can be used to calculate SNR versus off-track position. As shown in Fig. 2, experimental measurements (circles in Fig. 2) agree reasonably well with the curve calculated with a WR/WW of 0.73. This value of WR/WW was determined experimentally for the head been used. The off-track capability (width at a threshold SNR) increases with decreasing read width until the on-track SNR becomes lower than the threshold SNR.

In Fig. 3, SNR is plotted versus write width WW for two values of read widths. Note that the smaller reader is less sensitive to variation in the written track width WW . The plots are scaled so that $WW = 1$ corresponds to any chosen value of write width. For example, if $WW = 1 \rightarrow 100\text{nm}$, $WR \rightarrow 63\text{nm}$ and 73nm , respectively.

Introduction

Higher data rate recording requires faster head switching rise time. In order to improve the head switching time and reduce the time delay between write current and write field, shorter yoke length is considered. In this paper, Finite Element Micromagnetic Model [1-2] has been used to study the writer dynamics in perpendicular magnetic recording (PMR) trailing shield head design. In particular, frequency roll off of head field vs. dibit frequency and simulation of nonlinear transition shift (NLTS) are studied.

Results and Discussions

Figure 1 shows the cross section view of the head design that was used in this work. Shorter yoke length about half of long yoke length of 13 μm has been used to compare the write dynamics of recording head. In particular, study of write dynamic and effect of PMR yoke length in high frequency response of the recording head.

Figure 2 shows the normalized head field for a dibit response as a function of data rate for both short yoke and long yoke as well as the effect of write current overshoot amplitude (OSA). Short yoke has much better frequency response and slower roll off as compared to long yoke.

To quantify the effect of yoke length on data rate in terms of head media performance, modeling of nonlinear transition shift was performed. Micromagnetic media model was used to study the recording process using the simulated head field that was calculated using micromagnetic finite element model. Fifth harmonic elimination technique was used to model the NLTS. Figure 3 shows a comparison of NLTS for short vs. long yoke. Assuming a minimum requirement of 14dB NLTS (20%), short yoke can push the data rate up to 1.9Gbs. and long yoke up to 1.25 Gbs. The write current overshoot (OSA) was 100%. Model shows qualitative agreement with experimental with better performance for the shorter yoke.

Reduction in Switching Field for a Granular Perpendicular Medium Using Microwave Assisted Magnetic Recording.

S. Batra, W. Scholz
Seagate technology, Pittsburgh, PA

Recently, there is a renewed interest in ECC media [1,2] and microwave assisted switching [3] both of which offer the potential of reducing switching field thereby allowing writeability on higher HK medium needed to reduce grain size and increase areal density. We use micromagnetic simulations to study the write-ability improvements in a perpendicular recording system due to microwave (RF) assist field. In presence of an in-plane RF field, all the grains in the medium undergo a coherent precession when the medium grains are assumed to be uniform with identical magnetic properties and thermal fluctuation fields are not included ($T = 0$ K). A typical switching event is shown in Fig. 1, where M_z reverses from -1 to $+1$ in 1 ns while in-plane component undergoes coherent precession. The medium parameters chosen are $H_K = 22$ kOe, and $M_s = 400$ emu/cm³, $h_e = 0.037$, LLG damping value $\alpha = 0.02$ and grain size of 6 nm with medium thickness of 15 nm. For an applied in-plane RF field of 0.068 HK at a frequency of 28 GHz, we observe that medium can be switched with a uniform field (DC) of 0.31 HK applied at an angle of 20° , a significant reduction in the DC field compared to Stoner Wohlfarth (SW) switching field of 0.45 HK. The phase space of switching is a function of RF field magnitude, RF frequency and applied uniform field magnitude and direction. For the case of medium with uniform grain size and $T = 0$ K, switching results are consistent with the single spin results [4, 5]. As medium damping is increased, a higher value of uniform field is required, implying that the reduction in switching field is less compared to the case of lower damping value and is plotted in Fig. 2.

Next, we consider a realistic granular medium where grains are no longer uniform. In addition to medium parameters listed above, we assume $\sigma(H_K) \sim 5\%$, angular dispersion sigma of 2° , and grain size volume sigma of 20%. For this case, a uniform field of 0.37 HK applied at an angle of 20° is required to switch medium. Next, we turn on the thermal fluctuation by setting temperature of 300 K in addition to the distributions assumed in magnetic medium properties. For this case, we need to apply still a larger uniform field of 0.39 HK applied at 20° and the optimal RF frequency is increased to 34 GHz. An in-plane RF field of 0.068 HK at the optimal RF frequency requires a uniform switching field of 0.39 HK compared to Stoner Wohlfarth switching field of 0.45 HK applied at the 20° to the anisotropy direction. This is a significant reduction in switching field. We will show that this reduction is by microwave assist field lowering the switching field for the granular medium and not by the coherent precession of individual grains. Next, we comment on the RF frequency needed to observe reduction in switching field. We observe reduction in switching field over a broad frequency range, however, a frequency of 34 GHz gives a maximum reduction in switching field as shown in Fig. 3. This reduction in switching field depends on the damping in the medium and the magnitude and direction of microwave and DC bias field.

A Trailing Shield Perpendicular Writer Design with Tapered Write Gap for High Density Recording.

L. Guan¹, J. Smyth¹, M. Dovek¹, S. Chan², T. Shimizu²

1. Headway Technologies, Milpitas, CA; 2. SAE Magnetics (H.K.) Ltd, Hong Kong, China

Today's commercial PMR products are universally using a trailing shield for the write head design [1]. Key parameters for delivering sufficient write field and field gradient include the ABS dimensions, the main pole neck height (NH) and the trailing shield throat height (TH). With the continuous push for higher areal density, the main pole ABS area decreases $\sim 1/\text{TPI}^2$, as both pole width (PW) and pole thickness (PT) reduce linearly with TPI, resulting in a proportional loss to the write field strength. Typically, to compensate for the large field drop due to the scaling of the ABS area, the main pole neck height and shield throat height are reduced correspondingly. The effort of reducing NH or TH, however, has drawbacks on nominal performance and the controllability of dynamic performance (DP) parameters, such as magnetic write width (MWW) and reverse (LF over HF) overwrite (OVW). In particular, short TH may cause the saturation of trailing shield and result in poor field gradient. The sensitivity of DP parameters on NH/TH also increases with decreasing NH/TH, resulting poorer DP sigma for the same wafer/back-end process tolerance.

In this work, we investigated a new PMR writer design with tapered write gap [2][3] by finite element analysis (FEA) and experiments. Fig. 1 shows the ABS and cross-sectional schematics of taper write gap design. Two new design parameters are introduced: taper angle α and taper distance d . By tapering main pole at the trailing edge, larger trailing edge field and field gradient are achieved. Fig. 2 shows the down-track field profile of two designs: conventional design with $\text{TH} = 0.1\mu\text{m}$ and taper write gap design with $\text{TH} = 0.2\mu\text{m}$, $\alpha = 15^\circ$, $d = 0.2\mu\text{m}$. Taper write gap design shows the same leading edge field, but enhanced trailing edge field magnitude and field gradient, even with much longer TH. Thus superior SNR performance can be expected from better field properties of taper write gap design.

In addition to better SNR performance, another advantage of taper write gap design over short NH/TH design lies in the fact that there is a self-compensating mechanism in such design. In general, the write field is a function of multiple variables: $H(A1, A2, \text{NH}, \text{TH}) = f1(A1) \times f2(A2/A1) \times f3(\text{NH}, \text{TH})$, where $A1$ and $A2$ are the cross-sectional area of main pole at ABS and behind ABS respectively. The larger ratio of $A2/A1$, i.e. larger taper angle α or taper distance d , the better is flux concentrated. When taper angle α or taper distance d varies due to wafer process or back-end process, $A1$ will increase or decrease, but $A2/A1$ will change in the opposite way. So the two terms, $f1(A1)$ and $f2(A2/A1)$, compensate with each other, leaving the write field less affected. Fig. 3 shows the calculated OVW as a function of ABS area $A1$ for conventional trailing shield and tapered write gap designs. As one can see, taper write gap design shows much weaker OVW dependence on ABS area. Due to the same self-compensating mechanism, the NH/TH sensitivity, $f3(\text{NH}, \text{TH})$, is also reduced for taper write gap design. Overall, less DP sigma caused by wafer/back-end process can be achieved with tapered write gap design.

We have fabricated PMR writer with both conventional trailing shield and tapered write gap designs. Two lapping processes are applied to make HGA samples: (1) normal lapping process to study the nominal DP performance and (2) tilted lapping process to study the sensitivities of DP parameters to ABS position for two designs. The results will be discussed in details.

Recently there has been a significant interest in using the r.f. field to facilitate magnetization reversal. In the present work we will explore both analytically and numerically the optimal parameters of constant frequency microwave assisted magnetization reversal (MAMR) based on a single dipole model. We consider a magnetic sample with uniaxial anisotropy subjected to circularly polarized r.f. field H_1 oriented in the plane perpendicular to the easy axis, with the frequency ω , as well as the d.c. field H_{dc} which is oriented parallel to the easy axis and opposite to the initial direction of the sample's magnetization. By solving the Landau-Lifshitz equation in spherical coordinates[1] we discover that for a range of effective anisotropy fields H_{ani} given by Eq.1 such solutions become unstable, with an exception of the solution which corresponds to the reversal of the magnetization. Maximal switchable anisotropy is $H_{dc} + 8H_{rf}$.

We then solve Landau-Lifshitz equation numerically for two configurations: in the first case, the 3ns exposure of the media to the RF field precedes the application of the DC field, in the absence of the RF field, so called "pre-assist" configuration; in the second case the RF and DC field are applied simultaneously, so called "assist" configuration. A random noise introduced into the system. We measure the probability by calculating how many out of 10 calculations result in a switched state. The damping parameter β is assumed to have a value of 0.01. The amplitude of RF field in all numerical experiments is 2000 Oe. In the "pre-assist" configuration (Figure 1.) we see that circularly polarized fields are capable of reliable magnetization reversal, with results being almost independent from the value of the DC field applied after the RF field. Switching shows good correspondence to the analytical solution given. Linearly polarized fields are not performing as well jitter-wise. Results for the "assist" configuration are shown in Figure 2. With an exception of the operating frequencies shift, numerical results for circularly polarized field fit rather well the analytical model.

Effect Of Interlayer on Read Write Process in Perpendicular Recording.

K. Gao¹, V. Sapozhnikov¹, A. Zheng², O. Heinonen¹

1. Seagate Technology, Bloomington, MN; 2. Seagate Technology, Fremont, CA

Interlayer in perpendicular recording affects the distance between the head and the soft under layer (SUL, or keeper) and thus plays an important role in recording performance. In this paper, we investigate the effect of interlayer thickness on read write process in perpendicular recording. We show that depending on different head media combinations, different responses in the read write process can be expected and several previously well-known arguments may have its own limitation. In the write process, we use finite element method (FEM) to generate write field profile for a given recording head design, then use micromagnetic media simulation to provide media magnetic response. To validate the results, the M-H loop of the media was simulated and compared to the experiment measurement. A good agreement is obtained. For the same media, we determine write process transition quality using 4 different metrics, the total effective field at trailing edge of the head, the effective field gradient at transition region, the field profile change in the vicinity of the transition and transition curvature.

We show that the transition quality response is highly depending on the head media combination. Different choices of media designs have big impact on the transition quality. For conventional single layer media, with Stoner-Wohlfarth (S-W) type of switching, reduction of interlayer thickness will cause the peak effective field to be reduced. However, with ECC type of media, a monotonic increase in the peak effective field can be expected as the interlayer thickness is reduced.

For current media with ultra small writer dimension, we show that there exists a design space where reduce the interlayer thickness, the peak effective field, the effective field gradient, the write field profile at trailing edge and the transition curvature are all kept approximately same. A unique example is shown that for a particular combination of head media design, we observe that the measured media overwrite improves as the interlayer thickness is reduced. However, no SNR / BER gain is observed. Thus the model prediction is in good agreement with the spin-stand measurement.

In playback process, the spatial resolution of a reader is usually characterized by transition half-width T50, an important factor in head performance. We show that interlayer thickness reduction brings the mirror image of the recording layer closer to the reader. As illustrated in Figure 1, this affects T50 in two ways. First, because the effective HMS of the mirror image decreases, "T50" of the mirror image decreases (the mirror of the read back signal gets sharper). This decreases the total T50. Second, the amplitude of the mirror read back signal increases. Therefore, the contribution of the mirror T50 to the total T50 increases. This increases the total T50.

Due to the complexity of many different interaction terms in the playback process, we use micromagnetic simulation to study the subtle detail in addition to the analytical formula to see which of the two effects prevails by computing the sensitivity of T50 to the interlayer thickness. The sensitivity is obtained based on the media samples we used for the write process study, where a possible identical transition can be written. The design space in the simulation is enlarged to reflect the general response.

The parameters for the modeling exercise are: reader HMS = 8-20 nm, media transition parameter $a = 4-10$ nm, media record layer thickness = 15-25 nm, interlayer thickness IL=10-30 nm, and reader shield to shield spacing is chosen to match the experiment parts. The results show that DT50 = -0.086DIL which predict that in this particular playback process, a finite penalty is seen in the playback process. We show that this result is also consistent with the measurement for the given head media combination.

The write field profile for a particular head medium combination in perpendicular recording which has the same peak effective field, same effective field gradient, same field profile at trailing edge and same transition curvature for different interlayer thickness.

Illustrate the impact of interlayer thickness on playback process where both spacing loss and impact of resolution due to magnetic image of the reader are included.

Influence of negative field on media noise in combination of capped medium and shielded pole head.

T. Ichihara¹, H. Kashiwase¹, H. Nakagawa¹, H. Nemoto¹, M. Mochizuki²

1. Central Research Laboratory, Hitachi Ltd., Odawara, Japan; 2. Hitachi Global Storage Technologies, Fujisawa, Japan

By using a shielded pole head and a capped medium, high area density could be obtained with improvement of write-ability [1]. On the other hand, optimization of field distribution from shielded pole writer and that of exchange coupling in the cap layer of the medium were major issues for improvement of total R/W performance. In this study, it was found that the media noise increased drastically at particular linear density in some combinations of shielded pole heads and capped media. Furthermore, the phenomenon was investigated by MFM observation. Schematic illustration for a structure of the capped medium was shown in Fig. 1. Two antiferromagnetically coupled Fe-Co-Ta-Zr alloy layers were used for the SUL. Total SUL thickness was varied as 0, 10, 20 and 30 nm. A Co-Cr-Pt-SiO₂ granular layer with thickness of 13 nm and with M_s of 400 emu/cc, was used as a recording layer. A Co-Cr-Pt alloy with thickness of 8 nm was used as a cap layer on top of the granular layer. M_s of the cap layer was varied from 330 to 500 emu/cc. Shielded pole writers and GMR readers were used to investigate the R/W performance over a linear density range of from 50 kfc to 1300 kfc. Fig. 2 shows linear density dependences of normalized media noise power for the capped media with various M_s of cap layer. As increasing M_s of the cap layer, media noise of the linear density of around 550 kfc increased drastically. Since the increase of media noise was suppressed by increasing SUL thickness or decreasing write current, it was considered that the phenomenon came from the negative field around the edge of trailing shield [2]. Fig. 3 shows MFM images of written pattern with various linear densities on the capped media. When M_s of the cap layer was 500 emu/cc, maze-like domains were formed at AC erased region between each written pattern because of the larger exchange coupling in the cap layer with higher M_s . Furthermore, the width of the domain was comparable to the transition period of 550 kfc pattern, 46.2 nm. Fig. 4 shows crosstalk distributions of transition jitter estimated from MFM image in Fig. 3. For the medium in which M_s of the cap layer was 500 emu/cc, the transition jitter of 550 kfc pattern increased drastically. It was considered that the magnetization relaxation by field around trailing shield was enhanced at the 550 kfc pattern of which the transition period was comparable to the magnetic cluster size. These results indicated that optimization of field at the edge of trailing shield and optimization of magnetic cluster size for the capped media were important for improvement of total R/W performance. In conclusion, it was observed that the media noise of the pattern around 550 kfc increased drastically in combinations of shielded pole head and capped media with higher M_s cap layer and thinner SUL. MFM observation indicated that the phenomenon was correlated with the domain width at AC erased region and it was considered that the magnetization relaxation by the negative field around trailing shield was enhanced when the transition period of the pattern was comparable to the magnetic cluster size.

Investigation on magnetic fields from field generating layer in MAMR.

K. Yoshida¹, E. Uda¹, N. Udagawa¹, Y. Kanai²

1. Information and Communications Engineering, Kogakuin University, Tokyo, Japan; 2. Niigata Institute of Technology, Kashiwazaki, Japan

Introduction

Several kinds of technology have been proposed to be as the break through to overcome super-paramagnetism limitation in magnetic recording. HAMR(heat assisted magnetic recording) and BPM(bit patterned media) are thought to be promising candidates to realize ultra-high recording density over 2 Tb/in². They, however, require the drastic changes from the conventional fabrication technologies for a writing head and a recording medium. Recently, MAMR(Microwave assisted magnetic recording) was proposed by J. G. Zhu which utilizes the ferromagnetic resonance phenomenon that dramatically decreases magnetic switching field in writing process, enabling us to use the recording medium materials with extremely large magnetic anisotropy constant[1],[2]. MAMR might be also added as one of the candidates for the future technology. However, many physical aspects should be clarified to put practical technology. In this paper the characteristics of the magnetic fields from the field generating layer in MAMR are investigated with micromagnetic simulations.

Calculation procedures

Fig.1 shows a schematic diagram of a microwave field oscillator which comprises a field generating layer and a perpendicular anisotropy layer[2]. The polarization layer that supplies a polarized spin to the field generating layers was neglected for simplicity. The lengths of the perpendicular layer and field generating layer are 20 nm and 6 nm, respectively. The cross section of the x-coordinate is square with a length of 60 nm. The saturation magnetizations (M_s) and the anisotropy constant (K) of the perpendicular layer are 0.377 T and 5×10^5 J/m³, respectively. The M_s and K of the field generating layer are 2 T and 2×10^5 J/m³, respectively. The stiffness constant between the perpendicular and field generating layers is varied from 2 pJ/m to 10 pJ/m. The magnetization vectors are calculated with the Landau-Lifshitz-Gilbert equation with a spin torque term,

$$(1 + \alpha^2) d\mathbf{M}/dt = -\gamma \mathbf{M} \times (\mathbf{H}_{\text{eff}} + \alpha \mathbf{H}_{\text{st}}) - \gamma / M_s \mathbf{M} \times (\alpha \mathbf{M} \times \mathbf{H}_{\text{eff}} - \mathbf{M} \times \mathbf{H}_{\text{st}}) \quad (1)$$

$$\mathbf{H}_{\text{st}} = a_j \mathbf{M}_p = h \eta \mathbf{J} \mathbf{M}_p / (4\pi e M_s d),$$

where \mathbf{H}_{st} is the effective field due to spin torque, \mathbf{M}_p is the unit vector of the magnetization of the polarization layer, \mathbf{J} is the injected current density, η is the polarization factor of spin current, M_s and d are the saturation magnetization and thickness of the field generating layer, respectively. The a_j was set to be from 10 to 100 kA/m. A damping factor of 0.02 was used in the calculations. All the region was descretized into cubic cells of a 2nm length. The generated AC field were observed on the dashed plane(the x-y plane) with a distance of 15 nm from the down side of the generating layer.

Calculation results

Fig.2 represents the snap shots of the y-component of the magnetizations in the field generating layer in gray scal. The magnetizations rotate counterclockwise around the center of the square. The rough image of the magnetization directions are depicted in the picture at $T=0$ sec. The magnetizations do not rotate in unison. Fig.3 shows the trajectory of the generated AC field averaged in the observing plane that corresponds to a recording medium plane. The field oscillates in the x-y plane with a frequency of ~20 GHz. The oscillation amplitude is about 10 kA/m that is not sufficient to assist magnetization switching. This is because of the non-unison rotation of the magnetizations in

the generating layer. The amplitude can be increased by preventing the magnetizations of the field generating layer from rotating in non-unison.

Effect of media reversal mode on head footprint.

B. F. Valcu¹, B. Allimi², A. Dobin¹, R. Lynch¹, R. Brockie¹

1. Seagate Technology, Fremont, CA; 2. Department of Materials Science and Engineering, University of Connecticut, Storrs, CT

The magnitude of the applied field needed to reverse magnetization in a thin film with perpendicular anisotropy depends on the field angle: the field is minimum at 45 degrees and doubles when the angle is either 0 or 90 degrees, following the Stoner-Wohlfarth (SW) asteroid. Recording heads used for writing on thin film media have a non-uniform spatial distribution of the field: under the pole the magnetic flux is perpendicular to the surface of the media, while at the pole edge there is a significant longitudinal component and thus the field is tilted with respect to the perpendicular easy axis. If magnetization reversal follows the SW curve, then it must be significantly easier to write on the medium at the pole edge compared to the region under the middle of the pole. Consequently the footprint of the recording head on such a medium should have a 'doughnut' shape. Micromagnetic simulations of the perpendicular recording system predicted the 'doughnut', however there is little direct experimental evidence [1]. When the experiment is performed in the spin-stand, the disc is rotating under the head: the portion of the media that is not well written by the field from the center of the pole will ultimately travel under the pole edge where there is enough field angle to switch it.

We used a stationary 'drag' recording tester to measure the footprint of the recording head. The head is in direct physical contact with the medium. Initially a wide region on the disc is DC erased, by 'dragging' the head on the disc. Subsequently the head position is fixed in the middle of the erased region and the head is energized with a write current, such that media magnetization is reversed in the opposite direction. The head is then moved quasi-statically and the playback signal maps out the recorded footprint. Fig. 1 reveals that the shape is indeed that of a 'doughnut'.

There is a direct connection between the angular dependence of the switching field of the media and the recording head footprint. To experimentally prove that the footprint changes shape when media has a different reversal mode, we employed a bi-layer exchange spring film [2]. In this structure one layer has large perpendicular anisotropy, while the other layer is very soft. If the soft layer is thick enough, under the action of a reversal field the magnetization reverses incoherently, with a domain wall propagating from the soft layer inside the hard layer. The switching field (i.e. remnant coercivity H_{cr}) dependence on field angle deviates considerably from SW (see Fig. 2): at small angles the switching field is almost independent of field orientation.

The flat dependence of media switching field on angle, convolved with the spatial decrease in the magnitude of the write field as the distance to the pole center is increased, results in an effective field experienced by media that has a 'dome-like' profile. In Fig. 3 we show the experimental footprints for two bi-layer structures: for the one in which the soft layer is only 4 nm thick the reversal mode is coherent rotation (SW), thus the footprint has a 'doughnut' shape; for the other in which the soft layer is 22 nm thick the switching mode is non-coherent rotation and the footprint has a 'dome-like' shape.

Figure 3 Head footprints for exchange spring systems with the magnetic hard layer 12 nm thick and the magnetic soft layer 4 nm (left) and 22 nm (right). The structure with thick soft layer reverses non-coherently, as opposed to the Stoner-Wohlfarth behavior of the film with thin soft layer.

Magnetic recording readback responses in three-dimensions for multi-layered recording media configurations.

R. Wood¹, D. T. Wilton²

1. HDD AdTech, Hitachi GST, San Jose, CA; 2. School of Mathematics and Statistics, University of Plymouth, Plymouth, United Kingdom

In the past, simple two-dimensional (2-D) approximations have generally been adequate to represent the on-track response from a magnetic recording system. However, in the push to achieve ever higher storage densities two important factors have changed. First, the bit aspect ratio (track-width over bit-length) has decreased significantly. Second, the advent of perpendicular recording now means that there is a soft magnetic underlayer (SUL) included as part of the recording medium. Under these circumstances, 2-D analyses of head fields and head response functions, which assume infinite head and track widths, are no longer accurate. This is especially true at long wavelengths (low spatial frequencies) where the SUL renders the 2-D approximations totally inaccurate. A three-dimensional (3-D) analysis is thus necessary for getting good estimates of the 'on-track' response and is also essential in examining any side-reading/writing effects.

The approach taken here relies on an initial transformation into the 2-D spatial frequency domain and then the use of transmission matrices to relate the fields in the different layers. The general approach allows for complex structures with any set of 3-D magnetic sources and with an arbitrary number of layers. Each layer can have any anisotropic permeability, however, a linear B-H relationship must hold since the analysis is based on breaking down the magnetization into its Fourier components.

We apply this approach to the analysis of magnetic recording readback signals. For simpler configurations it is possible to write analytic expressions in the frequency domain. This is true, for example, for the system comprising a single recording layer, an anisotropic soft-underlayer (thickness d_s , permeability μ_{sx} , μ_{sy} , μ_{sz}) and suitable spacer layers giving a total separation from head to SUL of d_{sh} . This system is the subject of much of the discussion here. We examine in particular the low-frequency response associated with flux-flow in the soft underlayer and also the behavior of the main response for finite read- and write-widths. This work leads to an understanding of the nature of the "DC-null" and the related low-frequency side-reading phenomena. For example, the depth of the DC-null can be approximated by taking the larger of the write- or read-width, $\max(W_w, R_w)$, and dividing by twice the characteristic cross-track propagation-length, $\sqrt{(d_s d_{sh} \mu_{sz})}$. Also the Signal-to-Interference power ratio (rms bit response to rms low-frequency side-reading interference level) for random data can be approximated by $W_w b / [4\pi d_s d_{sh} \sqrt{(\mu_{sx} \mu_{sz})}]$, where b is the bit-length. Another useful contribution that will be presented is an analytic expression that approximates the 3-D on-track readback frequency response without involving an inverse transform along the cross-track, z -axis.

The figure below shows an example of the analysis where, to aid visualization, we have translated back to the spatial domain. Here, a track of $W_w = 150$ nm is written with an elliptical curvature (semi-axis = 50 nm) and a circularly-symmetric a -parameter ($a = 10$ nm). The reader is 100 nm wide and the gap between the high-permeability shields is 30 nm.

Figure. Although the analysis of this example proceeds entirely in the frequency-domain, here we take the inverse-FFT and view the results as solid surfaces in the spatial domain: a) Magnetic transition as written in the recording layer (thickness $\delta = 15$ nm, $a = 10$ nm) b) Normalized field at head surface but *with SUL absent* (magnetic spacing = 15 nm) c) Same as b) but with SUL introduced ($d_{sh} = 45$ nm, $d_s = 100$ nm, $\mu_{sx} = \mu_{sy} = 100$, $\mu_{sz} = 10$) d) Readback signal as a function of down-track and off-track position ($R_w = 100$ nm) e) Readback impulse response as a function of down-track and off-track position f) Same as e) but with the in-plane scales zoomed out and with vertical scale greatly exaggerated in order to illustrate the 'negative disturbance' caused by the return flux Note: the units on the horizontal axes are nanometers. The vertical axis is normalized magnetization (a) or vertical field (b, c) or reader response (d, e, f).

Direct observation of magnetocaloric effect with pulsed-field magnet.

T. T. Nguyen¹, E. Brück¹, C. D. T¹, O. Tegus², J. Klaasse¹, J. Buschow¹

1. Faculty of Science, Universiteit van Amsterdam, Van der Waals-Zeeman Institute for Experimental Physics, Amsterdam, Netherlands; 2. Inner Mongolia Normal University, Key Laboratory for Physics and Chemistry of Functional Materials, Hohhot, China

Most studies devoted for room temperature applications of magnetic refrigeration are now focused on materials showing giant magnetocaloric effect (MCE). However, as being a common feature of compounds with first-order field-induced magneto-structural transition, large MCE observed in these materials comes often with large thermal hysteresis which could make them unsuitable for applications because a real refrigerator is expected to be operated at rather high cycle frequencies [1].

After the discovery of giant MCE on MnFeP1-xAsx compounds [2], it was found that the MnFe(P,Ge) alloys also exhibit magnetocaloric effect in the same order of magnitude with tunable T_c in a large range of working temperatures. In the present work, samples of MnFe(P,Ge) were prepared by high energy ball milling and melt-spinning technique at 40 m/s speed-of-the-wheel. Shown in Fig.1a, the isothermal magnetic entropy change recorded for Mn1.2Fe0.8P0.75Ge0.25 melt-spun ribbon is 20 J/kgK under the field change of 2 T. Note that for this sample thermal hysteresis is only 1 K.

The fast magnetic measurements are performed on the 20T pulsed field magnet in the field up to 15 T at different starting temperatures (Fig.1b). The field vs. time profile is a half sinus with duration 100 ms. The magnetization process is close to being adiabatic at the field sweep rate of about 3×10^2 Tesla/s. At an ambient pressure of less than 10^{-3} mbar the heat exchange with the surrounding can be neglected and the contribution of eddy current heating due to field increase (and decrease) is also small. On the other hand, magnetocaloric effect makes the sample to be heated with increasing applied field. This heat amount is then totally compensated when the field decreases from 15 Tesla to zero-field. Because of intrinsic inertia of thermocouples, the monitoring of temperature during the field sweep can not be accomplished by just reading a thermocouple. Instead we exploit fact that the magnetization becomes lower with increasing temperature (Fig.1c). Based on the comparison of magnetization curves obtained either in adiabatic or isothermal process, we can calculate the adiabatic temperature change with respect to an equivalent field change. This elegant method was first introduced by Levitin et al [3]. In this way, the adiabatic temperature change of Mn1.2Fe0.8P0.75Ge0.25 ribbon is calculated to be approximately 3 K/Tesla (Fig.1d).

In summary, the pulse field technique is a good approach for directly monitoring the MCE in adiabatic condition even for very fast field-sweep rates. The experimental results observed with fast magnetic measurements confirm that the compounds of MnFe(P,Ge) can be used as refrigerants working at high frequency. The excellent magnetocaloric properties of MnFe(P,Ge) bring practical magnetocaloric cooling a step closer.

The dc & ac properties of soft magnetic materials for the operational conditions found in novel electrical devices.

H. V. Patel, M. J. Hall, O. Thomas, S. C. Harmon

Industry & Innovation Division, National Physical Laboratory, Hampton Road, Teddington, United Kingdom

The increased use of electromagnetic devices in strategic areas such as environmentally friendly transport places demands on the supply chain. To achieve more efficient modelling predictions and reliable devices, a study of the behaviour of soft magnetic material properties for operational conditions needs to be performed. Modelling of electrical machines requires reliable data if the specification is to be met without too many costly development cycles. The conditions of interest include operational magnetic flux density waveforms, mechanical stress and temperature. Existing standards [1] are essential for purchase and sale of electrical steel as well as other soft magnetic special alloys, however they are not easily adapted for operational conditions such as temperature and the application of mechanical stress. These conditions are common to many applications of magnetic materials and so techniques to determine the properties will benefit many users. In addition, material suppliers will be able to provide data that better matches the conditions of use and so material selection will be improved. If electrical machines are to replace heavy and high maintenance hydraulic and pneumatic systems (MORE electric concept) then they need to operate in extreme conditions [2]. Researchers involved in the development of embedded starter/generators for MORE electric transport estimate that the temperature would be 450 °C and the stress 450 MPa. For the automotive industry, these will probably be 200 °C and 200 MPa. A measurement technique is required that can produce these stress levels and temperatures simultaneously as well as the magnetic flux density waveforms encountered in use.

To determine the effect of stress on dc properties, it is possible to place a permeameter (in accordance with IEC 60404 part 4 [3]), in an Instron machine. In electrical machines it is the ac properties that are most important. When measuring specific total loss the standard methods require the flux density waveform to be sinusoidal, however actual waveforms for an electrical machine are not sinusoidal (figure 1 shows an actual waveform in a switch reluctance machine). It is necessary to know the specific total loss for this operational waveform. The generation and control of such waveforms is not possible using the analogue approach of IEC 404 parts 2 and 3, [2] and [4], and digital techniques are required.

The test specimen needs to have free ends for clamping in the jaws of an Instron machine and along with placing the material in an oven has made it necessary to move to an open circuit design. This removes the fundamental measurement principle of using a closed magnetic circuit. Figure 2 shows that demagnetization has an immediate effect and alters the measured BH curve.

This paper will discuss the specification of the measurement system, how this has been achieved in practice and how the presence of demagnetization has been considered. Materials under test were conventional grain-oriented electrical steel and Rotolloy 3. Due to the poor mechanical properties of Rotolloy 3, a Rotolloy 3 metal matrix composite re-enforced with carbon fibre has been developed, and the magnetic properties of this material will be discussed in the paper.

Eddy current effects and pinning effects in Fe and Ni single crystals with low defect densities.

S. Takahashi, S. Kobayashi

Faculty of Engineering, Iwate University, Morioka, Japan

Magnetic hysteresis loops reflect the domain wall displacement as well as the rotation of magnetic moments. The domain wall displacement is dominated by the pinning effect due to lattice defects and the eddy current effect. As the domain walls displace by the external field, the local magnetic moments within the domain wall change during the displacement and eddy current is induced in the domain wall. The force due to eddy current acts as frictional force in the domain wall displacement. The eddy current effect becomes predominant in the low temperature where the electrical conductivity increases. Dislocations act as obstacles when the domain walls move under the external field. In this study, the two effects have been studied in Fe and Ni single crystals with low defect densities by the minor hysteresis analysis discovered recently.[1,2] The seven magnetic properties and seven scaling rules are represented by a set of minor hysteresis loops. The scaling rules include

$$W_F^* = W_F^0 (M_a^*/M_s)^{nF},$$

$$W_R^* = W_R^0 (M_R^*/M_R)^{nR},$$

$$H_c^* = H_c^0 (M_R^*/M_R)^{nC},$$

where W_F^* , M_a^* , W_R^* , H_c^* , and M_R^* are minor-loop hysteresis loss, minor-loop magnetization, minor-loop remanence work, minor-loop coercive force, and minor-loop remanence, respectively, and M_s and M_R are saturation magnetization and remanence, respectively. The parameters of a minor loop depend on microstructures and the magnetic-field amplitude. W_F^0 , W_R^0 , and H_c^0 are minor-loop coefficients, which have a linear relation with coercive force and are more sensitive to lattice defects than coercive force.

The minor-loop coefficients increase by plastic deformation at room temperature in both metals. But the temperature dependence of the coefficients is quite different in Fe and Ni metals. The coefficients increase with the increase of true stress in Fe metal above $T = 200$ K and they increase remarkably with the decrease of temperature below $T = 200$ K as is seen in the temperature dependence of W_R^0 in Fig. 1(a). The increasing rate of the coefficients at low temperature is the largest in the sample without plastic deformation. While in Ni metal, the coefficients increase, take a maximum and decrease with decreasing temperature as shown in Fig. 1(b). The maximum point moves towards a lower temperature with increase of true stress.

The remarkable increase of minor-loop coefficients below $T = 200$ and 430 K in Fe and Ni metals, respectively can be explained by the appearance of eddy current effect, due to the increase of electrical conductivity with the decrease of temperature in both metals. The decrease of the coefficients below $T = 200$ K for Ni metal is due to the decrease of domain wall thickness associated with a rapid increase of magneto-crystalline anisotropy. Such anomalous increase of the coefficients below $T = 200$ K and in the medium temperature range from 200 to 430 K for Fe and Ni single crystals were found to be associated with the constriction of hysteresis loops with very low remanence and low permeability around coercive force.

Experimental Prediction of Iron Losses in Electromagnetic Devices.

G. Almandoz¹, E. Ritchie², J. Poza¹, A. Gonzalez³

1. University of Mondragon. Faculty of Engineering, Arrasate, Spain; 2. Aalborg University. Institute of Energy Technology, Aalborg, Denmark; 3. ORONA Elevator Innovation Center, Hernani, Spain

The performances of electromagnetic devices such as transformers or electrical machines depend strongly on the iron losses. The overall efficiency, the thermal behaviour or the compactness are some of the design aspects which are influenced by this phenomenon. So, it is necessary to predict these losses accurately if an optimum design of the device is required. Iron losses phenomenon in soft magnetic materials is described by the well known loss separation method in which the overall iron losses are divided into three components: hysteresis, eddy and excess losses [1]. This method can be applied with sinusoidal or arbitrary flux density waveforms [2]. The drawback of this analytic method is that it depends on a set of experimentally estimated coefficients so its accuracy is subject to a precise estimation of these coefficients. Furthermore it does not consider the effect of minor loops so that it may not be suitable for iron loss calculation in electric machines or transformers. In these devices minor loops might appear due to the geometry of the core or due to pulse width modulation (PWM) supply voltages. In this work an experimental method for iron losses prediction in electromagnetic devices is proposed. The main goal is to predict accurately the iron losses in the design process before building any prototype. This method is based on experimental tests performed using a Single Sheet Tester (SST). Fully automated SST with a closed loop control makes possible to analyze iron losses in soft magnetic materials with non sinusoidal flux density waveforms. Iron losses are computed integrating the area enclosed by the hysteresis loop so that possible minor loops are taking into account and the results don't depend on any coefficients. As example specific iron losses in the teeth and the yoke of a permanent magnet synchronous machine (PMSM) have been computed. Flux density waveforms in these parts of the stator core have been obtained from Finite Element Analysis (FEM) of the machine. The laboratory equipment comprises a SST, a wide bandwidth linear amplifier, an analog PI controller, two sensors and a Data Acquisition (DAQ) system based on a personal computer equipped with a multifunction DAQ card of National Instrument. The equipment is completely automated so that the user can perform different tests in an easy way thanks to the interface built in LabView. The proposed methodology consist in driving a magnetic material sample using a SST with the flux density waveforms calculated in FEM or experimentally measured in different parts of the magnetic core of a device. The magnetic core is divided in different parts so that the magnetic field distribution is approximately uniform in each of them. This way the specific iron losses measured using the laboratory equipment are the iron losses in this part of the magnetic core of the device. Then assuming that the magnetic field distribution in each part is homogeneous the overall iron losses can be calculated. In this digest the most relevant results are shown. In the full version more results will be included. Temporal flux density waveforms in two different points of the stator core when the motor works in open circuit mode have been calculated in FEM. These points are situated in a tooth and in the above part of a slot. In Fig1 calculated flux density waveforms in a tooth and in the yoke are shown. In Fig2 experimentally measured hysteresis loops are presented. In Fig3 experimentally determined iron losses are presented. These curves have been obtained driving the M80065D sample with the described flux density waveforms at different frequencies.

Miniature iron-gallium actuator with displacement magnifying mechanism.

M. Ghodsi¹, T. Ueno¹, C. Sze Keat², T. Yano², T. Higuchi¹

1. Precision Eng. Department, The University of Tokyo, Tokyo, Japan; 2. Mechano Transformer Corporation, Kawasaki, Japan

1. Introduction

In the last two decades, the requirements for precision and micro-displacement actuators have been increased. For example, these actuators are used for micropositioning [1] and vibration controls [2]. In most applications, piezoelectric (PZT) is used as an actuation element. However, the PZT has low Young's Modulus, needs high voltage source and because of its brittleness property, miniature size or arbitrary shape cannot be obtained easily. On the other hand, to increase the performance of the equipments especially in the space applications, it is required to make actuators smaller, lighter and with low power consumption. Because of these requirements, magnetostrictive seems a good candidate for miniature actuator. In 1999 large magnetostriction material made of iron-gallium alloy was developed. Although strain of iron-gallium is small (160-250 ppm), it is strong (large Young's Modulus $\approx 70\text{--}90\text{ GPa}$) [3] and has high flux density saturation (1.7 T). Furthermore, it will be saturated by low magnetic field (30 kA/m) [4] and its high permeability (≈ 200) makes it suitable for close magnetic circuits. These specifications combined with high ductility (easy machining) and operation in different temperatures [5] promise wide range of industrial applications for recently developed magnetostrictive material, iron-gallium alloy. In this research, iron-gallium bar is combined with a magnifying mechanism to make a high efficiency miniature actuator. Static and dynamic behaviours of the actuator are investigated.

2. Principle of Actuator

Figure 1(a) shows a schematic configuration of iron-gallium actuator. This actuator consists of two main parts that make a close magnetic circuit. First part is an iron-gallium bar and second part is a magnifying mechanism to amplify strain of the iron-gallium. To enhance the performance of magnetic circuit, the magnifying mechanism is made of high permeability magnetic steel. The length of iron-gallium bar is 10 mm and its cross section is square by 1 mm width (Fig. 1(b)). The maximum strain of annealed iron-gallium is 250 ppm. Thickness of magnifying system is 0.8 mm and energized coil is $\phi=0.05\text{ mm}$, 240 turns. Iron-gallium displacement is transmitted to the head by phosphor-bronze elastic arms. By energizing the coil, generated magnetic fluxes pass through the iron-gallium bar and increase its length. Similar to lever mechanism this enlargement is magnified and large vertical displacement is achievable by head.

3. Results and discussion

As shown in Fig. 1(b), the actuator is fixed on a brass fixture. By energizing the coil, a vertical displacement can be realized in the aluminium head. Photonic sensor ($14.7\text{ }\mu\text{m/V}$ in front slope) is used for the vertical displacement measurement. Figure 2, shows the displacement of actuator when the coil is energized by sinusoidal signal with different amplitudes. Although the maximum expected displacement of iron-gallium is $2.5\text{ }\mu\text{m}$, a large displacement of $23\text{ }\mu\text{m}$ is achievable. It means that, this actuator can magnify the displacement about 9 times. It is obvious that small hysteresis makes this actuator suitable for real applications.

Application of magnetoelastic sensors for monitoring of the combustion process in diesel engines for locomotives.

A. Bienkowski¹, R. Szewczyk^{1,2}, J. Salach¹

1. Institute of Metrology and Measuring Systems, Warsaw University of Technology, Warsaw, Poland; 2. Industrial Research Institute for Automation and Measurements PIAP, Warsaw, Poland

Monitoring of the combustion process in diesel locomotive engines is very important from the practical point of view. The commonly used strain-gauge sensors are not well suitable for this application, due to high temperature and corrosive environment of sensor operation. Moreover, in the case of this application the sensor should be as flat as possible, to reduce problems during the installation of it.

This paper presents a novel solution of utilizing ring-shaped magnetoelastic sensors with amorphous alloy cores in monitoring of the combustion process in diesel locomotive engines. Sensor is mounted on the binding screw of the head in a diesel engine. Special cylindrical backings enable uniform stress distribution, as well as protect the sensing element from twisting during the installation. Results of the tests of functional properties of developed sensor are also presented. These results indicate that sensor sensitivity, as well as its resolution, is sufficient for monitoring of combustion process.

Longitudinal and transverse magnetoimpedance in FeNi/Cu/FeNi multilayers with longitudinal and transverse anisotropy.

Magnetoimpedance (MI) consists in the change of the impedance of a ferromagnetic conductor under an external magnetic field [1-2]. Special efforts have been made recently for the development of thin film miniature MI sensors compatible with semiconductor electronics [1, 3-4]. A typical MI multilayer consists of two magnetic layers separated by a nonmagnetic conductive lead [1, 5]. Up to now most studies have concentrated on MI devices with transverse magnetic anisotropy, i.e. with the in-plane easy magnetization axis perpendicular to the direction of the current. This type of the anisotropy usually results in higher MI ratio and sensitivity for the longitudinal MI effect (external field is parallel to the current). In this work both longitudinal and transverse MI is studied for multilayered structures of FeNi/Cu/FeNi with either longitudinal or transverse magnetic anisotropy, at relatively low frequencies up to 500 MHz, convenient enough for technological applications.

The NiFe(150nm)/Cu(500 nm)/NiFe(150 nm) multilayered structures were prepared at room temperature by rf sputtering using metallic masks and glass substrates. Each multilayer has 50 μm (Permalloy) and 5 μm (copper) wide stripes. The length of the MI stripes was 12 mm. A constant field of about 100 Oe was applied in plane of the multilayered structure during deposition. Such an external field was either parallel to the Cu-leads, creating a longitudinal anisotropy (sample L), or perpendicular to it (sample T), creating a transverse anisotropy. The anisotropy field values were estimated from the shape of the M(H) curves obtained by MOKE studies.

The MI was measured as described in ref. [5]. MI ratio ($\Delta Z/Z$) is usually defined with respect to the saturated sample or the maximum applied field where Z is a minimum: $\Delta Z/Z = (Z(H) - Z_{\text{min}})/Z_{\text{min}}$. MI sensitivity (s) is defined as $s = (\Delta Z/Z)/\Delta H$, where 0.1 Oe field increments were taken in the calculation in order to avoid excessive noise.

Figure (a) shows the frequency dependence of the maximum longitudinal MI ratio for samples of L and T type. It is clearly seen that the longitudinal $\Delta Z/Z$ ratio is higher for T multilayers than for L multilayers in all frequency range under consideration. The maximum sensitivity for T samples was about 31%/Oe (at about 100 MHz) while for the L samples was only about 5.5%/Oe (at about 200 MHz) (see Table, Figure (b,c)). Transverse MI ratio for T samples is negligibly small below 100 MHz and only 1 % for higher frequencies (Figure (c)). However, transverse MI for L samples is much higher ($\Delta Z/Z(f=300\text{ MHz})=70\%$). Relatively high value of the longitudinal MI ratio ($(\Delta Z/Z(f=300\text{ MHz})=54\%)$) was also observed for L samples (Table, Figure (b)). In a frequency range of 90 to 300 MHz the longitudinal and transverse $\Delta Z/Z$ sensitivities of L samples are higher than typical sensitivities of giant magnetoresistance detectors (of about 2%/Oe). One can therefore propose a design with a single sensitive element detector with enhanced functional parameters for 2 way detection of magnetic field in the plane of the MI multilayer, instead of using two different MI elements.

Magnetorheological characteristics of carbonyl iron embedded suspension polymerized poly(methyl methacrylate) microbead.

J. You, B. Park, H. Choi

Department of Polymer Science and Engineering, Inha University, Incheon, South Korea

Introduction

Magnetic microspheres have attracted much interest in past decade due to their various potential applications in such as biosensor and specific molecular recognition areas [1, 2]. Among these magnetic microspheres, soft magnetic materials such as carbonyl iron (CI) have been investigated due to their reversible changes in their magnetic properties in response to external magnetic fields. The CI with these changeable magnetic properties has been considered as a good candidate material for magnetorheological (MR) fluid application with great attentions as promising damping materials [3], in which the MR fluid is a magnetic particle suspension dispersed in a viscous non-magnetic carrier fluid. Rheological properties such as yield stress and shear viscosity of the MR fluid can reversibly and instantly be changed as a result of dispersed magnetic particles building up chain-like structure under a magnetic field due to magnetic dipole-dipole interaction between particles [4, 5]. However, both sedimentation of the CI particles due to the large density mismatch with the carrier liquid and difficulties in re-dispersion after caking in the pure magnetic CI based MR fluid systems have been regarded as serious disadvantages. The magnetic microspheres of CI and poly(methyl methacrylate) (PMMA) composite was prepared to reduce the density mismatch in this study. The microsphere was prepared via in-situ suspension polymerization using poly(vinyl alcohol) and triblock copolymer as stabilizer and co-stabilizer, respectively. As a result, a core-shell structure of the microsphere was obtained, and then MR characteristics of the CI embedded suspension polymerized PMMA microbeads were investigated.

Experimental

The microsphere was fabricated via suspension polymerization of styrene in the presence of CI. The CI was dispersed in aqueous solution in which both poly(vinyl alcohol) and PEG-PPG-PEG triblock copolymer were dissolved. Purified styrene monomer, in which benzoyl peroxide was dispersed as an initiator, was added into the CI suspension. The polymerization was held at 80 degree C for 12hr. The dried product particles were dispersed into mineral oil for the MR application. The fabricated microsphere was examined using both SEM and TEM. In addition, MR properties of the product particle based MR fluid were measured in a steady shear mode using a rotational rheometer. The density and MR properties of the product particle were compared with those of pristine CI particles.

Results and Discussion

SEM image given in Fig. 1 represents surface morphology and shape of the product microspheres showing a round shape with porous surfaces and 10micron of average particle diameter. The surface of microsphere was observed to be constituted by many grains of PMMA, and the density of the composite particles was lowered to be 3.27 g/cm³ compared to the density of pristine CI with 7.89 g/cm³. From the change of surface morphology and reduced density, it was determined that the magnetic microsphere of composite was successfully fabricated.

Volume concentration of the product particles was fixed at 25 v/v % for MR suspension. Both shear stress and shear viscosity responses under steady shear condition were investigated as a function of shear rate for different magnetic field strength ranging from 0 to 343 kA/m. Figure 2 shows that shear stress was found to increase with applied magnetic field strength, resulting yield behavior,

and suggesting that the product microsphere of CI and PMMA composite could be well applicable into the MR fluid.

Effect of Slit Patterning Perpendicular to Magnetic Easy Axis In Thin Film Inductors.

T. Masai^{1,2}, Y. Kitamoto²

1. TDK, Minami-alps city, Yamanashi pref., Japan; 2. Innovative and Engineered Materials, Tokyo Institute of Technology, 4259 Nagatsuta, Midori-ku, Yokohama, Japan

[1. Introduction]

The demand of utilizing magnetic thin films in power inductors and high frequency inductors(1) is increasing. In spiral inductors using magnetic films with uniaxial anisotropy, low permeability in easy axis direction in MHz range reduces inductance. In order to improve the characteristics of magnetic thin film inductors in MHz range, it is important to control domain-wall displacement and increase its resonant frequency in magnetic easy-axis direction. Thus, we fabricated magnetic wire arrays by slit patterning perpendicular to easy axis in magnetic thin films and discussed the influence of the wire width on magnetic characteristics.

[2. Experimental]

CoZrTa soft magnetic thin films were prepared using dc magnetron sputtering. Thickness of the magnetic films was 500 nm. Slit patterning was made by lithography and wet etching as shown in Fig. 1. The longitudinal direction of magnetic wires is perpendicular to easy axis in the magnetic films. The wire width (L) was 0.02, 0.05, 0.1, 0.2, 0.5, 1.0, 2.0, 5.0, and 6.0 mm. The gap length (S) between magnetic wires of all the samples was 0.02 mm. Permeability was measured using an impedance analyzer.

[3. Results and discussion]

Fig. 2 shows frequency dependence of real part of relative permeability in the directions parallel and perpendicular to the magnetic wires. The perpendicular direction to the magnetic wires corresponds to magnetic easy axis in the thin films.

The permeability in the perpendicular direction decreases in the low frequency range below 100 kHz, but the resonant frequency originated from domain-wall displacement (the first drop of the frequency dependence in the perpendicular direction as seen in Fig. 2) increases with the decrease of the wire width. On the other hand, the permeability is kept at around 1000 in the range below 100 MHz and the resonance related to domain-wall displacement is not observed in the parallel direction, suggesting that the magnetic behavior in the parallel direction is based on magnetization rotation in the magnetic hard axis.

In order to investigate effects of the slit patterning in practical devices, we fabricated inductors shown in Figs. 3 and 4. A spiral coil was fabricated on a substrate by Cu-electroplating, and the magnetic wire array sample was bonded onto it. The magnetic field induced by the coil penetrates the patterned magnetic film. Therefore, it is expected that the influences of the patterned magnetic films appear in frequency characteristics of their inductance. The dependence of the inductance at 1 MHz on the magnetic wire width L is shown in Fig. 5. The inductance takes the maximum at L=0.5 mm. This behavior is explained by the shift of the resonant frequency in the magnetic easy-axis direction.

[4. Conclusion]

We fabricated the magnetic wire arrays by slit patterning perpendicular to magnetic easy axis in magnetic thin films with uniaxial anisotropy. The resonant frequency was shifted to higher frequency range. Moreover, we fabricated inductors using patterned magnetic thin films. The inductance at 1 MHz was increased by the slit patterning, and took the maximum at the wire width of 0.5

mm. These results show that the slit patterning perpendicular to the magnetic easy axis is effective to improve characteristics of inductance in the easy axis.

Miniaturization of antenna using Y-type hexagonal ferrite.

K. Kawano, Y. Okamoto

Product Development HQ, TAIYO YUDEN CO.,LTD., Takasaki-shi, Japan

The demand for the miniaturization of antenna, which is used for the mobile telephone, has been increased along with the downsizing of the mobile. Especially for the digital broadcasting services such as DMB and DVB-H, the miniaturization is one of key issues because the antenna size is inversely proportional to the frequency, which was assigned from 170 MHz to 800 MHz for these services. These frequency ranges are relatively lower and it indicates that the antenna will need the larger size.

It is well known that the size of the antenna can be miniaturized by the effect of wavelength shortening using the material with the permittivity and/or permeability. Generally, the dielectric material is widely used for the antenna application. On the other hand the soft magnetic material has been not used because there is not suitable material having the enough performance in the required frequency range. However, there might be possibilities to apply the magnetic material for antenna of the digital broadcasting services because the operation frequency is lower than 1GHz.

In this study, the possibility of the Y-type hexagonal ferrite is investigated for the effect of the miniaturization of the antenna. Y-type hexagonal ferrite with the chemical composition of $\text{Ba}_2\text{Co}_2\text{Fe}_{12}\text{O}_{22+x}$ is fabricated by the conventional ceramic sintering method. XRD measurement shows that the fabricated sample has the single phase. Figure 1 shows the frequency dependences of both permittivity and permeability of the material. As we can see, the imaginary parts of both are relatively small up to 1GHz, indicating the small material losses. Figure.2 shows the inversed F antenna designed for this study. This antenna has the size with 30mm length, 5mm width and 1mm thickness and the pattern of silver is screen-printed on the ferrite substrate. Voltage Standing Wave Ratio (VSWR) is calculated by high frequency structure simulator (HFSS) and it is found that the resonance frequency is $\sim 1.085\text{GHz}$. Experimental result of VSWR is shown in figure.3 and the resonance frequency is $\sim 1.09\text{GHz}$, which is very similar to the simulation result. The resonance frequency is shifted to $\sim 0.84\text{GHz}$ when the upper side antenna is covered by other substrate of the ferrite. This result indicates that the wavelength shortening is going to be effective when the antenna pattern is covered by the magnetic material as much as possible, and the volume of the antenna can be reduced to $\sim 50\%$. The antenna gain at 1.09GHz is shown to be -2.7 dB , which might need to be improved.

Development of Axial Flux Permanent Synchronous Motor by using High-Density Magnetic Composites.

H. Nakai¹, T. Arakawa¹, K. Hiramoto¹, S. Tajima¹, Y. Inaguma²

1. Toyota Central R&D labs., INC., Aichi, Japan; 2. Daido Institute of Technology, Nagoya, Japan

1. Introduction

The electric motors of electrical hybrid vehicles require a high torque/volume ratio. We have paid an attention to an axial flux permanent magnet synchronous motor (AFSM) to be able to generate a high torque, compared with a radial flux permanent magnet synchronous motor. The flux in the stator of an AFSM is distributed in three dimensions. Therefore, the use of a powder magnetic core was attempted, namely a high-density soft magnetic composite (HDMC) with a low core loss and three dimension isotropy. The aim of this paper is to confirm the performance of the AFSM with an HDMC.

2. Structure of the motor

The structure of the AFSM is shown in Figure 1. Torque is generated in the gap between the rotor and the stator, and a torque increase becomes possible because this gap area can be expanded. Therefore, the AFSM having double gaps has the capability for increased torque. The development target of the motor was set to the max torque 100 Nm and highest rotational speed 8000 rpm.

The HDMC has bending strength and resistivity in the relation of contradiction [1]. Efficiency decreases because the eddy current increases due to the decrease in resistivity when the necessary strength is secured for a maximum torque. Then, the tooth and the yoke are designed to be a division structure in order to achieve both a low loss and the necessary strength (Table 1 and Figure 2). The tooth material was selected in order to ensure an adequate bending strength, while the yoke material was selected in order to minimize the core loss.

The rotor core is composed of rolled magnetic steel sheets. The surface of the core has alternating magnets and silent poles. The purpose of this structure is to generate a reluctance torque in addition to a magnet torque.

3. Performance verification by prototype

Figure 3 shows a photograph of the prototype. The current-torque characteristics of the prototype are shown in Figure 4. The results indicate that the prototype falls below the calculated value though the torque target value was almost satisfied. Because the loss grew as shown in Figure 5, it is assumed that the disadvantageous eddy current of the stator is larger than the predicted value. It is thought that this loss increase is due to the PWM.

4. Conclusion

This examination was able to confirm that an AFSM with an HDMC as a stator core can achieve a high torque/weight ratio.

Validation of Voltage and Current Waveforms of Nonlinear Inductors Computed with a Novel Finite Element Methodology.

R. Salas, J. Pleite

Tecnología Electronica, Universidad Carlos III de Madrid, Leganés, Spain

MnZn soft ferrite cores are widely used as inductors and transformers in power electronic converters with switching frequencies between 10 kHz to 1 MHz [1]. In the design and simulation of magnetic components a model for the nonlinear behavior of the magnetic material is required [2]. The nonlinear effects in cores are saturation, hysteresis, and eddy currents.

In two previous papers [3-4] we proposed a modeling procedure for magnetic components based on FEA techniques. In this paper we extend the analysis of Refs. [3-4] and explore the applicability of our method to an RM shaped-soft ferrite core inductor which is included in a DC/DC converter operating at 40 kHz and 100 kHz. To do so we present a theoretical-experimental comparison of the voltage and current versus time waveforms of the inductor. As in Refs. [3-4] we will assume that the core exhibits saturation.

Theoretical voltage and current waveforms of the inductor $v_{mod}(t)$, $i_{mod}(t)$ were obtained as follows [3-4].

First, we assigned the BH curve of the material to the modeled core to be tested to take into account the saturation effect. The BH curve was experimentally measured using a two-winding ferrite-core transformer (FERROXCUBE TN23/14/7 ring core, 3F3 material [5]). The number of primary and secondary turns was 60.

Next we computed the flux versus current i , $\Phi_{mod}(i)$, using the Maxwell field simulator's magnetostatic solver [6]. Then the inductance versus i , $L_{mod}(i)$, is computed by differentiating Φ_{mod} with respect to i . Finally, $L_{mod}(i)$ is introduced into a buck converter designed in the PSIM circuit simulator [7] to obtain $v_{mod}(t)$, $i_{mod}(t)$ by transient simulation.

To illustrate how our method works we have applied it to a buck converter at 40 kHz and 100 kHz containing a resistor $R = 3.1 \Omega$, two capacitors $C_f = C_b = 450 \mu F$, a mosfet transistor (IRF530A), a diode (BYW29F), and a 10-turn soft ferrite core inductor (FERROXCUBE RM14/I core, 3F3 material [5]).

To experimentally check the accuracy of our method we computed $\Phi_{mod}(i)$ and compared the results to measurements, $\Phi_{exp}(i)$, Fig. 1(a). The experimental inductance $L_{exp}(i)$ and $L_{mod}(i)$ are shown in Fig. 1(b). $L_{exp}(i)$ was computed by differentiating numerically Φ_{exp} with respect to i . Finally, we compared $v_{mod}(t)$, $i_{mod}(t)$ to experimental waveforms $v_{exp}(t)$, $i_{exp}(t)$, Figs. 2-3. Time dependence of the instantaneous power $v \times i$ computed both from $v_{mod}(t)$, $i_{mod}(t)$ and from $v_{exp}(t)$, $i_{exp}(t)$ are also shown, Figs. 2(c)-3(c). As V_{in} (DC input voltage) increases, $i_{mod}(t)$ takes a more curved shape, Figs. 2(b)-3(b). This curved shape would not exist in the case of a linear model. Agreement between our theory and the experimental results is seen to be quite good. More detailed experimental results will be reported in a more detailed paper.

Spin control by doping non-magnetic ions in magnetic ordering type of multiferroic materials.

K. Choi¹, S. Kim¹, B. Lee², C. Kim¹

1. Physics, Kookmin Univ., Seoul, South Korea; 2. Hankuk University of Foreign Studies, Yongin, South Korea

Introduction

Recently, numerous researches have been focused on the magnetic ordering type of multiferroic materials, RMn_2O_5 , orthorhombic RMnO_3 (R=rare earth), delafossite CuFeO_2 , spinel CoCr_2O_4 , MnWO_4 , and hexagonal ferrite $(\text{Ba,Sr})_2\text{Zn}_2\text{Fe}_{12}\text{O}_{22}$ [1]. These materials are reported showing 'frustration magnet' due to canted spiral magnetic spin. These phenomena bring about incommensurate spin behavior and ferroelectricity by spin current model. Especially, CoCr_2O_4 materials have been investigated for multiferroic property and dielectric anomalies have been explained by spin current model. But CoCr_2O_4 materials have very small polarization ($\sim 2 \mu\text{C}/\text{m}^2$) [2]. Here, we control spin behavior by substituted non-magnetic ions in CoCr_2O_4 .

The objective of the present research is to elucidate the role of the Cr ion in the multiferroic effect by replacing the Cr ion in the multiferroic material with a similar transition metal ion Fe. The similar ionic radii of Fe^{3+} and Cr^{3+} mean that lattice distortion effects of the substitution may be ignored, and the electronic structure can be studied.

Experiment and results

The spinel $\text{CoCr}_{1.98}\text{Fe}_{0.02}\text{O}_4$ (CCO), $\text{Co}_{0.9}\text{Zn}_{0.1}\text{Cr}_{1.98}\text{Fe}_{0.02}\text{O}_4$ (CZCO), $\text{CoCr}_{1.88}\text{Al}_{0.10}\text{Fe}_{0.02}\text{O}_4$ (CACO) powders were prepared by wet chemical solution process. Weighted amounts of cobalt acetate, zinc acetate, aluminum acetate, chrome nitrate, and ^{57}Fe isotope were dissolved in acetic acid, ethanol, nitric acid, and distilled water. For doping ^{57}Fe to facilitate Mössbauer measurement, iron isotope was dissolved in a diluted HNO_3 and then the proper amount of ^{57}Fe added into the solution. The solution was refluxed at 80 °C for 12 hours to allow the gel formation and then dried at 120 °C in a dry oven for 24 hours. The dried powder was grounded and annealed at 1000 °C for 3 hours in air. The crystal structures of the samples were examined by x-ray diffraction with Cu K α radiation ($\lambda = 1.5406 \text{ \AA}$). Magnetic properties were characterized by the vibrating sample magnetometer (VSM). The Mössbauer spectra were recorded using a conventional spectrometer a electromechanical with a ^{57}Co source in a rhodium matrix.

The crystal structure was found to be single-phase cubic spinel with space group of $Fd3m$. The lattice constants a_0 were determined to be CCO = 8.340, CZCO = 8.328, and CACO = 8.305 Å, respectively. These results are due to that Co^{2+} (0.72 Å) and Zn^{2+} (0.74 Å) have the similar ionic radius and they occupies A (tetrahedral) sites and Cr^{3+} (0.63 Å) and Al^{3+} (0.51 Å) have the different ionic radius and they occupies B (octahedral) sites. The Bragg factor RB and RF were below 5 %, respectively.

The zero field cooled (ZFC) magnetization curves taken at 100 Oe for various temperatures are shown in Fig. 1. The ferrimagnetic transition were observed at around 90 ~ 97 K, which was determined as Néel temperature. ZFC curves showed an abnormal magnetic transition (T_S) at 28 K (CCO), 18 K (CZCO), 20K (CACO), which are associated with spiral magnetic order in the systems. With Al ions substituted in B site, the magnetic transition temperature decreases, but the magnetization increase. Mössbauer spectra of CACO were taken at various temperatures ranging from 4.2 to 93 K as shown in Fig. 2. Two magnetic phases were developed and showed two sharp sextets of spectra below T_S . The isomer shifts at all temperatures range are about 0.3 mm/s relative to Fe metal, which means that both Fe ions are Fe^{3+} states. The electric quadrupole splittings (ΔE_Q) were

found to be nearly zero values below T_N . The magnetic hyperfine fields of outer and inner sub-spectrum were $H_{\text{hf}} = 480$ and 462 kOe, respectively. These effects can be explained by Al substitute specification B site. These results bring forth the decreasing Néel and spin-reorientation temperature and increasing magnetic moments.

Dielectric and magnetic properties of low-temperature sintered Ni_{0.24}Cu_{0.21}Zn_{0.55}Fe_{1.96}O₄+xPb_{0.95}Sr_{0.05}(Zr_{0.52}Ti_{0.48})O₃ composites.

L. Jia, H. Zhang, S. Bao, Z. Zhong
university of electronic science and technology of China, chengdu, China

Introduction

Recently the magnetoelectric materials prepared by combining together the ferroelectric and ferromagnetic materials in which the coupling interaction between two phases could produce interesting effect and provide opportunities for potential applications, such as compact electrical filters for suppressing electromagnetic interference (EMI) and magnetic electric sensors have dawn significant interest due to their multifunctionality [1-2]. In the present work, Pb_{0.95}Sr_{0.05}(Zr_{0.52}Ti_{0.48})O₃ (PZTS) was chosen as a ferroelectric phase because of its superior ferroelectric characteristics and Ni_{0.24}Cu_{0.21}Zn_{0.55}Fe₂O₄ was chosen as a ferromagnetic phase because of its high permeability at low sintering temperature. A series of the new co-fired composites which process both inductive and capacitive properties were synthesized. The relationships between the microstructure evolution and electromagnetic properties of the composite materials with various amounts of PZTS were presented.

Experimental detail

The composites with composition of Ni_{0.24}Cu_{0.21}Zn_{0.55}Fe_{1.96}O₄+xPb_{0.95}Sr_{0.05}(Zr_{0.52}Ti_{0.48})O₃ (where x=0-25 wt%) were prepared by a standard solid-state reaction method. The highly active Pb_{0.95}Sr_{0.05}(Zr_{0.52}Ti_{0.48})O₃ (PZTS) powders with average grain size of about 150 nm were synthesized by a self-propagating method [2]. The raw materials, NiO, α -Fe₂O₃, ZnO and CuO, of high purity, were mixed and milled. The mixed powders were calcined at 850 °C for 2 h in the air. Then the powders were mixed with ultrafine PZTS powders and a small amount of flux, and milled, dried and pressed. The pressed disc-shaped pellets and toroidal samples were sintered at 900 °C for 3 h in the air and then cooled in the furnace. The phase composition of the samples was identified by a means of X-ray diffraction using CuK α radiation. A scanning electron microscopy was used to observe the microstructures of the samples. The complex permeability and the complex permittivity of the samples were measured by an HP4291B impedance/materials analyzer in the frequency range of 1 MHz-1.8 GHz. Saturation flux density (Bs) and coercive force (Hcb) values were measured by an IWATSU SY-8232 B-H analyzer. The bulk density was determined by the Archimedes method.

Results and Discussion

The peaks in the XRD patterns are identified to be characteristics of both spinel phase and perovskite phase in all samples with PZTS. It was confirmed that there is no visible chemical reaction between two phases. The main results are shown in Table 1. In the undoped PZTS sample, abnormal grain growth was observed clearly. On the contrary, all samples with PZTS have compact microstructures without huge grains, the grain size decreases with the increasing x.

The variation of complex permittivity of the composites with frequency confirmed that when x varied from 0 to 25 wt%, the dielectric constant at 1MHz increased from 11 to 31, the ferroelectric resonance peaks shifted toward a low frequency, and the dielectric loss was improved. The increase of dielectric constant is mainly attributed to the introduction of PZTS, which raises the amount of dipoles in the composite materials. As a result, the increase of dipoles leads to the increase of local displacements (dielectric polarization) in the direction of external applied electric field for electrons, and the increased polarization causes a significant enhancement of the dielectric constant. The variation of complex permeability with frequency showed that the initial permeability

decreased with PZTS content. As the PZTS content increased from 0 to 25 wt%, the μ_i decreased from 218 to 70, while the imaginary part of permeability decreased from 3.7 to 0.3. The resonance frequency (f_r) shifted toward a high frequency with the increase of PZTS content. It is probably the main reason attributed to the decrease of magnetic moment per unit volume. In addition, the presence of weak magnetic PZTS in the composites pins the domain wall motion, which lead to a decrease of initial permeability. And the addition of perovskite component observably inhibits the grain growth, so, and thus causes a decrease of domain wall contribution, which is mainly determined by grain size. From Snoek's formula, the natural resonance frequency shifts toward higher frequency with the decrease of initial permeability. From Table 1 we can also see that, as the PZTS content increases, the Q-factor increase markedly. Combining the previous microstructure analysis, we conclude that mainly be caused by the increase of dispersive air gaps [3] and the decrease of eddy current loss, which is accompanied by the addition of PZTS. According the measured data, it can be concluded that the composites have excellent performance in wide frequency rang and can be used for embedded inductors either embedded capacitors.

Processing related magneto-dielectric properties of Ni-Zn-Co ferrite ceramics.

L. Kong, Z. Li, G. Lin

Temasek Laboratories, National University of Singapore, Singapore, Singapore

1. Introduction

It is well known that reduction of antenna size has always been a challenge to the designer, especially for HF (2-30 MHz) and VHF (30-300 MHz) bands where conventional antennas have rather large physical sizes. For practical reasons, the physical dimensions of an antenna should be compatible with the radiation performance, which requires materials for antenna applications to have specific magneto-dielectric properties. These properties include high refractive index and impedance-matched to free space, together with low dielectric and magnetic loss tangents. However, such materials are rarely found in nature [1, 2]. Hence, exploration of this class of materials is of scientific and technological significance.

In this paper, we present our recent study on the effect of processing on the magneto-dielectric properties of Ni-Zn-Co ceramics ($\text{Ni}_{0.88}\text{Zn}_{0.07}\text{Co}_{0.05}\text{Fe}_{1.90}\text{Mn}_{0.02}\text{O}_4$). Three methods, one-step sintering, one-step sintering with high-energy ball milling and two-step sintering, were used to prepare the ferrite ceramics. The ceramics were characterized in terms of phase composition, grain growth, microstructure development, DC resistivity, relative complex permeability and relative complex permittivity over 1 MHz - 1 GHz.

2. Phase formation and densification

For one-step processing, it is found that the ferrite phase formation seemingly started at 600°C. However, reaction is not complete after calcining at 900°C. The large temperature span for ferrite phase formation is attributed to the nonhomogeneity of the mixture. In contrast, the reactivity of the mixture is greatly enhanced as a result of the high-energy ball milling. Ferrite phase formation also started at 600°C, but ferrite is already the main phase at this temperature and single phase ferrite is obtained at 700°C. It means that the high-energy ball milled powder requires a phase formation temperature at least 200°C lower than that required by the one-step sample. The enhanced reactivity of the high-energy milled powder is due to the refinement of the oxide grains/particles.

The mixture milled by high-energy ball milling also had a better densification behavior, by showing that the samples derived from the milled powder possessed higher measured densities than those prepared by other two methods. The samples prepared via two-step processing were of the highest porosity.

3. Dielectric and magnetic properties

The samples derived from the high-energy ball milled powders had better dielectric properties than other samples, in terms of dielectric loss tangent. The better dielectric properties of the samples can be attributed to their higher densities, because lower porosity is a key to achieving low dielectric loss tangent.

Similarly, the high-energy ball milling processing led to samples having higher static permeability. The magnetic properties of the ferrite ceramics, as a function of sintering temperature, can be described by the magnetic circuit model.

Several samples prepared by different means have been found to possess promising magneto-dielectric properties (matching permeability and permittivity and low loss tangent) over 30-90 MHz, as shown in the figure attached, which might be potentially useful for miniaturization of VHF antennas.

Dielectric properties of the charge-ordered oxyborate Fe_2OBO_3

M. Sanchez-Andujar², J. Mira¹, B. Rivas-Murias², S. Yanez-Vilar², N. Biskup³, J. Rivas¹, M. Senaris-Rodriguez²

1. *Fisica Aplicada, Universidade de Santiago de Compostela, Santiago de Compostela, Spain*; 2. *Química Fundamental, Universidade da Coruña, A Coruña, Spain*; 3. *ICMM, Consejo Superior de Investigaciones Científicas, Madrid, Spain*

Isostructural A_2OBO_3 ($\text{A} = \text{Mn}, \text{Fe}$) compounds display, within the same structure, charge, magnetic and orbital ordering at different orbitals. As for the charge order in these mixed-valence materials ($\text{A}^{2+}/\text{A}^{3+}$), the origins of this phenomenon are different when comparing both compounds: whereas Mn_2OBO_3 shows it through Jahn-Teller distortions [1] (i.e., electron-lattice interactions) the mechanism in Fe_2OBO_3 is of electrostatic origin [2] (electrostatic repulsions between charges). This has allowed attributing the differences to the role of t_{2g} vs. e_g interactions in both compounds [3]: Fe^{3+} and Mn^{2+} present the same electronic configuration but there is an extra t_{2g} electron in Fe^{2+} and an extra hole in the e_g orbital of Mn^{3+} .

Recently Angst et al. [4] have completed the picture of Fe_2OBO_3 by finding integer valence states of the Fe ions in the charge-ordered phase, awarding this compound the honor of being the clearest example of ionic charge order so far.

Concerning the search of new dielectric materials, there has been a recent surge of interest in exploring alternative strategies beyond the typical structural approach. Among them we have been focusing on materials that display condensation of electronic charges [5]. It is therefore obvious that, within this approach, Fe_2OBO_3 becomes highly appealing.

For this purpose we have synthesized this material in polycrystalline form by a ceramic method [3] and we have measured the dielectric permittivity of the raw sample. The values of dielectric permittivity are very high, suggesting the presence of Maxwell-Wagner effects. In fact, the data are fitted to a Maxwell-Wagner expression.

In order to understand the dielectric behavior of this compound an impedance spectroscopy analysis was carried out. Via this method it is possible to estimate whether the dielectric response corresponds to the material bulk response or not. Different regimes are found depending on the temperature: for $T < 200$ K the values are associated to the material bulk response, in the range $200 \text{ K} < T < 300$ K there is a mixed regime and for $T > 300$ K the response cannot be associated to the response of the bulk material, i.e., it is of extrinsic nature.

The presence of such extrinsic effects is masking the intrinsic dielectric response of the material. In order to observe it, the sample was sandwiched between mica layers in order to eliminate the contributions of free charge carriers and the formation of Schottky barriers at the contact-sample interface.

When measuring the sample prepared in this way (results shown in the figure) it is observed a plateau in the dielectric permittivity above 150 K, at a value around 45 (with a slight increase at higher temperatures, see inset).

The charge order is observed in this oxyborate below 320 K, but the order is of short range. At around 150 K this charge order becomes long-range with a clear consequence on the dielectric behavior. In this context, it is worth mentioning that this step observed at around 150 K in the dielectric response versus temperature is also coincident with the onset of antiferromagnetic ordering, pointing to a coupling of dielectric and magnetic properties.

Magneto-electric Effects in Single Crystal Hexaferrite-Piezoelectric Bilayers.

V. Mathe, G. Srinivasan

Physics, Oakland University, Rochester, MI

Abstract: Ferrite-piezoelectric heterostructures show strong magneto-electric (ME) interactions that are mediated by mechanical forces [1]. The first measurements of low-frequency ME effects have been reported for bilayers of single crystal hexagonal M, Y, and Z-type ferrites and lead zirconate titanate (PZT). Studies were performed on bilayers of Ba-Al-M, Sr-Al-M, Zn_2Y , or Co_2Z and PZT. Bilayers with M-ferrites show the weakest ME coupling and the strongest coupling is measured for samples with Y-type ferrites. In M-type ferrites, ME voltage coefficients increase with increasing Al-substitution. Theoretical estimates of ME coefficients are in good agreement with data.

Introduction: Ferrite-piezoelectric layered structures exhibit an ME effect that is related to the interaction between magnetic and electric subsystems mediated by elastic deformations [2]. When a bilayer is subjected to a bias field H and ac magnetic field dH , magnetostriction induced mechanical strain is transferred to PZT and manifests as an ac voltage dV due to piezoelectric effects. The strength of ME effect is defined as the voltage coefficient $\alpha_E = dV/dH$, where t is the thickness of PZT in the bilayer. Studies in the past reveal a giant low-frequency ME effect in bilayers with ferrite, terfenol-D or shape memory alloys and PZT or PMN-PT [3]. But the ac ME effects would vanish when the magnetostriction saturates. Since hexaferrites have high, non-saturating magnetostriction at high bias fields, one can accomplish strong high-field ME effects. Here we present the data and theoretical estimates of ME coupling in hexagonal ferrites and PZT.

Results: Bilayers were made with Al-substituted M-type, $\text{Ba}(\text{Sr})\text{Fe}_{12-x}\text{Al}_x\text{O}_{19}$ ($x = 0-2.0$), Zn_2Y , and Co_2Z . The ferrite was bonded with a thin layer of epoxy to a 1 cm dia, 0.5 mm thick PZT disc that was poled in an electric field of 30 kV/cm. The magnetostriction was measured with a strain gage. Data on H dependence of α_E was obtained by measuring dV across PZT in an ac field dH at 100 Hz. The measurements were made for two field orientations, transverse (T) when H and dH were parallel to each other and to the sample plane and longitudinal (L) for the fields perpendicular to the sample plane.

Figure 1 shows data for bilayers of Sr-Al-M and PZT. For the M-type, the longitudinal ME coefficient is quite small, on the order of 1 mV/cm Oe, whereas the transverse coefficient is quite high, as seen in Fig.1. The coefficient $\alpha_E(T)$ shows a gradual increase with increasing H and tracks the variation in magnetostriction with H . When Al is substituted, there is an increase in $\alpha_E(T)$ with x up to 0.8. Further increase in x results in weakening of the strength of ME coupling. Samples of Ba-Al-M showed weaker ME coupling than for Sr-Al-M.

Figure 2 shows the H -dependence of $\alpha_E(T)$ for bilayers of Zn_2Y -PZT and Co_2Z -PZT. Both hexaferrites have easy plane anisotropy, and $\alpha_E(T)$ is much higher than for $\alpha_E(L)$, similar to the case for M-type ferrites. The data in Fig.2 indicates the strongest ME coupling for the bilayer with Y-type ferrite. The ME coefficient increases with H up to a bias field of 10 kOe, a value close to the in-plane anisotropy field, and then decreases for higher H .

Theoretical estimates of $\alpha_E(T)$ using our model in Ref.2 are in good agreement with the data in Figs. 1 and 2.

After the high temperature superconductivity, the revival of giant magnetoresistance and more recently the magnetoelectric phenomenon have further fuelled the interest in rare-earth oxides. In the hexagonal family of the RMnO₃ oxides [1] long range magnetic and polar orders could coexist. The magnetic order of the Mn moments is determined by antiferromagnetic in-plane Mn-O-Mn superexchange, which is much stronger than the interplane Mn-O-O-Mn exchange. As a result, at T_N, Mn orders in a typical for frustrated antiferromagnets 120° arrangement within the *ab* basal plane. The R-ions magnetic moments eventually order at much lower temperatures, however they could influence the magnetic structure at higher temperatures. In order to approach the mechanisms behind the intriguing properties of this highly anisotropic compounds and employ them in possible applications, studies on single crystals are required.

Here we report the anisotropic magnetic response of YbMnO₃ single crystal. We will limit our discussions to the high temperature region, where the Yb moments are in paramagnetic state. YbMnO₃ platelet-like single crystals have been grown by flux method as described elsewhere [2].

The low dc-field cooled, FC, and zero field cooled, ZFC, susceptibility in a field applied along the *c*-axis is given (at an expanded scale) on Fig 1. It clearly shows a peculiarity at T_N ≈ 81 K, which signals the onset of long range order between Mn moments. An important feature of this transition is the difference between FC and ZFC susceptibility measured at low magnetic field, which sets right below T_N. The temperature at which the two susceptibilities split decreases with increasing the applied field and the difference between the two susceptibilities diminishes at high enough fields. Such behaviour is not a characteristic of an ideal antiferromagnetic structure, for which the Mn moments are supposed to compensate below T_N, but signals the existence of net magnetic moment and coercivity. Unlike the *c*-axis case, no any peculiarity at T_N is observed on the susceptibility measured with a field applied within the basal *ab*-plane and the FC and ZFC susceptibilities coincide for all temperatures down to 2 K. The above observations are in agreement with the measured ac-susceptibility response. As seen from Fig.3, both the real and the imaginary components of ac-susceptibility along the *c*-axis exhibit frequency dependent maxima just below T_N (unambiguously identified by the onset of magnetic losses). No peculiarity at T_N is observed on the ac-susceptibility measured with field applied within the basal *ab*-plane. This behaviour is reminiscent to the one observed for LnMnO₃ single crystal, which exhibits weak ferromagnetism attributed to canting of the antiferromagnetic moments due to antisymmetric Dzyaloshinskii-Moria interaction [3]. From the value of magnetic moment measured along the *c*-axis at 8 K and assuming that this moment results from canting of Mn³⁺ moments, one could estimate a canting angle of about 0.35° from the *ab*-plane.

The inverse susceptibility (Fig.2) along the hexagonal *c*-axis obeys Curie-Weiss law at temperatures above 150 K. When the field is applied within the basal *ab*-plane it deviates from the linear dependence until temperatures as high as 350 K. From the Curie constant C_g = 2.1 × 10⁻² K.emu/g an effective paramagnetic moment μ_{eff} = 6.8 μ_B is estimated in a good agreement with the theoretical value of μ_{eff} = 6.7 μ_B calculated from the Yb³⁺ free-ion and the spin-only value for the Mn ion. Linear fit of the data along the *c*-axis gives paramagnetic Curie temperature θ_c = - 170 K, while the high tem-

perature approximation of *ab*-plane susceptibility yields θ_{ab} = - 257 K. The strongly anisotropic value of θ is in contrast to negligibly small difference in the susceptibility along different crystallographic directions measured in RMnO₃ with non-magnetic R (as it has been demonstrated for YMnO₃ [4] as well as revealed by our unpublished data on LuMnO₃). This points to the decisive role, which the R ion plays in determining magnetic anisotropy and also warns that the widely used T_N/|θ| criterion as a measure for the degree of frustrations should be applied with precautions for such highly anisotropic systems.

The existence of uncompensated components of magnetization leading to weak ferromagnetism, eventually coupled to polar order, may have important consequences for occurrence of magnetoelectric response and hence for applications.

Pressure effect on the magnetic ordering in BiMnO₃

C. Chou^{1,2}, C. Lin^{1,2}, S. Taran^{1,2}, C. Huang^{1,2}, J. Her^{1,2}, C. Sun^{1,2}, C. Chan^{1,2}, H. Sakurai³, E. Takayama-Muromachi³, H. Yang^{1,2}

Pressure-effect on the ac susceptibility($\chi(T)_p$) has been performed for the polycrystalline BiMnO₃. The multiferroic materials that combine ferroelectric and ferromagnetic(FM) ordering are of fundamental and technological interest as coupling between different order parameters such as pressure, electric, and magnetic fields[1-4], enables several ways to interact with these materials. One of the well known multiferroic material, BiMnO₃, has two structural phase transitions. At ~770 K, the Pbnm orthorhombic structure is turned to the C2 monoclinic, but, at ~450 K, where it shows ferroelectricity, the structure is changed from monoclinic(1) to monoclinic(2)[2,3]. It is also a FM insulator with the FM Curie temperature, T_C , at 99~105 K[2-4]. In general, the long range ferromagnetism, such as in La_{1-x}Ca_xMnO₃ manganites is due to the double exchange interaction(DE), is associated with metallicity. However the magnetism of the BiMnO₃ having insulating state is rather unusual. As one knows that pressure can control the overlap between the cation and anion orbital, thus it will be interesting to study the effect of pressure on the FM phase of BiMnO₃.

<p>

In order to check the quality of our sample, ac susceptibility($\chi(T)$) and magnetization(M(T)) have been measured. The $\chi(T)$ in three different frequencies shows maximum χ' at $T_{max} = 98$ K, indicating the FM Curie temperature[4]. The field-cooled dc M(T) (H = 100 Oe, Fig. 1) shows the FM ordering at around same temperature, and the result agrees with recently published papers on this system[2-4]. It is interesting to see that with increasing magnetic field the FM ordering temperature shifts towards higher temperature (see the Fig. 1).

<p>

The M-H hysteresis loop of BiMnO₃ taken at $T < T_C$ shows weak ferromagnetism indicated by small coercive field[2-4]. Because BiMnO₃ is an insulator, RKKY and DE are not suitable to explain its FM ordering. Recently, several publications[3,5,6] have pointed out that the superexchange interaction is applicable to elucidate the FM-insulating behavior in BiMnO₃. Earlier in a similar system LaMnO₃, having superexchange interaction, the pressure effect has been found to show some interesting properties[7]. It is a hint that pressure effect on the magnetic ordering of present system would be interesting.

<p>

Figure 2 shows the $\chi(T)_p$ of BiMnO₃ under several external pressures ranging from 0 to 15 kbar. Under no pressure the curve shows one hump at around T_{C1} . With increasing pressure up to 11.3 kbar, the position of T_{C1} goes on decreasing. It is interesting to note that beyond this pressure, an additional hump appears at lower temperature (defined by T_{C2}). This hump becomes more obvious and shift toward lower temperature as the pressure is increased, following with a simultaneous suppression of the original T_{C1} peak (see inset of Fig. 2). Above 14 kbar, T_{C1} peak disappears. Since the structure is unchanged below 450 K and undistorted under pressure (even at 27 GPa)[1-3], the magnetic behavior may not be associated with structure. The possible reason for the appearance of the additional peak and the suppression of T_C under pressure may be due to the competition of two different exchange processes which can be tuned by the external pressure. Along this line, detailed

neutron diffraction under high pressure is in planning and will be much helpful to solve the magnetic structure.

Magnetic properties of Ga substituted $\text{NiCr}_{1.9-x}\text{Ga}_x\text{Fe}_{0.1}\text{O}_4$

G. Ahn¹, S. Park¹, S. Park², C. Kim²

1. HANARO Utilization Technology Development Center, Korea Atomic Energy Research Institute(KAERI), Daejeon, South Korea; 2. Dept. of Physics, Kookmin University, Seoul, South Korea

I. INTRODUCTION

The ferrimagnet chromites (ACr_2O_4 ; $A=\text{Co}, \text{Zn}, \text{Ni}$, etc) are cubic normal spinel, in which A ions occupy the tetrahedral sites and Cr ions occupy the octahedral sites. Recently, many researchers have been interested in the properties of chromite material with multiferroic effects[1,2]. The $\text{NiCr}_{2-x}\text{Fe}_x\text{O}_4$ system, there is a cubic to tetragonal ($c/a < 1$) transition for the Fe concentration $x \leq 0.2$ under room temperature.

In this work, we have studied the $\text{NiCr}_{1.9}\text{Fe}_{0.1}\text{O}_4$ with Ga doping, and evaluated the impact on magnetic properties by x-ray diffraction, neutron powder diffraction, magnetization, and Mössbauer spectroscopy measurements.

II. EXPERIMENT

Polycrystalline samples of the $\text{NiCr}_{1.9-x}\text{Ga}_x\text{Fe}_{0.1}\text{O}_4$ ($x=0.0, 0.45, 0.95$) were prepared with the solid state reaction method. The ultimate single phase samples were obtained by annealing for 12 h in atmosphere at 1200 °C. The crystalline structure was analyzed using a Philips x-ray diffractometer with $\text{Cu K}\alpha$ radiation and neutron diffraction at Korea Atomic Energy Research Institute Reactor HANARO HRPD (High Resolution Powder Diffractometer, $\lambda = 1.8348 \text{ \AA}$). The temperature dependence of magnetization curves were also obtained with a vibrating sample magnetometer (VSM). The hyperfine magnetic property of samples was measured by using Mössbauer spectroscopy.

III. RESULT AND DISCUSSION

The crystalline structure of $\text{NiCr}_{1.9-x}\text{Ga}_x\text{Fe}_{0.1}\text{O}_4$ ($x=0.0, 0.45, 0.95$) were found to be a cubic spinel with space group of $Fd-3m$ at room temperature. Figure 1 shows some of the neutron diffraction patterns for $\text{NiCr}_{1.45}\text{Ga}_{0.45}\text{Fe}_{0.1}\text{O}_4$ at various temperature ranges. The neutron diffraction patterns for $\text{NiCr}_{1.45}\text{Ga}_{0.45}\text{Fe}_{0.1}\text{O}_4$ above 4 K showed that the magnetic peaks were overlapping on the nucleus peaks. The magnetic peaks decreases when temperature increases and it disappears at Néel temperature.

The temperature dependence of zero field cooled (ZFC) curves for the $\text{NiCr}_{1.9-x}\text{Ga}_x\text{Fe}_{0.1}\text{O}_4$ ($x=0.0, 0.45, 0.95$) were taken under low external field of 100 Oe. The ferromagnetic transition of $\text{NiCr}_{1.9-x}\text{Ga}_x\text{Fe}_{0.1}\text{O}_4$ ($x=0.0, 0.45, 0.95$) were observed at 150 K, 125 K, and 90 K, respectively.

Figure 2 shows the Mössbauer spectra of $\text{NiCr}_{1.9-x}\text{Ga}_x\text{Fe}_{0.1}\text{O}_4$ ($x=0.45, 0.95$) at 4.2 K. Mössbauer spectra of the Ga substituted $\text{NiCr}_{1.9-x}\text{Ga}_x\text{Fe}_{0.1}\text{O}_4$ ($x=0.45, 0.95$) were measured at various temperatures ranging from 4.2 to 295 K. The Mössbauer spectrum of $\text{NiCr}_{1.45}\text{Ga}_{0.45}\text{Fe}_{0.1}\text{O}_4$ indicates that there are two magnetic phases, which are due to the two different sites of the Cr^{3+} state.[1] However, in case of the Mössbauer spectrum of $\text{NiCr}_{0.95}\text{Ga}_{0.95}\text{Fe}_{0.1}\text{O}_4$ indicates that there are three magnetic phases. As well-known, NiGa_2O_4 has an inverse spinel structure at room temperature. Therefore, the increasing of the Ga substitution, Ga ions enter into both octahedral (B) and tetrahedral (A) sites; simultaneously the same amounts ratio of Fe ions occupied to the B and the A sites.

Synthesis and magneocaloric effect of functional perovskites by sol-gel reaction.

K. Jeongju¹, A. Yangkyu¹, C. Eun Jung²

1. Chemistry, Konyang University, Nonsan, Chungnam, South Korea; 2. Ophthalmic Optic, Konyang University, Nonsan, Chungnam, South Korea

In recent years, interest in research on the magnetic refrigeration technology has been considerably enhanced because of its potential impact on energy savings and environmental concerns [1]. Magnetic refrigeration utilizes the magnetocaloric effect (MCE), which is the characteristic of magnetic materials to heat up when magnetized and cool down when demagnetized [2].

Perovskite-type lanthanum manganese oxides have been of considerable interest in the last decade due to their colossal magnetoresistivity effect (CMR). From the view point of application in the magnetic refrigeration, a material that exhibits a flat MCE versus magnetic field H response over the desired operation temperature range is needed [3]. Perovskite-type lanthanum manganese oxides are usually prepared by conventional solid state reaction method that needs temperature (1273–1873K) and longer annealing time to obtain homogeneous composition and desire structures [4].

In this paper, we present the study of magnetic entropy change in $\text{La}_{0.75}\text{Ba}_{0.10}\text{Sr}_{0.15}\text{MnO}_3$ for magnetic refrigeration around room temperature by sol-gel reaction.

Fig. 1 shows the X-ray diffraction pattern of the perovskite compound obtained by sol-gel reaction. The results are consistent with the data of perovskite crystal structure. The perovskite particles show spherical shapes and have the average diameter of about 1micrometer as shown in Fig. 2. Fig. 3 shows the low-field magnetization as a function of temperature in zero-field-cooled (ZFC) process for the samples calcinated at 1273 K for 12h. The Curie temperature T_c is 342K, which is determined by a minimum of dM/dT curves shown in Fig. 3. Fig. 4 shows the isothermal magnetization curves of perovskite particles.

The magnetic entropy change can be calculated from the magnetic field variation using the following equation:

$$\Delta S_M(T)_{\Delta H} = \int_{H_i}^{H_f} \left\{ \partial M(T, H) / \partial T \right\}_H dH \quad (1)$$

Eq. (1) can be rewritten as following:

$$\Delta S_M(T)_{\Delta H} = \delta H / 2 \delta T \{ \delta M_1 + 2^{n-1} \sum_{k=2}^n \delta M_k + \delta M_n \} \quad (2)$$

From magnetization isotherms we calculated the change in entropy near the ordering temperature using Eq. (2). The results are shown in Fig. 5. Under a magnetic field of 1 T, the maximum entropy change is 0.41 J/kgK at $T_c = 342$ K.

This feature suggests that it could be a suitable candidate as working substance in magnetic refrigeration technology near room temperature.

Introduction

The study of the magnetoelectric (ME) effect, namely, the induction of electric polarization (magnetization) by applying magnetic (electric) fields, has attracted perpetual interest for more than four decades because of its potential for advanced ME devices [1]. However, the ME effect studied to date has been too small at low magnetic fields and/or the working temperatures are too low for practical device applications. One of the most important requirements for ME material used in practical applications is a magnetic insulator having a high magnetic ordering temperature. In this sense, ferrites, which are magnetic oxides containing iron as the major metallic component, are prominent candidates [2]. These materials combine room temperature ferromagnetic and insulating properties and have long been used in technological applications such as magnetic recording and high-frequency devices. Recently, hexagonal barium ferrites of the composition $\text{Ba}_{0.5}\text{Sr}_{1.5}\text{Zn}_2\text{Fe}_{12}\text{O}_{22}$ (Zn-Y) were found to possess a strong electric polarization and magnetization which is also an insulator in the zero-field ground state [3]. In this paper we report the growth and characterization of Zn-Y single crystals for their magnetoelectric studies.

Experimental

Single crystals of the composition $\text{Ba}_{0.5}\text{Sr}_{1.5}\text{Zn}_2\text{Fe}_{12}\text{O}_{22}$ were grown in platinum crucible using a high temperature furnace. The primary mixtures of BaCO_3 , SrCO_3 , ZnO , Fe_2O_3 , and Na_2CO_3 in the required mol ratios was blended and thoroughly ground together in a pestle for 1 hour. The finely blended powder is filled in a platinum crucible with approximately three-fourths of the volume. The platinum crucible is then placed in a top-lift enclosed furnace and fired at the temperature of 1450 °C for 12 hours to homogenize the melt. After completely homogenizing the melt for 12 hours, it is slowly cooled at the rate of 2.5 °C/hr to 1000 °C, and then cooled more rapidly in the furnace to room temperature. The, thus obtained, crystals were slowly separated by leaching in hot dilute nitric acid from the platinum crucible.

Results and Discussion

The obtained crystals exhibited the typical hexagonal ferrite growth habit with a plate like geometry. Figure 1 (a) shows the hysteresis loop measured in the perpendicular and in-plane directions of the Zn-Y single crystal. The saturation magnetization was measured to be 21.9 emu/g and the uniaxial anisotropy of 10 kOe respectively. Figure 1 (b) shows the x-ray diffraction spectrum of the Zn-Y single crystal. The x-ray diffraction pattern confirms that the structure is an extended single crystalline array of Zn-Y with in-plane crystallographic orientation. The microwave properties of the single crystal will be presented.

Conclusions

$\text{Ba}_{0.5}\text{Sr}_{1.5}\text{Zn}_2\text{Fe}_{12}\text{O}_{22}$ single crystals have been successfully grown from melts using a flux system of BaCO_3 - SrCO_3 - Na_2CO_3 . The obtained crystals exhibited the typical hexagonal ferrite growth habit with a plate like geometry and are of 2-3 mm in thickness. Saturation magnetization, anisotropy field, and coercivity values are close to the bulk values. The control of electric polarization by using magnetic fields in these ferrites will be presented.

Increment of saturation magnetization and reduction of electric coercive field in multiferroic Bi ferrite films by adding cobalt.

H. Naganuma, J. Miura, S. Okamura

Department of Applied Physics, Tokyo University of Science, Tokyo, Japan

Multiferroic BiFeO₃ materials have attracted much interest as ferroelectric materials because first-principle calculation predicted that the BiFeO₃ films possess the extremely large spontaneous polarization of 100 C/cm². In fact, in experiments, high remanent polarizations of 50 - 150 C/cm² were reported. However, the electric coercive field as well as the leakage current density of these films was quite large. Therefore, the dielectric breakdown of BiFeO₃ films occurred at below the electric field of domain switching. One of the candidate ways to improve the high electric coercive field (domain switching field) as well as high leakage current density is adding the additives. Actually, both the electric coercive field and the leakage current density of BiFeO₃ films were reduced by adding La. On the other hands, BiFeO₃ showed small spontaneous magnetization due to its antiferromagnetic spin configuration, which hinders the multiferroic property of BiFeO₃. In present study, we suggest that a local ferrimagnetic spin configuration can expect to form by substituting the iron atoms at the *B*-sites with other 3*d* transition atoms because of the differences in magnetic moment between the *B*-sites. Indeed, the magnetic moment increased by adding a manganese atom to bulk BiFeO₃.¹⁾ Additives can anticipate reducing electric coercive field as well as leakage current density, and enhancing magnetic moment.

Figure 1 shows the x-ray diffraction patterns for the 5 at.% Co-added BiFeO₃ film and pure BiFeO₃ film. Both films showed many diffraction peaks due to BiFeO₃ structure, and no other secondary phases could be observed.

Figure 2 show the ferroelectric hysteresis loops measured at room temperature (a), (b) and 90 K (c), (d). At room temperature, the expanded ferroelectric hysteresis loop was observed for the pure BiFeO₃ film. By contrast, ferroelectric hysteresis loop with relatively high squareness was obtained for the Co added BiFeO₃ film. Improvement of the squareness of the ferroelectric hysteresis loops in the Co added BiFeO₃ film is due to reduction of the leakage current density (not shown here). At 90 K, leakage current density was sufficiently suppressed according to leakage current property (not shown here), therefore the electric coercive fields can compare. The electric coercive field dependence of the remanent polarization was shown in Fig. 2(e) and 2(f). It can be clearly seen that the electric coercive field of BiFeO₃ film was reduced by adding the cobalt without the reduction of remanent polarization.

Figure 3 shows the magnetic curves for the 4 at.% Co-added BiFeO₃ film and pure BiFeO₃ film measured at room temperature. Although weak ferromagnetism was observed for pure BiFeO₃ film, the spontaneous magnetization as well as coercive field was appeared by adding cobalt. Further more, the saturation magnetization increased by adding cobalt. These results suggest that the cobalt addition might induce a local ferrimagnetic spin configuration by substituting the iron atoms at the *B*-sites to cobalt.

In conclusion, we investigated Co additional effect on ferroelectric and magnetic properties in BiFeO₃ film. It was revealed that cobalt addition affects not only reducing electric coercive field and leakage current density but also increasing saturation magnetization and magnetic coercive field. This is the first report about the additive which was able to simultaneously improve these multiferroic characteristics.

The influence of reactive gases addition in a gas mixture during ion-beam sputtering procedure on magnetic properties of the $(\text{Co}_{45}\text{Fe}_{45}\text{Zr}_{10})_x(\text{Al}_2\text{O}_3)_{100-x}$ nanocomposite films has been investigated. The films with metallic alloy ratio $20 < x < 65$ at.% were sputtered in the chamber evacuated either with pure Ar under pressure P_{Ar} of 6.7×10^{-2} Pa (set 1 films) or Ar + O₂ with partial pressure $P_{\text{O}} = (1.3-5.0) \times 10^{-3}$ Pa (set 2) or Ar + N₂ with $P_{\text{N}} = (1.31-2.13) \times 10^{-2}$ Pa (set 3) gas mixtures. Magnetization, permeability at 20-200 MHz, atomic force microscopy (AFM) in AC MFM regime and Mössbauer spectroscopy (MS) studies were performed at 300 K. The presence of nanoparticles with sizes of 2 - 10 nm was confirmed by transmission electron microscopy and phase contrast AFM microscopy.

Comparison of Figs 1-3 shows that for set 2 and 3 films the region of superparamagnetic state was expanded far beyond the percolation threshold $x_c \approx 41-45$ at.% observed for the set 1 films [1,2]. The last became apparent in a lack of sextet in MS [2], conservation of non-hysteresis behavior of magnetization curves (see, Fig. 1) and lowering of real μ' and imaginary μ'' parts of complex magnetic permeability μ (see, Figs. 2 and 3) far beyond x_c in comparison with the films of set 1. MS have shown that such peculiarities were due to the formation of oxide or nitride shells around nanoparticles preventing magnetic interaction between them even at the direct electric contacting of nanoparticles covered with these shells [1].

Analysis of Figs 1-3 and earlier results [1-3] allows for the conclusion that the values of μ and magnetic state of the composites under study are strongly dependent on the chemical composition of gas mixture in the sputtering chamber. In this connection we should like to underline two main features that are characteristic for the nanocomposites studied.

Firstly, at room temperatures the low- x composites display low values of μ (compare Figs. 2 and 3), great values of DC resistivities [1-2], lack of hysteresis for the magnetization curves (Fig. 1) and of sextet component in MS [2] that is characteristic for the superparamagnetic state. The presence of this feature in the samples far below x_c is not generally dependent on the the composition of gaseous atmosphere during film deposition, although the x region where the superparamagnetic state is observed was shifted to higher x values with the addition of reactive gases into the vacuum chamber.

Secondly, for the studied nanocomposites with $x > x_c$ their magnetic state, including the AC MFM response [1,3] and values of high-frequency μ' and μ'' (Figs. 2 and 3), is strongly dependent on the composition of gaseous atmosphere in the sputtering chamber. Specifically, the superparamagnetic state and labyrinth-like AC MFM contrast (see, [3]) were conserved even beyond the percolation threshold.

Introduction

The line-start interior permanent magnet synchronous motor (LSIPMSM) presents an interesting and energy-high-efficient alternative for induction motors widely used in low-cost electric drives, where the usage of a voltage-source inverter is too expensive. Even in these drives the dynamic behavior is important. To evaluate it, a reliable dynamic model of the motor is required. However, the presence of a squirrel-cage and rotor saliency because of magnetic flux barriers, which have to accommodate the magnetic segments of permanent magnets below the squirrel-cage, present serious obstacles for determining model parameters by the finite element method or experimental method. Thus, determining LSIPMSM dynamic model parameters presents an engineering challenge, which is in this work effectively solved by applying a stochastic search algorithm [1], called differential evolution (DE) [2]. DE has been previously used in optimization of magnetic bearings [3] and for determining magnetically nonlinear characteristics of power transformers [4].

In this work a magnetically linear lumped parameter dynamic model of LSIPMSM is discussed. Its parameters, which are constants, are determined by DE, while the optimization objective is the best possible agreement between the measured and by the model calculated time-behavior of model variables. As far as the authors of this paper are aware, the proposed paper for the first time proposes the usage of DE for determining parameters of LSIPMSM dynamic model.

Lumped parameter dynamic model of the LSIPMSM

The two-axis dynamic model of a three-phase LSIPMSM is used, which is presented in Fig. 1. The voltage balance in the stator and rotor windings of the discussed LSIPMSM is described by equations (1a), (1b), and (1c), (1d), respectively. They represent the electrical subsystem of the LSIPMSM and are written in the d-q reference frame, where the d-axis is aligned with the permanent magnet flux linkage vector. The mechanical subsystem is described by the torque equation (2) and equation (3) describing motion.

Determining model parameters by the DE

The stator resistance R_s can be directly measured on the motor's terminals, while the flux linkage due to permanent magnets ψ_m can be determined from the measured back-emf. All other model parameters in (1a) through (3) have to be determined in the optimization process. The DE searches for model parameters in the optimization process providing minimal value of squared difference between measured and calculated currents and motor speed. In order to prevent model parameters from being adjusted for one transient only, measured response from more than one transient should be used in the optimization process. In the given case the tested LSIPMSM was first fed with 25 Hz and then with 50 Hz voltage supply, thus causing two transients. Parameters determined by the DE were used in the dynamic model to calculate time-responses of currents and motor speed. The comparison of calculated and measured currents and motor speed is presented in Fig. 2. More details will be provided in the full paper.

Introduction

In recent high speed electrical machines became more attractive in many industrial applications such as machine tools, centrifugal compressors, vacuum pumps, turbine generators, and so on. Due to their high efficiency, small size and light weight, high speed electrical machines are likely to be the key technology for many future applications of motion control and drive systems. A system can be made much smaller and lighter at the same power level by increasing the operation speed [1]-[3].

So far, in most of high speed technology applications, a mechanical gearbox has been utilized to couple a conventional electric motor and the high speed mechanical load. Using a mechanical gearbox has the obvious disadvantages of reducing efficiency and reliability of the system, occupying a large space and increasing cost. Another way to achieve high rotational speed is to use an inverter. The inverter transforms the 60 Hz frequency and voltage into a desired high frequency and voltage [4]. This output can be produced with a high speed machine, eliminating the need for a gearbox and greatly reducing the size, complexity, and weight of the machine by trading speed for torque. A direct drive system in which a machine is coupled directly to a load is much more compact and highly efficient and requires much less maintenance.

This paper deals with design and experiment of high speed permanent magnet synchronous motor (PMSM) for axial-flow turbo fan supplying compressed air into the burner of industrial boiler. Usually, air fed into combustion of a boiler is supplied by a belt driven conventional fan, that has many disadvantages such as big noise, big size, less efficiency due to a fixed speed, and so on. However, the boiler with an axial-flow turbo fan using high speed PMSM has many advantages over the one with belt driven conventional fan. First, we designed high speed PMSM for axial-flow turbo fan using electromagnetic analysis method in this paper. Second, the analytical results are compared with those obtained from a finite element method (FEM). Finally, we manufactured and performed experiment of high speed axial-flow turbo fan with designed high speed PMSM.

Design specifications and constraints

High speed PMSM consists of 2-pole permanent magnet rotor and 24-slot stator corresponding with rotor. As stated above, we designed high speed PMSM using electromagnetic analysis method in this paper. The analytical results are compared with those obtained from a FEM. Table 1 shows the design specifications and constraints.

Results and discussion

Fig. 1(a) shows the magnetic flux line distributions due to permanent magnet predicted by FEM results obtained from the commercial package ANSOFT MAXWELL. Fig. 1(b) and 1(c) show the comparison of between analytical and FEM results for the flux density distributions and back-EMF. The analytical results are shown in good agreement with those obtained from FEM results. In our manuscript paper, we will present driving performance.

Finite element analysis of stator winding faults in permanent magnet brushless AC motors.

J. A. Farooq, T. Raminosoa, A. Djerdir, A. Miraoui

Electrical Engineering and Control Systems, University of Technology Belfort Montbeliard, Belfort, France

Abstract—The paper presents an investigation of various stator winding faults in permanent magnet synchronous motor by finite element simulation analysis. Finite element method (FEM) was chosen to take into account most of the physical phenomenon and because its results are generally close to real machines. The satisfactory results of FEM simulations thus eliminate the need to realize high cost prototypes. The different studied faults include: phase inter turn short circuit, phase to phase fault and three phase short circuit fault. The simulation results can serve as step towards development of fault diagnosis algorithms.

Index Terms—Fault diagnosis, Finite element method, Permanent magnet machine, Stator faults.

I. INTRODUCTION

Permanent magnet motors (PMSM) are now widely used for their attractive features like compactness and high efficiency. Thus to improve their reliability, research on fault modeling, simulation and detection is demand of the day. Most of the earlier work in this respect has been done on induction motors [3-5]. Dai et al. [2] have studied some stator winding faults for permanent magnet brushless DC machines by finite element (FEM) simulations. Gerada et al [1] uses reluctance network to simulate stator winding faults for permanent magnet brushless AC machines, but none of them have treated the important case of an internal phase to phase winding fault.

In this work we have simulated most of the possible stator faults that can really occur. FEM approach was adopted since it is well known to give results close to real machines.

II. SIMULATION RESULTS AND DISCUSSION

The machine analyzed in this paper is a 3 phase, 12 pole with distributed winding and external rotor configuration. The windings are star connected with isolated neutral point. Fig. 1 shows its cross section view with a modified stator winding scheme to introduce various internal faults.

For the case of inter-turn short circuit in one phase, 3rd harmonic appears in the faulty phase current (Fig. 2 and 3), whereas 2nd and 4th harmonic appear in the torque and speed (Fig. 4 and 5).

For the case of phase to phase short circuit, 3rd harmonic appears in the current of the two faulty phases (Fig. 6 and 7). Depending on the severity of the fault 2nd harmonic may also appear in these currents (Fig. 8 and 9). Moreover it is noted that the phase currents flowing in the winding after the fault point are in negative sequence. This will create a rotating field in the opposite direction and can produce high eddy currents in the magnets which can lead to their demagnetization.

In addition for the case of phase to phase fault (Fig. 6) the current amplitudes in the faulty phases are approximately twice the rated value, so the classical protection systems may not react immediately. Therefore, the obtained results can be used to develop an efficient diagnosis algorithm to prevent further propagation of the fault.

1. KETI, Bucheon, South Korea; 2. Hanyang University, Seoul, South Korea

1. Introduction

Recently, interior permanent magnet synchronous motors (IPMSM) are widely used in industrial applications, which require high power density [1]. Several control methods have been proposed in order to reduce the loss of IPMSM and improve their performance. One of the control strategies is the maximum torque-per-ampere (MTPA) control. The possibility of operating methods depends on parameters of IPMSM. Specially, the d- and q-axis inductances vary depending on the d- and q-axis current respectively, and as a result the control performances are affected by the magnetic cross saturation. This paper presents a simulation method to decide correct the current vector of IPMSM. It is important that permanent magnet flux, resistance of stator iron loss, and d- and q-axis inductances are evaluated at the nonlinear equivalent magnetic circuit model. Especially, the d- and q-axis inductances are affected by the magnetic cross saturation. In this paper, these parameters are calculated by finite element analysis (FEA).

2. Description of Proposed Analysis Method

The MTPA control of IPMSM, previously, has been developed by using the voltage equation of that, and the voltage equation is derived as if the magnetic cross saturation is ignored and L_d and L_q are assumed to be constant parameter [2]. It seems that the operating performances become worse and the control system may become unstable. Therefore, in order to improve the operating performances, the decision method of the current vector should be considering the effects of magnetic cross saturation. In this paper, the proposed computation method is based on the iteration algorithm shown in Fig. 1. Also, the iteration method can be solved by using a numerical optimization algorithm. In order to choose a proper current vector that satisfy condition of the MTPA control, the proposed analysis method uses the inductance, which is obtained from the FEA, that consider the magnetic cross effect. In each iteration step, the inductances, which correspond to the current vector, are replaced to the voltage equation.

3. Results and Discussion

The motor is in the employment of the compressor of the air conditioner. The simulation results of the torque and the current vector trajectory controlled by the constant power and torque (MTPA) control are shown in Fig. 2. and Fig. 3. The d- and q-axis inductances are used in the analysis considering the effect of the magnetic cross saturation.

In Fig. 2, the black solid-symbol curves represent results without the effect of the magnetic cross saturation, and the MTPA trajectories shown as the white open-symbol, in which the proposed analysis method is used. The MTPA trajectory from the proposed analysis method is that smaller armature current amplitude, thus this current vector decision may conduct the efficiency improvement of the IPMSM as shown in fig. 3. In final full paper, experimental results and discussions will be provided, and analysis results are compared with experimental results for verification of the analysis method.

Introduction

Interior permanent magnet synchronous motors (IPMSMs) are used for variety of industrial applications. In traction and spindle drives, constant output power operation and wide speed range are desirable. In order to extend the speed range of IPMSM, the magnetic field, due to the permanent magnets (PMs), is at the increase of the speed weakened by phase advance of stator current in order to exert a demagnetizing component of armature reaction field. The great disadvantage of such motor drives is the rapid decrease of motor output torque with the increase of the level of flux weakening (FW).

IPMSMs can offer high-efficiency drive by properly utilizing magnet and reluctance torque components. The reluctance torque components of the IPMSMs can be increased only by increasing the saliency ratio. It has been reported that the proper adding of weak permanent magnet material into the rotor structure of synchronous reluctance motor (SRM) can improve motor performance [1]. Such a motor is then usually called permanent magnet assisted synchronous reluctance motor (PMASRM) or interior permanent magnet synchronous motor with flux barriers (IPMSMFB). Leakage flux between barriers and saturation in the core increases pretentiousness of such motor design [2, 3].

The aim of the paper is the design and analysis of PMASRM which will exhibit similar maximal torque per current density and higher output power capability and efficiency than the existent IPMSM. Both motors, the existent IPMSM and PMASRM should have the same rotor and stator diameter, the same stator construction, the same axial length, the same number of poles, the same active electrical steel material and the same amount of NdFeB magnet material.

Method of analysis and results

The calculation of motors' performances was carried out on the basis of the FEM calculations of magnetic conditions. The influence of iron losses on the output power capability and constant-power speed range was included in the analysis by the posterior iron loss calculation [4]. Various parameters of PMASRM rotor structure were taken into account at determination of suitable rotor construction. These parameters are: thicknesses of flux barriers, number and angular locations of flux barriers, width of the tangential and radial rotor ribs, location and number of PM segments per pole and residual flux density of used PM material. On the basis of FEM analysis the rotor of PMASRM with three-flux barriers was built. Rotor lamination of IPMSM and rotor lamination of PMASRM are presented in Fig. 1a and Fig 1b. For PMASRM the PM material was placed only in the flux barriers closest to the rotor shaft (Fig. 1c), while the air was accounted for in the flux barriers closest to the rotor surface. The calculated performance of the conventional IPMSM was confirmed with the measurements in the range of speed 3000-10000 rpm, while the calculated performance of the PMASRM was confirmed with the measurements at speed 1500 rev/min only, due to the low voltage winding arrangement and due to the temporary measurement equipment limitations. Some calculated and measured results are presented in Fig. 2. Efficiency of the PMASRM versus speed (Fig. 2b) was calculated for the same current densities as for IPMSM current densities, obtained from the measurements of the load conditions.

Conclusion

Results of the output power capability comparison between IPMSM and PMASRM (measured and calculated) show that PMASRM exhibits higher output power capability and better efficiency than the existent IPMSM for the same level of flux weakening. At the same current density level and at the same level of flux weakening, the total iron losses of the PMASRM are similar to the iron losses of IPMSM. PMASRM exhibits higher iron losses than IPMSM in rotor and lower iron losses than IPMSM in stator.

Performance of IPMSM for Electro-Hydraulic Power Steering with Electric Driven Pump Unit.

Y. Kim¹, S. Rhyu¹, J. Hur¹, J. Hong²

1. KETI, Bucheon, South Korea; 2. Hanyang University, Seoul, South Korea

1. Introduction

As the needs of motorization in automobile system increase, the electro-hydraulic power steering (EHPS) system is in the spotlight. Because EHPS system does not need a drive belt, takes up very little space and easy to position in the car, additionally, energy consumption is lowered, which leads to reduced fuel consumption [1].

The electric driven pump unit for EHPS system is consisted of a hydraulic pump, a pump motor and an electric control unit (ECU), and the hydraulic pump is run by electric motor. The electric motor is controlled by the ECU. The ECU adapts the power of the pump motor based on both the speed of the car and the turn speed of the steering wheel. Moreover, ECU, electric motor and hydraulic pump are all in one unit-which is also a replacement part. This paper will describe the development of the interior type permanent magnet synchronous motor (IPMSM) controlled by ECU, introduce the equivalent magnetic circuit method to analyze and design for the IPMSM, and finally provide the experimental results of the IPMSM.

2. IPMSM for EHPS system

IPMSM is expanding the application extent for commercial applications, such as electric vehicles, pumps, compressors. Because that it is possible to employ both reluctance and magnetic torque and to drive a motor over a wider speed range through the use of field weakening control. Specially, the motor for EHPS system is needed to have low torque ripple and cogging torque as well as high efficiency of that. In the paper, first, optimal shape design for reducing the cogging torque is accomplished by using the response surface method. Fig 1 show design variables to minimize the cogging torque. Second, the torque characteristics is presented by considering the nonlinear electromagnetic characteristic of this IPMSM [2]. For the characteristic analysis, 2-D FEM and equivalent magnetic circuit method are used and analysis results are compared with the experimental results for verification of the analysis method.

3. Results and Discussion

Fig. 2 shows the analysis result of the cogging torque. The optimization of design variables are accomplished by using the response surface method. Fig 3 shows the experimental devices for the proto type IPMSM.

Fig. 4 and Fig 5 show the experimental results of the dynamo-test. When the speed command is 4000 rpm, performances of the motor is shown in Fig. 4, When the Torque command is 3.4 N-m, performances of the motor is shown in Fig. 5. From these results, motor efficiency is about 90% at the 1 kW point and the efficiency of including the ECU is about 85%. Finally, the more detailed results and discussion will also be given fully in full paper.

Influence of driving methods on dynamic torque characteristic of high-speed permanent magnet synchronous motor with hall sensor.

S. Jang¹, U. Lee¹, D. You¹, J. Park¹, T. Sung²

1. Chungnam National University, Daejeon, South Korea; 2. Korea Electric Power Research Institute, Daejeon, South Korea

Introduction

High-speed motors are becoming attractive in applications such as micro-turbine generators, pumps, and fans [1]. Especially, due to the feature such as high efficiency, small volume and high power density, high-speed Permanent Magnet Synchronous Motor (PMSM) has gained the increasing popularity in many fields [2-4]. In PMSM with the various applications, driving method has generally two types. One is six-step drive by hall sensors and the other is sinusoidal drive by encoder type sensors. The six-step driving method is based on the feedback of rotor position obtained at fixed points from typically every 60 electrical degrees for commutation of the phase current. This driving method has the advantage of self-starting by absolute position and the rapid acceleration by quasi-rectangular shape currents with various harmonics. However, the current harmonics created by the difference between the discrete reference voltage and sinusoidal back EMF by PM rotor speed increase torque ripple at high-speed. The sinusoidal driving method with continuous sinusoidal reference voltage has a few current harmonics in relation with the sinusoidal Back-EMF. This means that dynamic torque is produced with very little ripple at the high speed. In spite of these merits, sinusoidal drive is not generally used for industry applications because of the dynamic range restriction of encoder at the high speed. Therefore, to improve dynamic characteristics and efficiency in PMSM operation, this paper presents the sinusoidal drive by the estimated rotor position obtained from hall signals and clock of controller over the specific speed. In our analysis, the dynamic torque is estimated by electromagnetic field with space harmonics and time harmonics generated from current and PM magnetization. And verification of analysis is performed by Finite Element Method (FEM) and the experimental results.

Experimental results according to driving mode

Fig. 1(a) shows the cross-section of 4-pole, 3-phase surface-mounted PM machine with a parallel magnetized PM rotor and a slotted stator core. Fig. 1(b) presents an eddy current type dynamometer as mechanical load. It is coupled to the manufactured high-speed PMSM to measure current harmonics. Fig. 2(a) shows phase back EMF and the phase reference voltage waveform by the continuous current (180 electrical degree) mode under six-step drive. Here, one sector has 60 electrical degrees. Fig. 2(b) shows the sinusoidal reference voltage obtained by estimated rotor angles based on hall sensor signals and the back EMF waveform under sinusoidal drive. As shown in figure, the sinusoidal reference voltage corresponds with the back EMF. Fig. 2(c) shows that the initial driving method under six-step mode is replaced by sinusoidal mode at specific speed. The torque of six-step driving method is higher than that of sinusoidal driving method at low speed and the torque ripple of six-step method is higher than that of the sinusoidal method. Therefore, the changing driving method has the advantage of rapid speed response at initial drive and reduces vibration and loss characteristic of PMSM at high speed.

Fig. 3 shows experimental result of current harmonics to recognize influences from mode change. There are distinct differences between the two consequences. While the current harmonics has multiple components at the six-step mode due to nonlinear of switching as shown Fig. 3(a), there dominate the first harmonic component at sinusoidal mode as shown Fig. 3(b). The more detailed

results and discussion will be given in final paper. The mathematical expressions related to analytical results will also be given fully in final paper.

Thrust Ripple Minimization of Permanent Magnet Linear Synchronous Motor by the Notch and the Auxiliary-teeth.

D. Lee, K. Jang, G. Kim

Electrical Engineering, Changwon National University, Changwon, South Korea

A slot type permanent magnet linear synchronous motor(PMLSM) is used widely as the driving source for factory and office automation because it has the advantages of high-efficiency and high-energy density. But, there are the disadvantages that a noise and a vibration of the apparatuses are induced and the control ability of the instruments is curtailed because of thrust ripple[1]. Therefore, thrust ripples reduction is an essential requirement in slot type PMLSM.

The thrust ripples of the slot type PMLSM can be classified into categories: (i) the ripple due to the detent force caused by magnetic reluctance difference of slot-teeth structure, (ii) the ripple due to the detent force caused by end-effect, (iii) the ripple due to the harmonic components of permanent magnet.

So, in this paper, the notch and auxiliary-teeth are installed on armature core to reduce the detent force caused by magnetic reluctance difference of slot-teeth structure and end-effect. And, the permanent magnet shape is changed to reduce the thrust ripple due to the harmonic components of permanent magnet.

Table 1 shows the specifications. Fig.1 shows the armature of notch model and measurement equipments of the PMLSM.

Fig. 2, Fig. 3 and Fig.4 show the detent force and the thrust characteristic. As shown in table II, the peak values of detent force are decreased remarkably by notch and auxiliary-teeth. Also, the thrust is decreased. PM shape changing is ignored because the effect of it is very small to reduce detent force. So, in this paper, the optimum model is proposed, notch and auxiliary-teeth are applied at the same time.

As the results, the peak-value of detent force of optimum model is 10.27[N] which is 14.7[%] of basic model. The peak value of thrust is decreased from 898.9[N] to 847.9[N]. But, the distortion ratio of thrust is decreased from 7.52[%] to 1.93[%] because the 2nd, 5th and 6th harmonics components of optimum model are decreased remarkably in comparison with that of basic model by notch and auxiliary-teeth. Therefore, the vibration and noise are decreased and operating characteristic of PMLSM is improved as distortion ratio is reduced remarkably.

A Study on the Vibration Characteristic According to PM Arrangement in PMLSM.

D. Lee, S. Lee, K. Jang, G. Kim

Electrical Engineering, Changwon National University, Changwon, South Korea

A slot type Permanent Magnet Linear Synchronous Motor(PMLSM) has high efficiency, high energy density and high control ability. But, detent force is always produced by the structure of slot teeth and end effect. As detent force is acted as noise and vibration of the apparatuses, it is decreased the control ability because it acts as thrust ripple[1].

Generally, the best part of researches in PMLSM is to reduce detent force. But, the research of PMLSM does not exist about the vibration. So, the vibration characteristic of PMLSM according to PM arrangement is experiment and analysis in this paper.

Fig. 1 shows the PM arrangement on the stator. The basic model, a general skew model and the V-skew model are shown. The structure of stator and mover except the PM arrangement are same.

Fig. 2 shows developed forces of skew model. The detent force, thrust, normal force, and lateral force are operated in the PMLSM. Usually, the detent force, normal force, and the lateral force act as negative effect in the PMLSM.

Table 1 shows detent force, thrust, distortion factor of thrust and lateral force. The detent force of general skew and V-skew model decreased remarkably than No-skew model. The peak-value of lateral force of general skew model is 31.95 [N]. The other side, the lateral force of No-skew and V-skew model becomes 0[N] because they have symmetry structure about Z-axis direction.

Fig. 3 shows the accelerometer and location of acceleration sensor for vibration experiment.

Fig. 4 shows the mechanical vibration frequency when the impact hammer is hit to x-direction.

The vibration is measured according to the velocity changing. Fig. 5 shows experimental results of vibration.

Fig. 6 shows the vibration frequency by FFT at 2[m/s]. The vibration of x-direction is generated greatly because mover is free operated in the x-direction. But, the vibration of y-direction and z-direction are smaller than it of x-direction because the movement is limited owing to upholding for LM guide in the y-direction and z-direction. So, that is meaningless to measure the vibration dimensions of y-direction and z-direction.

Therefore, the vibration of x-direction according to the velocity is shown in Fig. 7. In the Fig. 7(a), the vibration of basic model is generated greatly at 50[Hz] as the effect of detent force. The vibration of detent force for other models must be generated at 16.66[Hz] because the periodic of detent force is different by skew. That is very smaller to because detent force is reduced. But, the vibration of detent force is reduced by increasing inertial force according to increasing velocity. When the velocity is under 1.0[m/s], the vibrations of all models are similar. But, the vibration of skew model is increased greatly in case of velocity at 1.5[m/s] and 2.0[m/s] because the lateral force is increased.

Flux Barrier Design to Improve Torque Characteristics of Double-layer Interior Permanent Magnet Synchronous Motor.

S. Kim¹, J. Jung¹, J. Hong¹, S. Lee²

1. Department of Mechanical Engineering, Hanyang University, Seoul, South Korea; 2. Research Center, Korea Institute of Industrial Technology, Gwangju, South Korea

I. Introduction

Interior permanent magnet synchronous motor (IPMSM) is widely used for many industrial applications such as electric vehicles and home appliances due to its high power density and wide speed range. From the torque performance point of view, however, the IPMSM has two drawbacks. That is, torque ripple and cogging torque are relatively large as compared with a surface mounted permanent magnet motor. These problems are produced mostly by the discontinuous reluctance variation because of the slotted structure of stator core and saturation of magnetic circuit [1]. In particular, the magnetic saturation of IPMSM operated in wide speed range through flux weakening control greatly varies according to load condition. Therefore, the shape optimization of IPMSM is demanded to improve torque characteristics, but it is very complex and difficult work, because a lot of design variables and the interactions between them must be considered. However, this paper shows it is possible to enhance torque performance by the optimal design of flux barrier without considering other design parameters. At that time, response surface method (RSM) is applied as an optimization method [2]. In the end, the more details on the optimization and RSM will be given fully in final paper.

II. Prototype Model and Specifications

Fig. 1 shows the configuration of prototype model for driving air-conditioning compressor in hybrid electric vehicle. The specifications given in the model are listed in Table I.

III. Flux Barrier Design Optimization

A1, A2 and A3 displayed in Fig. 2 are design variables selected in this paper. The objective function and constraint condition for the optimal design of flux barrier are as follows:

Objective function:

- Torque ripple at the base speed less than 10%
- Torque ripple at the maximum speed less than 30%
- Peak value of cogging torque less than 0.1Nm
- Total harmonic distortion (THD) of back-EMF less than 4%

Subject to:

- Average torque at the base speed more than 5.5Nm
- Average torque at the maximum speed more than 2.55Nm

Fig. 3(a) and (b) show the flux barrier and fabricated configuration of Final model.

IV. Results and Discussion

Fig. 4(a) displays the torque waveforms of final model obtained by finite element analysis (FEA) at the base and maximum speed. At this time, input current is 15.95A and 12.5A, and current angle is 32.5o and 63.6o respectively. In Fig. 4(b), test and FEA result of cogging torque are compared. Fig. 5(a) and (b) show the back-EMF waveform measured at 3500rpm and harmonic analysis of the waveform respectively. The more detailed test results and discussion will be included in final paper.

Study on High Efficiency Performance in Interior Permanent Magnet Synchronous Motor with Double-layer PM Design.

L. Fang, J. Jung, B. Lee, J. Hong

Department of Mechanical Engineering, Hanyang University, Seoul, South Korea

-Introduction-

The interior permanent magnet synchronous motors (IPMSM) have wide applications to household goods, industrial use, and electric and hybrid vehicle propulsion. Compared to DC motors and AC induction motors, the IPMSM have superior performance characteristics, that including high efficiency, high torque density, and wide constant power operating range[1]. In this study, a high efficiency IPMSM used as a traction motor in vehicle propulsion system is introduced firstly to be a prototype model, and then double-layer design is applied to the IPM rotor for improving the motor efficiency performance further.

The double-layer structure is created by splitting the single-layer PM into two pieces, and forming double flux barriers. From the rotor structure point, the double-layer IPMSM has the beneficial attributes of both the synchronous reluctance motors(SynRM) and the PM motors. Taking advantage of SynRM attributes, the high rotor saliency can be achieved by increasing split layer, which is benefit to the reluctance torque production. In the case of generating specific torque rating, the increasing of reluctance torque production lower the dependency on magnet torque production. Correspondingly, the copper loss decreases with the reducing of armature current relating to magnet torque production. In this study, the introduced prototype single-layer model is optimal designed into double-layer structure with the help of a coupled optimization method that design of experiment(DOE) and response surface methodology(RSM)[2]. An optimum double-layer structure is quickly determined and the advantages of double-layer IPM design on the efficiency improvement are verified through the motor performance comparison. The torque production and efficiency performance are calculated by using the equivalent circuit method(ECM)[3] and finite element method(FEM).

-Equivalent Circuit Method (ECM)-

Equivalent circuits for IPMSM based on the synchronous d-q reference frame including core loss consideration are presented in Fig. 1. The mathematical model is built from the equivalent circuit. The d-axis and q-axis voltages and hybrid torque equations are given as (1), (2) and (3) respectively. In the equivalent circuit, R_a is armature winding resistance per phase, R_c is equivalent iron loss resistance, ψ_a is flux linkage of PM per phase(rms), L_d and L_q are d-axis and q-axis inductance, P_n is number of pole pairs, β is the lead angle of phase current ($=\arctan(-i_d/i_q)$).

-Prototype Model and Optimum Model-

A 15-kW high efficiency IPMSM used as traction motor is given as prototype model. It has 16-pole and 24-slot, with concentrated windings arranged in stator part, as Fig. 2(a) shows. Using the same amount of magnet, an optimum structure of double-layer IPM is designed with the object of high efficiency at constant torque range. Fig. 2(b) shows the optimum double-layer IPMSM model.

-Results Comparison-

Fig. 3 shows the results comparisons between the prototype single-layer model and the optimum designed double-layer model. The same torque performance along all the speed range is restricted, as Fig. 3(a) shows. The improving of efficiency performance is observed from Fig. 3(b). The hybrid torque production that reluctance torque and magnet torque are compared separately in Fig. 3(c). The copper loss existing in armature windings is reduced when the magnet torque decreased, which

is verified in Fig. 3(d). In general, the motor efficiency improving is achieved by enhancing reluctance torque production to compensate the reducing of magnet torque production.

A new PMLSM having 9 pole 10 slot structure and its shape optimal design for detent force reduction.

C. Koh, I. Hwang, H. Yoon

School of Electrical & Computer Engineering, Chungbuk National University, Cheongju, South Korea

A permanent magnet linear synchronous motor (PMLSM) having conventional structure of $4\tau_p=3\tau_s$ (or $2\tau_p=3\tau_s$) where τ_p and τ_s are PM pole and winding slot pitches, respectively, has quite big detent force, and applications to a place requiring precise position and speed control have been limited [1]. In this paper, a new PMLSM having structure of $9\tau_p=10\tau_s$ (9 pole 10 slot structure) is suggested to reduce the cogging force, and the detent force is minimized by optimizing both armature core length and shape of the exterior teeth simultaneously.

A cogging force from one slot of armature core can be represented, using Fourier series expansion, as follows:

$$f_c(x) = \sum A_n \sin(n\omega x + \alpha_n) \quad (1)$$

where the summation is over the harmonic components ($1 \leq n \leq \infty$), A_n and α_n are the magnitude and phase angle of the n -th harmonic component, respectively. Using (1), the total cogging force of a PMLSM having 12 poles and 9 slots, as an example of $4\tau_p=3\tau_s$ structure, can be proven to consist of only $3n$ order harmonic components as follows:

$$F_{12p9s}(x) = 3 \sum A_n \sin(n\omega x + \alpha_n) = 9 \sum A_{3n} \sin(3n\omega x + \alpha_{3n}) \quad (2)$$

where the first and second summations are for the harmonic components ($1 \leq n \leq \infty$), and winding slots ($1 \leq i \leq 3$), respectively, θ_i is the position of the i -th slot. In the same way, the suggested PMLSM having 9 pole 10 slot structure can be proven to have only $10n$ order harmonic components in its cogging force as follows:

$$F_{9p10s}(x) = \sum A_n \sin(n\omega x + \alpha_n) = 10 \sum A_{10n} \sin(10n\omega x + \alpha_{10n}) \quad (3)$$

where the first summation has the same meaning as in (1) and the second is for the winding slots ($1 \leq i \leq 10$). Comparing (3) with (2), it is clear that the suggested PMLSM reduces the cogging force very much because the magnitudes of the $10n$ harmonic components are, in general, much smaller than those of the $3n$ harmonic components.

On the other hand, the detent force of the suggested PMLSM is reduced by optimizing both armature core length and shape of the exterior teeth. In the optimization, the detent forces are approximated to a response surface using Multi-quadric radial basis function with pareto-optimal sampling points obtained by using Latin hypercube design employing *MinMax* and *MaxMin* criteria and the corresponding detent forces calculated from finite element analysis[2].

Fig. 1 and Table I compare the optimized design of the suggested PMLSM with that of conventional one having 12 poles and 9 slots where the overall lengths of armature core are 206.8(mm) and 185.6(mm), respectively. For the optimized designs, the finite element analysis gives the detent forces of 1.95[N] and 12.56[N], as shown in Fig. 3(a), and the thrust forces of 246.53[N] and 230.81[N], as shown in Fig. 4(a), at the same armature current of 709.37(AT)/phase for the suggested and conventional PMLSMs, respectively.

In order to validate the performance of the suggested PMLSM, a sample PMLSM is constructed as shown in Fig. 2. While driving the PMLSMs using ADAX-08LL2 servo system, the detent and thrust forces are experimentally measured by using load cell. Fig. 3(b) shows the suggested PMLSM reduces the detent force to 14.42[N] from 24.9[N] of the conventional one. Fig. 4(b) shows a comparison of the thrust forces. As the armature current increases, the suggested PMLSM

gives bigger thrust force than the conventional one. At the armature current of 3.8[A], the suggested PMLSM gives 6.7% bigger thrust force than the conventional one.

The role of uncompensated spins in exchange biasing.

H. J. Hug^{1,2}, I. Schmid¹, P. Kappenberger¹

1. Nanoscale Materials Science, Empa, Duebendorf, Switzerland; 2. Institute of Physics, University of Basel, Basel, Switzerland

The origin of the exchange bias (EB) effect has been traced back to the existence of pinned uncompensated spins (UCS) in the antiferromagnet (AFM) or at its interface. However, the understanding of the underlying mechanism is still clouded by contradictory reports: Ohldag et al. [1] used XMCD to extract the direction and density of pinned UCS from the vertical shift of element specific magnetization loops. In their interpretation, the positive vertical shifts reflects a parallel coupling of the UCS to the spins of the ferromagnet (FM). Tsunoda et al. [2] used a similar experimental method but did not find any vertical shift. Furthermore, Kappenberger et al. [3] (magnetic force microscopy) and Eimüller et al. [4] (XMCD PEEM) reported an antiferromagnetic coupling between the UCS and the FM spins.

In this work different perpendicular exchange-biased AFM/FM multilayers were prepared. The FM layers consisted of CoPt and CoPd multilayers. For the AFM layers either CoO (sample S1) or MnIr (sample S2) was used. These samples were then studied by vibrating sample magnetometry (VSM) and high resolution low-temperature magnetic force microscopy (MFM).

The VSM-loops obtained after field-cooling in 1T showed positive vertical shifts for all samples that arises from pinned UCS aligned parallel to the FM spins. For the MFM experiments, the samples were set into an up/down stripe domain state at room temperature (RT) and zero-field cooled to 8.3K. The MFM images of samples S1 (fig. 1(a)) and S2 (fig. 1(b)) reveal regular stripe patterns due to domains in the FM layers. Figs 1(c) and (d) show MFM data acquired after saturation of the FM layers. Then, weak and more granular stripe patterns remain visible even in the highest field we could apply (7T). Surprisingly, the comparison of figs. 1(a) and (b) with figs. 1(c) and (d) reveals an inverted contrast. In conclusion, the pattern visible after saturation of the FM layers is due to a pattern of pinned UCS, that are aligned antiparallel to the spins of the FM.

Our VSM and MFM results prove the existence of two distinct groups of pinned UCS. Thus, one such group (called “p”) aligns parallel to the FM while the other group (called “ap”) aligns antiparallel to the FM. In the VSM experiments performed after field cooling in 1T the total magnetic moment of the p-group dominates that of the ap-group. In the MFM experiments the uncompensated AFM spins are cooled in zero external field but are still subjected to weaker field generated by the FM domains (about 200mT). The MFM clearly reveals that the ap-group dominates over the p-group. It is noteworthy that the ap-spins align antiparallel to the (local) cooling field generated by the FM domain pattern. From this we conclude that the ap-spins are exchange coupled to the FM spins and thus are responsible for the EB-effect. To study the dependence of the p-moment on the cooling field, an EB-sample with a high RT remanence was fabricated, saturated at RT and then cooled in various fields ranging from zero to 7T. After zero-field cooling a negative vertical shift of the M(H)-loop was found. The vertical shift became positive for moderate cooling fields and remained constant up to 7T. The EB-effect did not change sign and became slightly smaller in high cooling fields. These results confirm that a saturated FM generates pinned ap-spins in the AFM via exchange coupling, while the p-spins are generated by the cooling field. Hence, only the ap-spins are responsible for the EB-effect.

Given that most experimental techniques (including those used in our work [5]) measure the sum of both spin groups indiscriminately, contradictory results can arise. Our work may provide guide-

lines for the design of experiments which can correctly determine the densities of those UCS that do contribute to the EB effect.

Fig.1: MFM images: domain pattern of the FM layers observed after zero-field cooling the samples containing CoO (a) and MnIr (b) as an antiferromagnet to 8.3K. After saturating the FM layers the weak and grainy contrast of the MFM images (c) and (d) arises from pinned UCS of the AFM layers. A comparison of (a) with (c) and (b) with (d) clearly reveals the existence of pinned magnetic moments of the AFM that are antiparallel to the magnetic moments of the FM layers.

Measuring exchange anisotropy in Fe/MnPd using inductive magnetometry.

K. J. Kennewell¹, X. Ji², J. Hu¹, K. M. Krishnan², R. L. Stamps¹

1. School of Physics, University of Western Australia, Crawley, WA, Australia; 2. Materials Science and Engineering, University of Washington, Seattle, WA

Measures of exchange bias determined from resonance differ significantly from those obtained using conventional magnetization experiments [1]. Quasi-static magnetization measurements of $M(H)$ infer values of exchange anisotropy from coercivity and magnetization loop shifts [2]. Coercivity and other features of magnetization loops are averaged over entire samples, and typically involve a variety of history dependent magnetization processes. Because of these complications, actual magnitudes of exchange anisotropy are difficult to extract from magnetization measurements. By way of contrast, ferromagnetic resonance measurement instead characterizes the curvature of the free energy, which is dictated by the effective fields acting on a magnetization near equilibrium [3]. Analysis of the frequencies as a function of field strength and orientation can provide measures of local fields created by the exchange anisotropy.

In this work [4], we present results from investigations using an inductive ferromagnetic resonance technique [5, 6] of exchange anisotropy and exchange bias in epitaxial Fe/MnPd. A 13.5GHz network analyzer (Agilent 8719ET) is used as both the excitation and measurement device, coupling to the sample through a mutual inductance with a coplanar stripline. The stripline and sample are placed in an externally applied field up to 900 Oe, and the sample can be rotated in-plane. The sample was grown on a single crystalline MgO substrate oriented along the [001] direction using ion beam sputtering [6] in an ultrahigh vacuum at less than 10^{-8} Torr.

Fig. 1 shows data obtained from resonance experiments in which the field is applied along different in-plane directions at a constant 10.8GHz. The results are interpreted in terms of effective anisotropies acting on the Fe films [7, 8]. The fourfold anisotropy of the Fe thin film layer has effective fields with roughly the same magnitude as the maximum applied field range, so a complete field profile as a function of frequency is not seen. However, the fourfold behaviour is clearly visible and the unidirectional exchange anisotropy is seen as a difference in resonance between $\theta=\pi$ and 2π .

Fig. 2 shows measurements of the resonance frequency aligned along the samples hard axis. The frequency lowers as the magnetization is pulled into the hard direction, reaching a minimum at the same field where the magnetization aligns with the applied field. Note two resonance branches are modelled in the figure for each applied field direction. Only one branch is observed experimentally due to the symmetry breaking nature of the exchange anisotropy. Interestingly, there is a jump in frequency for the transition to the hard direction for field values near the frequency cusp. We propose these anomalous frequencies are evidence of dispersion of the unidirectional magnitudes and directions about the field cooling direction.

Dependence of the training effect on the antiferromagnet structure in the domain state model for exchange bias.

A. G. Biternas, U. Nowak, R. W. Chantrell

Department of Physics, University of York, York, United Kingdom

The application of giant magnetoresistance spin valve read head is wide-spread in high-density magnetic recording and draw a great deal of attention in exchange-coupled systems of ferromagnetic-antiferromagnetic (AFM) bilayers. These so called exchange bias systems exhibit unidirectional anisotropy, where a horizontal shift of the hysteresis loop is observed in the ferromagnet after an initial cooling process in a field. After a sequence of consecutive hysteresis cycles, a reduction of this effect is observed at constant temperature. This reduction is called the training effect. In the present paper, Monte-Carlo simulation techniques are used to investigate the training effect of the exchange bias field using the domain state model [1,2]. The behavior of the training is investigated for different values of antiferromagnet thickness and dilution with defects.

The data for each AFM dilution and thickness value were fitted to two different laws, firstly, the empirical power law $H_{cb}(n) = H_{cb}^{e-p} + \kappa/\sqrt{n}$ for $n > 1$, where n the number of consecutive hysteresis loops and H_{cb}^{e-p} the equilibrium exchange bias field, and secondly, the recursive sequence: $H_{cb}(n+1) = -\gamma(H_{cb}(n) - H_{cb}^{e-rs})^3 + H_{cb}(n)$, derived from a discretized Landau-Khalatnikov equation by Binek *et al.* [3,4].

According to Zhang *et al.* [5], training effect changes from one type to another with decreasing antiferromagnet thickness. They considered Type I training effect to be when the two branches of the hysteresis loop move to opposite directions, shrinking it from both sides. Type II training effect is when the two branches move to the same direction with a smaller shrinkage of the hysteresis loop.

As shown in Fig. 1 increasing the thickness of the antiferromagnet changes the type of training effect from Type II to Type I. Also, the exchange bias field and the training effect magnitude decreases with increasing thickness. This is due to the fact that it is harder to form domain walls which are perpendicular to the interface.

Figure 2 shows the dependence of the training effect on the dilution of the antiferromagnet. The exchange bias field increases as a function of AFM dilution up to the value of 50%, where it has its maximum. For low dilutions the field is close to zero. Also, the training effect is more intense at dilutions greater than 20%. Below that the training effect is weak. These results are found to be in qualitative agreement with the experimental data of Keller *et al.* [6] in epitaxially grown Co/CoO bilayers systems diluted with nonmagnetic substitutions ($\text{Co}_{1-x}\text{Mg}_x\text{O}$). The dilution dependence of both exchange bias field and magnitude of the training effect are related in the sense that for high and low dilutions the exchange bias decreases as well as the training effect. These results can be interpreted within the domain state model for exchange bias where the magnetization reversal of the ferromagnetic layer causes irreversible changes in the antiferromagnet domain structure.

Temperature Dependence of IrMn Pinning: Single Crystal versus Polycrystalline Effects.

P. Pong, C. L. Dennis, W. F. Egelhoff

Magnetic Materials Group, National Institute of Standards and Technology, Gaithersburg, MD

Introduction

Recently it has been found that the instability of the antiferromagnet against thermally activated changes is the reason of the difficulty to study the exchange bias phenomenon [1]. Extreme caution is necessary when studying the antiferromagnet behaviour because the actual state of the antiferromagnet can only be inferred from the ferromagnet behaviour with careful design of field sequence and temperature cycling. Fernandez-Outon et al. investigated the possible origins of thermal instabilities of antiferromagnet and they suggested that large increase in coercivity for polycrystalline IrMn at 10K is due to the freezing spins at the grain boundaries [1]. In this paper, we have investigated both single crystal and polycrystalline IrMn in order to verify the model of Fernandez-Outon et al.

Experimental Methods

The thin films were deposited on thermally oxidized silicon wafers by dc magnetron sputtering in an ultrahigh vacuum chamber with a base pressure of 2×10^{-10} Torr. The metal films were deposited at room temperature in 2 mTorr Argon. The oxide barrier layer was made by first depositing a thin Al or Mg metal and then oxidizing it in an oxygen plasma (4 mTorr Argon, 2 mTorr Oxygen) for 2.5 minutes. The magnetic hysteresis loop measurements were carried out with a SQUID magnetometer (MPMS, Quantum Design, USA) at the temperature of 300 K, 200 K, 100 K, and 10 K. The crystalline structures of the thin films were studied with RHEED.

Results and Discussion

Three magnetic tunnel junction film structures were made: (1) sample A – substrate / 100 Cu (100) / 10 IrMn / 5 Co / 0.5 Al / 2 Al₂O₃ / 20 Conetic (Ni₇₇Fe₁₄Cu₅Mo₄) / 10 Cu / 10 Ta, (2) sample B – substrate / 20 Conetic / 1 CoFeB / 1.5 MgO / 2.5 Co / 10 IrMn / 10 Au, (3) sample C – substrate / 20 Conetic / 0.5 Co / 1 Al₂O₃ / 0.5 Co / 2.5 Conetic / 0.5 Co / 10 IrMn / 10 Cu (all units in nm). The RHEED study shows that the IrMn on top of the Cu of sample A is single crystal structure while the IrMn of sample B and C are polycrystalline structures. The coercivities of the pinned layer loops were measured from the centers of the loops to the zero field in the hysteresis measurements at four different temperatures. The results are shown in Figure 1. All three samples show increases in their coercivities of their pinned layer loops from room temperature to 10 K. These increases are due to the stronger pinning strength of the IrMn at lower temperatures. In Figure 2 the coercivities are expressed as percentages in reference to the coercivities measured at room temperature. Comparatively speaking, the coercivities of the pinned layer loop (H_{pin}) of sample A which contains single crystal IrMn did not increase with the lower temperatures; however, the H_{pin} of both sample B and sample C increased considerably to about 1000 % and around 10000 % respectively as the temperature decreased from room temperature to 10 K.

Conclusion

The large increase of coercivity in polycrystalline IrMn was reproduced; however, no remarkable increase of coercivity was observed in single crystal IrMn. The coercivity of the single crystal IrMn showed very little change upon cooling to 10 K. These results provide strong evidence for the model of Fernandez-Outon et al.

The exchange bias (EB) effect refers to the shift of the hysteresis loop along the field axis direction in ferromagnetic/antiferromagnetic (FM/AFM) bilayers. This is the consequence of the unidirectional anisotropy induced in the FM layer which results from the exchange coupling across the FM/AFM interface. The exchange biasing of amorphous soft ferromagnetic materials is important both for a fundamental understanding as well as for various applications including giant magnetoresistance (GMR) sensors.

Here we investigate the EB effect in bilayers of an amorphous FM (CoFeB) and a crystalline AFM (IrMn) in a top-pinned configuration [1]. When the crystalline IrMn layer is deposited on top of the amorphous CoFeB layer, no EB is observed.

On insertion of a thin crystalline FM layer of NiFe between the amorphous CoFeB and the crystalline IrMn, exchange coupling appeared and it was dependent on the thickness of the NiFe layer. The dependence of the absolute value of the EB field H_{EB} and of the coercivity H_C on the thickness x of the NiFe layer is plotted in Fig 1(a). We observe that the appearance of EB occurs when the thickness of the NiFe layer is about 2 nm or thicker. By further increasing x the H_{EB} rises to a maximum and then decreases for larger x values. At the same time, H_C increases with increasing x and stays almost constant at larger x values.

We demonstrate by X-ray diffraction that the appearance of EB in the CoFeB/NiFe/IrMn system is directly related to the appearance of the (111) texture of the IrMn layer [1]. This can be easily observed by comparing Fig. 1(a) with Fig. 1(b), the latter showing the dependence of the integrated intensity under the (111) IrMn peak on the thickness of the NiFe layer. In other words, the (111) texture of the IrMn layer is associated with the AFM state of the IrMn layer, which in contact with the FM layer gives rise to EB.

A significant enhancement in the blocking temperature of the CoFeB/NiFe/IrMn layers was observed on increasing the thickness of the NiFe layer [1]. This effect is also directly correlated with the (111) texture responsible for the antiferromagnetic phase of the IrMn layer, which developed progressively with increasing thickness of the NiFe layer. The blocking temperature was found to vary linearly with the intensity under the (111) X-ray diffraction peak of IrMn.

The above system can be used to induce a controllable EB anisotropy or pinning of the amorphous FM. It can serve as free-layer part of a magneto-resistive sensor with a strongly pinned FM (reference) layer. This sensor would allow to easily align the two FM layers (free and reference) orthogonal to each other, giving rise to a linear response of the sensor's electrical resistance with respect to the applied magnetic field.

A detailed magnetic and structural analysis of the correlation between the EB, blocking temperature and the (111) texture of IrMn will be given. Moreover, the effects of replacing the NiFe layer by a CoFe layer on EB as well as the resistance measurements of a GMR sensor with two orthogonal anisotropy directions will be presented.

Exchange coupling between an antiferromagnetic (AF) layer and a ferromagnetic (F) layer plays an important role in spin valve heads and magnetic random access memories (MRAM). Even though the extensive experimental and theoretical investigations have been carried out [1], detailed mechanism of exchange biasing at AF/F interface is still unclear. In this study, we report a comparison of the magnetic force microscope (MFM) images between microstructured epitaxial and polycrystalline CoFe/MnIr bilayers to throw a light on the exchange biasing in microscopic scale.

(001) oriented epitaxial bilayers composed of Ir (5 nm) / Co₉₀Fe₁₀ (10 nm) / Mn₈₀Ir₂₀ (30 nm) / Au (30 nm) / Cr (10 nm) / MgO (001) were prepared by a molecular beam epitaxy (MBE) method. A static magnetic field of 200 Oe was applied along [100] direction during the deposition of MnIr and CoFe layers. The bilayers were annealed at 330 °C in a field of 850 Oe after the deposition. Polycrystalline bilayers were prepared in the same way as the epitaxial bilayer, except for the film construction of Ir (5 nm) / Co₉₀Fe₁₀ (10 nm) / Mn₈₀Ir₂₀ (30 nm) / Au (30 nm) / surface oxidized Si substrate. Magnetic properties of the sheet films were measured by alternating gradient field magnetometer and torque magnetometer. The structure of the film was characterized by *in-situ* RHEED and *ex-situ* X-ray diffraction. The films were micro-patterned by using e-beam lithography followed by Ar⁺ ion etching. The shape of the microstructured bilayers was checked by atomic force microscopy (AFM) and the magnetic domain structure was investigated by magnetic force microscopy (MFM).

RHEED observations and XRD profiles showed that the epitaxial bilayer has (001) orientation and grows on MgO(001) with the crystallographic relationship of Co₉₀Fe₁₀ [100] // Mn₈₀Ir₂₀ [100] // Au [100] // Cr [110] // MgO [100]. While the polycrystalline bilayers was confirmed to have (111) preferred orientation. Figure 1 shows torque curves for (a) (001) oriented epitaxial and (b) polycrystalline bilayers. Both bilayers exhibited almost the same exchange anisotropy (unidirectional anisotropy) of 0.2–0.3 erg/cm². Even though the field was applied along [100] direction for the epitaxial bilayer, the easy direction of exchange anisotropy deviated about 15 deg from the [100] direction. On the other hand, the easy direction of the polycrystalline bilayer is parallel to the direction of the applied field during the post annealing.

Figure 2 shows the MFM images of circular patterned CoFe/MnIr elements with 500 nm and 300 nm diameters. As shown in Fig. 2 (a), each epitaxial element has its own easy direction (exchange bias), while the mean direction of the exchange bias was confirmed to be consistent with the corresponding torque curve (Fig. 1 (a)). The distribution of easy direction was found to be significant for the 300 nm diameter elements (Fig. 2 (b)). In the case of the polycrystalline elements, the distribution of the easy axis was also found as shown in Fig. 2 (c), however the distribution for the 500 nm elements seems to be narrower than that for the epitaxial elements with 500 nm diameter. These results imply that the distribution is related to the crystal grain size and the magnetocrystalline anisotropy of the antiferromagnetic MnIr layer.

The significant enhancement of the thermal stability in Co/Cu/Co/IrMn spin valve through insert 1nm FeMn layer.

L. Wang, Q. Q. Qin, H. X. Wei, X. F. Han

Institute of Physics, Beijing, China

The Ta(5nm)/Co(4nm)/Cu(2.5nm)/Co(4nm)/Ir22Mn78 (10nm), Ta(5nm)/Co(4nm)/Cu(2.5nm)/Co(4nm)/Fe50Mn50 (10nm), Ta(5nm)/Co(4nm)/Cu(2.5nm)/Co(4nm)/Ir22Mn78 (1nm)/Fe50Mn50 (9nm) and Ta(5nm)/Co(4nm)/Cu(2.5nm)/Co(4nm)/Fe50Mn50 (1nm)/Ir22Mn78 (9nm) spin valve were fabricated, after half hour annealed at 473 K, we found that the GMR ratio with IrMn-based decreased dramatically while FeMn-based spin valve still kept the same value. Through inserting 1nm FeMn layer into the IrMn/Co interface, we found that the thermal stability of the IrMn-based spin valve can be improved greatly. Hysteresis loops and other microstructure analyse show that the inserting 1nm FeMn layer not only can increase the coupling energy of the Co/IrMn at the interface, but more important, due to the less content of the Mn in FeMn alloy than that of IrMn, it can also effectively reduce the Mn diffusion into the Co/Cu/Co interface which have a greatly influence on the GMR ratio. Since in MRAM and other TMR device, it is necessary to anneal at high temperature to improve the oxide layer, as a mostly common used AFM materials, the tunneling junction suffer from the Mn diffusion of the IrMn layer which greatly damaged the insulator interface, this work will give more choices for fabricating high quality spin valve devices for different applied field.

Exchange bias in Cu/Ni/FeMn trilayer with perpendicular magnetic anisotropy.

L. T. Tu, C. Kim

Department of Materials Science and Engineering, Chungnam National University, Daejeon, South Korea

I. Introduction

The exchange bias phenomena in ferromagnetic(FM)/ antiferromagnetic (AFM) typically exhibits a shift of the hysteresis loop for the bilayer film. Usually, the exchange bias is observed in (FM-AFM), with the magnetization of the FM film oriented in the film plane. However, recently, the exchange bias effect has been induced along the perpendicular magnetic anisotropy direction in bilayer and multilayer [1]. The perpendicular exchange bias was reported in [Co/Pt], [Co/Pd], [Pt/FeCo] multilayer with FeF₂, CoO, FeMn and IrMn.

In this paper, we study about perpendicular exchange bias in Cu/Ni bilayers with a FeMn film deposited on the top of Ni[5].

II. Experimental

Several series of trilayers with compositions Cu(100nm)/N(4nm)/FeMn(tFeMn nm)/Cu(5nm) were deposited on Si(001) wafers by dc-magnetron sputtering with base pressure of 2×10^{-7} Torr and Ar working pressure of 0.4 mTorr. During the deposition, a magnetic field of 250 Oe was applied perpendicular to the film plane. The values of tFeMn from 2 to 12 nm. Hysteresis loops, with the magnetic field applied normal to the film plane, were measured using vibrating sample magnetometry (VSM). The epitaxial orientation relationships and microstructural characteristics of the films were studied by X-ray diffraction (XRD).

III. Results and discussion

The dependence of FeMn thickness on the exchange bias field and coercivity in the Ni(4 nm)/FeMn(tFeMn nm) samples were showed in Fig. 1. The H_{ex} is zero for below antiferromagnetic critical thickness of 2 nm, then rapidly increases to maximum at tFeMn = 5 nm (H_{ex} =305 Oe) and reached to near saturation value at tFeMn = 8nm. The exchange bias field is decreasing in range from 5 to 8 nm of FeMn. Because the FeMn is antiferromagnetic but insufficiently pinned by magnetocrystalline anisotropy. As the FeMn thickness increases further, the Ni magnetization becomes more and more pinned and totally pinned above 8 nm. This is the reason for the exchange bias near saturation value [2]

The FeMn thickness dependence of coercivity in the Ni/FeMn system is also shown in Fig.1. The maximum coercivity resulted when tFeMn is 2nm[2,3].

The exchange bias field and coercivity are also studied as a function of angle. The angle θ is the angle between the magnetic field and normal to the film. The angle θ changes in sample rotation with respect to an axis lying in the film plane. Fig.2 showed when the field applied parallel with the film normal, the exchange bias field is obtained maximum value. The H_{ex} = 0 when the field applied in plane with film plane. The XRD pattern of Cu(100nm)/Ni(4 nm)/FeMn(5nm)/Cu(5nm) sample shows the (001) orientation for the Si and Cu layer (fig. 3) [3].

IV. Conclusion

The thin film of Cu/Ni/FeMn with perpendicular exchange bias has been investigated. The exchange bias field and coercivity were studied as a function of thickness. The maximum exchange bias field is obtained around 305 Oe at 4 nm of Ni and 5 nm of FeMn. The dependence of exchange bias field H_{ex} and coercivity H_c are also measured with maximum value when the field applied normal with film plane.

Parallel and perpendicular exchange biases in epitaxial FePt-FeMn multilayers with different crystalline orientations.

N. N. Phuoc, T. Suzuki

Information Storage Materials Laboratory, Toyota Technological Institute, Nagoya, Japan

Although perpendicular exchange bias has recently received much attention, its physical origin is still in controversy. In particular, the question that the AF spin structure at the interface, which is assumed to be important to the mechanism of perpendicular exchange bias, follows the AF bulk structure [1] or has a random canting distribution [2, 3] remains unclear. The present work is therefore motivated to study systematically the correlation between parallel and perpendicular exchange bias and the crystalline orientations to clarify that point.

Samples with the stacks of $[\text{FePt}(x \text{ nm})/\text{FeMn}(10 \text{ nm})]_{10}$ were fabricated onto MgO(100), MgO(110) and MgO(111) substrates using the ion beam sputter-deposition system with the base pressure better than 2×10^{-6} Pa. An X-ray diffractometer and a vibrating sample magnetometer were employed to characterize the structural and magnetic properties of the samples.

Figure 1-(a), (b) and (c) show the θ -2 θ XRD patterns for $[\text{FePt}(10 \text{ nm})/\text{FeMn}(10 \text{ nm})]_{10}$ multilayers deposited onto MgO(111), MgO(110) and MgO(100) substrates, respectively. The observation of the strong FePt and FeMn peaks corresponding to the crystalline orientations of the substrates indicate that samples are in fcc phase. The Φ -scans shown in Fig. 1-(d), (e), and (f) unambiguously demonstrate that the present samples are epitaxially deposited thin films. The rocking curves in Fig. 1-(g), (h), and (k) show that the sample grown onto MgO(100) has a narrower c-axis orientation than that deposited onto MgO(110) and MgO(111).

The dependences of parallel and perpendicular exchange biases (H_E), unidirectional anisotropy constants (J_K) and blocking temperatures (T_B) for $[\text{FePt}(x \text{ nm})/\text{FeMn}(10 \text{ nm})]_{10}$ multilayers deposited onto MgO(100), MgO(110) and MgO(111) are shown in Fig. 2. It is of interest to see that for the FePt thickness small, the value of exchange bias for samples grown onto MgO(111) is significantly higher than that grown onto MgO(110) and MgO(100) and consequently the J_K value in the case of MgO(111) is nearly independent of FePt thickness, presumably attributed to the role of the spin structure of the AF bulk, which may favor to be stable in (111) direction. Another interesting point is the discrepancy between parallel and perpendicular blocking temperatures, which can be interpreted in terms of the spin canting at the interface, thus causing the ordering in parallel direction is higher than that in perpendicular direction [3]. The ratio of parallel and perpendicular exchange biases (not shown here) is not only dependent on the crystalline orientation but also on the thickness of FePt, which will be further discussed in details in the presentation.

In summary, a systematic study of FePt-FeMn multilayers grown onto MgO substrates with different orientations has been carried out with some interesting results. In particular, the fact that the ratio of parallel and perpendicular exchange biases is strongly dependent on FePt thickness and crystalline orientation tentatively suggests that the role of interface anisotropy, random fluctuations of AF spins at the interface and the spin structure of AF bulk should be carefully taken into account for the study of perpendicular exchange bias mechanism.

Enhanced Exchange Anisotropy by ultra-thin $\text{Co}_x\text{Fe}_{100-x}$ ($x > 80$) Layer Insertion at the Interface of L1_2 -ordered $\text{Mn}_3\text{Ir}/\text{Co}_{65}\text{Fe}_{35}$ Bilayers.

 2. Department of Electronic Engineering, Tohoku University, Sendai, Japan

Large exchange anisotropy is indispensable for an ultra-high density recording in hard disk drives, because the decreasing element dimensions causes a decline of exchange bias properties in spin-valve devices. L1_2 -ordered Mn_3Ir can induce large exchange anisotropy in spin-valve tunnel magnetoresistance head elements [1], and possibly has a potential to further enhance the exchange anisotropy. Referring the case of disordered Mn-Ir, it was reported that the unidirectional anisotropy constant, J_K , shows a remarkable compositional dependence in $\text{Co}_x\text{Fe}_{100-x}/\text{MnIr}$ bilayer system. The J_K takes a maximum value at $x = 70$ and rapidly decreases with further increase of Co content as shown in Fig. 1 [2]. The rapid decrease of J_K at $x > 70$ might be due to a bcc-fcc phase transformation in $\text{Co}_x\text{Fe}_{100-x}$ [3]. We can thus expect to enhance the J_K when the $\text{Co}_x\text{Fe}_{100-x}$ ($x > 80$) maintains bcc structure. In this study, we successfully achieved the enhancement of the exchange anisotropy with the technique of ultra-thin $\text{Co}_x\text{Fe}_{100-x}$ ($x > 80$) layer insertion at the interface of L1_2 - $\text{Mn}_3\text{Ir}/\text{Co}_{65}\text{Fe}_{35}$ bilayers. Bilayer samples in a stack sequence of substrate/Ta(5)/Ru(10)/ L1_2 - $\text{Mn}_3\text{Ir}(10)/\text{Co}_x\text{Fe}_{100-x}(0.5)/\text{Co}_{65}\text{Fe}_{35}(4)/\text{Ru}(0.9)/\text{Ta}(3)$ (thickness in nm unit) were prepared on thermally oxidized silicon wafer with a magnetron sputtering apparatus. The substrates were held at room temperature during the deposition, except for that of the MnIr layer. The MnIr layers were deposited at the substrate temperature of 200°C and with the Ar sputtering gas pressure of 2.0Pa in order to obtain the L1_2 -ordered phase [1]. The $\text{Co}_x\text{Fe}_{100-x}$ insertion layers with various compositions were prepared by co-sputtering of Co and $\text{Co}_{65}\text{Fe}_{35}$ targets, and the Co compositions were ranged from 65 to 98 at.%. Thermal annealing was performed in vacuum at 320°C for 4hrs under applied field of 15kOe. The composition of insertion layer and thickness of each layer were determined with X-ray fluorescence analysis. The microstructure of the bilayers was examined with X-ray diffraction and grazing incident X-ray diffraction (GID) with Cu-K α radiation source. M-H loops were measured with a vibration sample magnetometer. The J_K was calculated with the equation of $J_K = M_s d_F H_{ex}$, where $M_s d_F$ is the areal saturation magnetization of $\text{Co}_x\text{Fe}_{100-x}/\text{Co}_{65}\text{Fe}_{35}$ bilayers, and H_{ex} is the exchange bias field. Fig.2 shows the change of J_K as a function of the Co composition in $\text{Co}_x\text{Fe}_{100-x}$ insertion layer. The J_K of the bilayer without insertion layer is 0.93erg/cm² as shown by open circle in Fig. 2. In the bilayers with insertion layer, the J_K increased with increasing the Co composition of the insertion layer and the maximum value of J_K was obtained at the range of 85 to 98 at.% of Co. Fig.3 shows GID profiles of L1_2 - $\text{Mn}_3\text{Ir}/\text{Co}_{65}\text{Fe}_{35}$ bilayers (a) without and (b) with the $\text{Co}_{90}\text{Fe}_{10}$ insertion layer. Thin and thick solid lines provide the profiles for as-deposited and annealed bilayers respectively. The peak at $2\theta_x = 44.7^\circ$ is assigned as bcc-CoFe(110) diffraction and fcc-CoFe does not contribute to this diffraction peak. In Fig.3 (a), there is no remarkable difference of the diffraction peak between the as-deposited and annealed bilayers. On the other hand, in Fig3 (b), we can observe the increase of diffraction intensity in the annealed bilayer. These results mean that crystal structure of the ultra-thin $\text{Co}_{90}\text{Fe}_{10}$ insertion layer was transformed to bcc structure by thermal annealing, following the bcc structured $\text{Co}_{65}\text{Fe}_{35}$ layer. Therefore, we can conclude that the enhancement of exchange anisotropy with ultra-thin $\text{Co}_x\text{Fe}_{100-x}$ ($x > 80$) insertion layer is owing to the bcc phase formation in the insertion layer.

Lateral grain size effect on exchange bias in polycrystalline FeNi/FeMn bi-layer films.

P. Sharma, T. Huang, A. Sun, J. Hsu
Physics, National Taiwan University, Taipei, Taiwan

Introduction

In this work the lateral grain size effect on exchange biased ferromagnetic (FM)/antiferromagnetic (AFM) polycrystalline bi-layer films has been investigated. In the past various investigations on grain size effect have been carried out [1-3]. The adopted approaches for altering grain size were the FM/AFM thickness, and deposition conditions etc. However, considering exchange bias as an interface phenomenon then only lateral grain size would play a part rather than its thickness. Indeed varying FM/AFM thickness changes the lateral grain size but to some certain extent the texture, grain orientation and interface roughness also changes. Therefore, the effect of varying FM/AFM thickness on exchange bias could be the combined effect of all parameters. In order to separate out the grain size effect, if by some means variation of lateral grain size is imparted without varying FM and AFM thickness and deposition conditions, its effect can be well understood. In this work, lateral grain size variation was achieved by depositing identical NiFe/FeMn bi-layer on the varying Ta buffer layer thickness, assuming that larger Ta grains would promote greater lateral grain area and so the coupling.

Experimental

In the present investigation, Ta(t nm)/NiFe(5 nm)/FeMn(20 nm) film with varying Ta thickness ($t = 5, 10, 15, 20, 25, 30, 35, 40, 45$ and 50 nm) were deposited on glass substrate by dc magnetron sputtering. During deposition process the base pressure was less than 7×10^{-6} Pa and Ar gas pressure was maintained at 0.27 Pa. The deposition rates for all layers were set at 0.1 nm/s. In order to produce unidirectional anisotropy, a magnetic field of the order of 24 kA/m was applied during deposition. No field cooling was carried out after deposition.

Results and discussion

The variation of exchange bias field (H_{eb}) and coercivity (H_c) with Ta thickness is shown in Fig. 1. It shows that exchange bias is monotonically increased from 6.4 kA/m ($t_{Ta}=5$ nm) to 18.7 kA/m ($t_{Ta}=35$ nm). Further increasing Ta thickness up to 50 nm, H_{eb} is slightly decreased. H_c is also found to increase gradually with Ta thickness. To understand this surprising increase in H_{eb} with identical NiFe and FeMn thicknesses, we have systematically investigated the influence of crystallographic texture, roughness and lateral grain size of FeNi/FeMn bi-layer from XRD, AFM and TEM studies respectively.

In the X-ray studies it was found that Ta thickness as well as its texture does not affect (111) texture and so the exchange bias field. Cumulative macroscopic roughness was found constant for all Ta thickness. Therefore, the contribution from roughness to H_{eb} is identical for all samples. Since we did not observe the texture and roughness effect, the increase in H_{eb} might be due to its grain structure. The cross-sectional TEM images of FeNi/FeMn bi-layer film deposited on $t_{Ta} = 5$ and 35 nm are shown in Fig. 2 (a, b). The lateral grain sizes at the interface with $t_{Ta} = 5$ nm underlayer are nearly 3 - 5 nm and 10 - 12 nm respectively. Ta underlayer grain structure clearly influences the growth of top FeNi and FeMn layers since large grains extend through interface to FeNi and FeMn layers. High-magnification images on the right hand of Fig. 2 show the columnar growth through grain-to-grain epitaxy mechanism, which confirms that lateral grain size of NiFe is also increased, even with the constant FM/AFM thickness. Since no texture and roughness effect were identified in identical bi-layer systems, we ascribe such increase in H_{eb} to the increase in lateral

grain size area, which consequently increases the interface coupling. The detailed description of all parameters will be presented in the full paper.

I. INTRODUCTION

The shift of a magnetic hysteresis loop away from zero field in a system composed of a ferromagnet (FM) coupled to an antiferromagnet (AF) when the FM/AF bilayer is field-cooled below the Neel temperature (T_N) of the AF is called exchange bias [1]. It is known [2] that the AF Mn ($T_N \sim 100$ K) can form different stoichiometric oxides such as AF MnO ($T_N \sim 119$ K) and ferrimagnetic Mn_3O_4 ($T_c \sim 42$ K), depending on the method of preparation and oxygen content during Mn-oxide deposition. In this work we investigate the exchange bias behavior in NiFe/Mn-oxide bilayers by incorporated different $\%O_2/Ar$ ratios during the bottom Mn-oxide layer deposition by ion-beam bombardment. The results indicate the metallic Mn layer provides stronger exchange coupling than the Mn-oxide layers when they are in contact with the top NiFe layer. Annealing the different Mn-oxide compositions results in a sudden decrease in H_{ex} that is attributed to the formation of the MnO phase. The structural evolution of the Mn and the Mn-oxide by ion beam bombardment and annealing is in good agreement with magnetic properties of the respective films.

II. EXPERIMENTAL METHOD

A dual ion-beam deposition technique [3] was used to prepare the NiFe (10nm)/Mn-oxide (20nm) bilayers. A Kaufman source was used to focus an argon ion beam onto a commercial $Ni_{80}Fe_{20}$ (at%) or the Mn target surface while the End-Hall source was used to clean or in situ bombard the substrate during deposition with mixture of O_2/Ar that was varied from 0% (Mn) to 41% (Mn-oxide) O_2/Ar . No external field was applied during deposition. Bottom Mn-oxide layers were annealed at 700 °C for 10 minutes using a rapid thermal annealing (RTA) method and then capped with the top NiFe layer. The crystal structures of the NiFe/Mn-oxide bilayers were characterized with x-ray diffraction (XRD) using a Rigaku D/MAX2500 diffractometer. A JEOL (JEM-2010) transmission electron microscope (TEM) operating at 200 kV was used for microstructural analysis. Magnetic measurements were performed in a commercial SQUID magnetometer (Quantum Design MPMS-7) where the thin film was field cooled (20 kOe) with magnetic field applied parallel to the film plane from 300 K down to 5 K. In these measurements, the exchange bias field, H_{ex} , is defined as the shift in the hysteresis loop along the field axis with respect to zero field.

III. RESULTS AND DISCUSSION

A smooth interface between the top NiFe layer and the bottom Mn-oxide layer was revealed via the cross-sectional TEM. The bottom Mn-oxide film layers prepared with 0% O_2/Ar consisted of the b.c.c. Mn ($a = 8.87$ Å) phase whereas composite Mn and rock-salt MnO ($a = 4.84$ Å) phases were found in films prepared with 8% O_2/Ar . However, increasing the $\%O_2/Ar$ to 41% O_2/Ar resulted in the formation of the tetragonal Mn_3O_4 ($a = 5.81$ Å, $c = 9.55$ Å) phase.

Magnetometry results have shown larger 5 K exchange bias fields (H_{ex}) in NiFe/metallic Mn bilayers compared to NiFe/Mn-oxide (8% to 41% O_2/Ar) bilayers. The NiFe/Mn bilayers exhibit the largest $H_{ex} \sim -310$ Oe amongst all samples. In addition, the decrease of H_{ex} with increasing $\%O_2/Ar$ (8 to 21 % O_2/Ar) was attributed to the in-situ oxidation reaction of the metallic Mn into MnO due to ion-beam bombardment [3]. Further, the larger H_{ex} when the bottom Mn-oxide layer was prepared with higher $\%O_2/Ar$ (21 to 41 % O_2/Ar) was attributed to the formation of the ferrimagnet

Mn_3O_4 . Surprisingly, a sudden drop in both the H_c and the H_{ex} was observed when annealing these Mn-oxide layers before being capped with a NiFe layer. The presence of the AF MnO phase after annealing seems to be the origin of the decreased H_{ex} and H_c due to weaker exchange coupling between the NiFe and MnO that is a result of the lower magnetocrystalline anisotropy of the MnO ($K \sim 280$ erg/cm³), compared to that for the Mn_3O_4 ($K \sim 10^7$ erg/cm³).

Effect of the ferromagnetic layer thickness on the blocking temperature in IrMn/CoFe exchange couples.

G. Vallejo-Fernandez, L. E. Fernandez-Outon, B. Kaeswurm, K. O'Grady
Physics, The University of York, York, United Kingdom

The exchange anisotropy across a ferromagnetic/antiferromagnetic F/AF interface is of great importance both from the fundamental and technological point of view. In order to achieve high recording densities in hard disk drives (HDDs), the reduction of the total thickness of the spin-valve stack is crucial [1]. Since the AF is the dominant layer in the total thickness of the sensor, most studies in the literature are focused on how to implement the thermal stability of the AF layer while reducing its thickness. Usually, the thermal stability of a given system is quantified in terms of the blocking temperature at which the exchange bias H_{ex} goes to zero. Factors such as the ordering parameter S , the AF grain size, seed layers, dilution concentration and the crystallographic orientation of the AF layer have been reported to have a dramatic effect [e.g. 1]. However, there is a lack of data in the literature regarding the effect of the F layer on the thermal stability of exchange bias systems [2]. In this work we present a detailed study on the thermal stability of IrMn/CoFe exchange couples as a function of the thickness of the F layer t_F .

Samples with composition Si/Ru(5nm)/IrMn(10nm)/CoFe(t_F)/Ru(10nm) where $t_F = 3, 4, 5, 8$ and 12nm were prepared using a HiTUS sputtering system [3]. Magnetic measurements were carried out using an ADE model 10 VSM fitted with a continuous flow cryostat enabling temperature control to better than 0.5K/hour. Bottom-biased structures were preferred to avoid changes in the microstructure of the AF layer ensuring that any changes in the magnetic measurements are due entirely to the F layer. Hysteresis loops were measured following a detailed measurement procedure where thermal activation is used to probe the state of order of the AF layer [4]. By increasing the temperature T_{ACT} at which the exchange couple is thermally activated with the F layer in negative saturation, the hysteresis loop of the F layer can be shifted along the field axis from negative to positive values. All the measurements are done in thermal activation free conditions. Examples of the hysteresis loops obtained following this protocol are shown in Figure 1a. Figure 1b shows the dependence of the exchange field on the thickness of the F layer showing the well known $1/t_F$ behaviour.

Figure 2a shows the distribution of blocking temperatures for the systems studied while the variation of the median blocking temperature $\langle T_B \rangle$ with t_F is shown in Figure 2b. For small F thicknesses, $\langle T_B \rangle$ decreases within error. However, for thicker F layers (12nm) a reduction of ~17% is observed.

In recent work we have described a method to calculate the anisotropy constant of metallic polycrystalline AF materials based on a measurement of $\langle T_B \rangle$ and a careful knowledge of the grain size distribution within the system studied [5]. In that work, the effect of the exchange field from the F layer H^* was neglected. By studying samples with different F thicknesses we can now quantify that effect. Preliminary data show that neglecting H^* induces a small deviation (<4%) in the measurement of K_{AF} when $t_F < 4$ nm. However, for thicker F layers (12nm) this deviation can be as big as 30%. This estimate is based on the extrapolation of the curve shown in Figure 2b, i.e. the case $H^* = 0$.

Probing the influence of in-plane roughness on magneto-resistance in spin-valves using off-specular reflectivity techniques.

J. Park¹, C. Furjanic¹, D. Draganova¹, C. Chen¹, S. M. Watson², J. A. Borchers², M. Carey³, P. Sparks¹, J. C. Eckert¹

1. Physics, Harvey Mudd College, Claremont, CA; 2. NIST Center for Neutron Research, Gaithersburg, MD; 3. Hitachi Global Storage Technologies, San Jose, CA

In recent studies of exchange-coupled multilayers, off-specular neutron reflectivity has played a key role in characterizing the field-evolution of in-plane magnetic domains and revealing local ordering between adjacent magnetic layers [1-3]. To investigate the effect of roughness on magneto-resistance in spin-valves (SV), we have used off-specular x-ray and neutron reflectivity to study two series of SV's with Si/SiO₂/5 nm Ta/3 nm Co₅₀Fe₅₀/1 nm Ni₉₈Fe₂/3 nm Cu/X Co₆₅Fe₃₅/1.6 nm IrMn/1 nm Cu/5 nm Ta with X = 11 or 15 nm produced by DC magnetron sputtering. Though the two series were produced during the same run, they have different structural roughness.

Specular x-ray reflectivity measurements indicate that the interfacial roughness for one of these sample series is larger as the fall-off of the scattering with increasing Q is much faster. Fits to the specular reflectivity of the "smooth" X = 11 nm sample suggest that the average roughness of the interface in the sample is ~1.2 nm, while the average roughness of the "rough" 11 nm sample is > 3 nm. Diffuse background measurements also show evidence of correlated in-plane roughness through the depth of the "rough" samples.

This roughness difference translates into significant contrast in magneto-resistance (MR) of the samples. The MR loops of the smooth sample (red line) and a rough sample (black line) measured at 6K are shown in Fig. 1. The most notable difference is the shift in the coercive switching field of the free layer. The coercive fields are estimated to be ~11.8 mT and ~16.1 mT for the smooth sample and the rough sample, respectively.

Previous specular PNR studies of these samples [4] revealed that domain walls parallel to the interfaces develop in the pinned layer upon field cycling in samples for X > 9 nm. To search for complementary perpendicular domain walls that give rise to magnetic diffuse scattering, we performed transverse Q_x scans for the X = 15 nm sample at fields of 32 mT and 670 mT at 5 K, corresponding to the antiparallel and saturated states respectively. The (++) and (- -) non-spinflip cross sections for a Q_z of 0.046 Å⁻¹, shown in Fig. 2, reveal a sharp peak at the specular position on top of a broad diffuse peak. The width of the diffuse peak does not change with field, and the splitting of the diffuse peak tracks that of the specular. The diffuse scattering thus seems to arise from structural in-plane roughness, consistent with the x-ray results. From the inverse of the full-width-at-half-maximum of the diffuse peak [1,3], we approximate an in-plane structural correlation length of 100 nm.

The characteristics of the off-specular scattering change with field, and a diffuse, magnetic spin-flip peak seems to emerge in the canted magnetic state [3] associated with the MR maximum during the second field cycle. Additional measurements are planned to determine if this scattering arises from the formation of in-plane magnetic domains.

From our current measurements, we thus far conclude that in-plane structural roughness (possibly induced by subtle differences in substrate surface preparation) leads to increased coercivity of the free layer in a rough SV sample. Future work will provide a detailed analysis of the transverse scans

in order to separate diffuse scattering from structural roughness, magnetic roughness and magnetic domain formation.

Intuitive operation of magnetically driven fish-type microrobot using smart interface.

T. Honda, K. Ono, J. Yamasaki

Department of Applied Science for Integrated System Engineering, Kyushu Institute of Technology, Kitakyushu, Japan

Introduction

Since a microrobot including a magnet can be operated by external magnetic fields, it would be suitable for difficult applications in industrial and biomedical fields. Based on this concept, some attempts have been made on microrobots working for pipeline inspection and treatment inside a human body [1,2]. On the other hand, we have proposed a new type of magnetically driven microrobot for amusement and educational use. In our previous paper, we demonstrated that a fish-type microrobot could swim like a real fish in water tank wound with a coil [3]. In order to improve its controllability, we have developed a turning control system using a smart interface. This paper describes its principle and testing results.

Structure and actuation principle

Fig. 1 shows a fish-type microrobot. It consists of a body balanced with a float and a weight, and a propulsive mechanism including an oscillator and a bending part. The oscillator is composed of a NdFeB magnet with a rotary axis and a pair of arms. The bending part is composed of a polyimide cantilever and a polyethylene caudal fin. The arms of the magnet and the both sides of the caudal peduncle are linked by means of two threads. Fig. 2 shows the actuation of the propulsive mechanism. When a magnetic field is applied perpendicular to the water surface, the magnet rotates due to magnetic torque and then one side of the arms pulls the thread, which causes the cantilever to deflect to one side. In alternating magnetic fields, therefore, two arms pull the threads alternatively. Thus the caudal fin oscillates and generates a thrust. In case of turning, the fin oscillation is biased to right or left side by applying the alternating magnetic field biased with DC magnetic field.

Smart interface

In our previous paper, the waveforms of the magnetic field were programmed beforehand [3]. Therefore, the operation feeling was poor. To solve this problem, we have proposed a smart interface that provides intuitive operation. Fig. 3 shows an interface, which consists of a plastic card with one end fixed by a gripper and other free. A strain gauge is attached to the fixed end, and connected to an amplifier supplying power to the coil. When the free end of the interface is manually bent, the magnetic field corresponding to the strain is generated in the water tank.

Testing results

Fig. 4 shows the waveform of the magnetic field in the drive coil while the microrobot was operated by the interface. To begin with the robot turned right by oscillating the interface biased right, and then turned left by switching the bias of the interface to the opposite side. The operation feeling was intuitive because the movement of the caudal fin synchronized with that of the interface.

Three-dimensional motion of a small object by using a new magnetic levitation system having four I-shaped electromagnets.

T. Ohji, H. Hara, K. Amei, M. Sakui
University of Toyama, Toyama, Japan

Introduction

In a common active magnetic levitation system, a floating object is controlled stably by an electromagnet with a narrow air-gap to reduce leakage flux. However, in order to move a floating object dynamically, it is necessary to arrange electromagnets for horizontal motion and to make an air-gap wide for vertical motion at the expense of leakage flux. Magnetically levitated micro-robot system enabling three-dimensional motion using a large-scale electromagnet with a pole-piece is reported[1]. We propose a new magnetic levitation system having a compact electromagnet, which composes of four I-shaped electromagnets.

Configuration and features

Fig. 1 shows the configuration of the controlled electromagnet, the floating object, and the control system. The controlled electromagnet comprises top iron plate, four NdFeB magnets, and four I-shaped electromagnets (EM1-4). The volume of the electromagnet is around 360 cm³. Permanent magnets magnetized in same direction generate bias magnetic flux and contribute to a power-saving and an air-gap increase. The floating object is composed of two NdFeB magnets and a light non-metal body. The mass of the object is around 50 g. Three displacement sensors detect the object position, and the information is fed to the control system through an A/D converter. Control signals calculated in a DSP are supplied to each I-shaped electromagnet through a D/A converter and a power amplifier. In order to control each x-, y-, and z-direction, four I-shaped electromagnets are divided into three sections as shown in Fig. 2. Four I-shaped electromagnets are regarded as a parallel connection in case of z-direction control. In case of x- direction, they are regarded as the parallel circuit of EM1 and EM3 and the parallel circuit of EM2 and EM4, and an inversed current is applied to each circuit. By this way, each controller for stabilizing the object can be designed separately. Finally, calculated three control signals are allocated to four input signals through a V-converter.

Experimental results of three-dimensional motion

By using model-following servo control technique, the stable levitation and three-dimensional motion were achieved. Fig. 3 shows the trajectory of the floating object. The deviation of the actual position from the desired position in continuous motion is less than 0.8 mm. Fig. 4 shows the input voltage change of each I-shaped electromagnet. It turns out that the electromagnet controls the behavior of the object while creating the magnetic field for the circular motion.

Conclusions

The proposed magnetic levitation and translational motion system having simple and compact controlled electromagnet is fabricated in our laboratory. Smooth and wide-ranging three-dimensional motion was achieved experimentally.

A Novel Design of a Disk-Shaped Bearingless PM Motor for Artificial Hearts.

J. Asama, Y. Kishi, A. Chiba

Electrical Engineering, Tokyo University of Science, Noda, Japan

I. Introduction

A centrifugal pump type of artificial heart supports a blood circulation of patients from serious heart disease. For no blood contamination, a long term use, and low blood damages, mechanically frictional parts, such as ball and slide bearings, should be eliminated in an artificial heart. To meet these demands, magnetic bearings and bearingless drives are applied [1]-[3]. Furthermore, a physical structure of the artificial heart should be as thin as possible because these devices are often implanted vertically in the lower side of the patients. In this paper, a novel design of a disk-shaped bearingless permanent magnet (PM) motor is proposed for implantable centrifugal artificial hearts. The height of the proposed bearingless PM motor is designed to be 10mm. The objective of this paper is to demonstrate the effectiveness of the proposed bearingless PM motor using the finite element method (FEM).

II. Principle of Bearingless PM Motor

Fig.1 shows the exploded view of the proposed bearingless PM motor. The stator consists of twelve U-shaped magnetic cores. Two independent motor and suspension windings are wound around these cores. End windings expand in the radial directions. In this way, this bearingless motor can be thin.

The rotor consists of two disks (upper and lower) and a PM ring. In the disk, PMs are magnetized in the radial direction (radial PM) and inset into the rotor disks. In Fig.2, the PM ring is magnetized in thrust direction (thrust PM) and inserted between these disks. Suppose the magnetized direction of the thrust PM is upward, those of the upper and lower radial PMs are inner and outer directions, respectively. The thrust PM flux flows in the rotor and stator cores through air-gaps. Therefore, this bearingless PM motor works as an eight-pole synchronous motor.

The radial rotor motion is actively controlled. By exciting the suspension windings, unbalanced magnetic field is generated at the air-gaps, and then, the radial suspension force is generated. Thrust and tilting motions of the rotor are passively restricted by the bias PM flux. Thus, the rotor can be levitated.

III. FEM Analysis Results

It is noted that the height of the bearingless PM motor is 10mm. The rotor diameter is 45mm. Other analysis conditions are omitted in this paper. First, radial suspension force was calculated when the current is applied so as to produce the force in the X-axis. Although the suspension force was larger than the PM attractive one, the direction of suspension force does not correspond to the X-axis at a certain rotating angular position, θ_r . This error is evaluated by using an angle between the force direction and the X-axis, ϕ_e . In the case of the winding configuration shown in Fig.3a, the error angle ϕ_e was large, as shown in Fig.4. To decrease it, both an angle of radial PM arc, ϕ_{pm} , and a winding configuration are changed. As a result, ϕ_e was minimized. In addition, thrust and tilting stiffnesses under this analysis condition are high enough for magnetic levitation. It is concluded that the disk-shaped bearingless PM motor is feasible.

Effect of the active damper coils of the superconducting magnetically levitated bogie in case of acceleration.

S. Ohashi

Electrical and Electric Engineering, Kansai University, Osaka, Japan

A superconducting magnetically levitated (JR Maglev) transportation system has been developed in Japan. Fig.1 shows a cross section of the system. This system which is based on the side wall electrodynamic suspension (EDS), keeps the air-gap length at about 10 cm. Although the EDS system has the advantage of stable levitation without active control, the result of the numerical simulation shows that the damping factor of the levitation system is small. So the active damper coil system has been proposed.

Levitation forces is generated by passing the SC coils on the bogie[1]. The eight-figure null-flux connection is used for the levitation coil on the ground. If the bogie passes under the center of the eight-figure coils, levitation force is generated. Levitation force is calculated by the virtual displacement method. Current induced in the levitation coils is calculated as follows[2]; the EDS system is given as an air-core coil system, and modeled as electric circuits. Then solving the electric circuit equations, we can calculate the current of the levitation coils. The motion of the bogie is calculated by putting these electromagnetic forces. Iterating these procedures, the transient motion of the bogie is given. Fig. 2 shows the arrangement of the active damper coils. They are set in front of the SC coils. Voltage is applied on them to control the vibration of the bogie. Fig.3 shows method for control against vertical oscillation. Because eight-figure connection is applied on the levitation coils, the polarity of the voltage applied on the upper and lower damper coils are different. The calculated results show that the active damper coils works effectively when the voltage in proportion to the vertical acceleration of the bogie is applied [3]. Their dimension is defined as follows; the energy consumed in them is calculated when the bogie oscillates vertically for the natural oscillation. The damper coils when the energy takes maximum value is defined as the optimal one.

Running simulation of the bogie is shown. Vertical oscillation of the bogie when the bogie runs at first $v=120$ m/s and accelerates up to 140 m/s. As velocity of the bogie is changed, vertical position of the bogie is changed. Thus vertical oscillation of the bogie occurs. Fig.4 shows without damper coils, 5 with passive damper coils and 6 with active damper coils (as shown in Fig.3). Effect of the damper coils are clearly shown. Effect of the damper coils under other bogie condition and characteristics against the bogie acceleration will be shown in the final paper.

Assessing the Maglev Force Capabilities of Two Passive Flat Guideway Topologies when using Electrodynamic Wheels.

J. Bird

1. Advanced Technology Center, General Motors Corporation, Torrance, CA; 2. Electrical and Computer Engineering, University of Wisconsin-Madison, Madison, WI

Despite high-speed magnetic levitation vehicles (maglev) being commercial available, intercity urban planners world-wide continue to balk at the immense capital cost associated with installing currently available maglev designs. This is unfortunate since maglev has some unique characteristics, such as low pollution and high-speed. If the maglev guideway construction costs could be brought radically down then perhaps maglev would be more frequently used. In order to minimize the guideway costs the guideway needs to be passive (non-electrified) and preferably horizontally flat. Flat passive guideways will also be more easily integrated into the existing transportation infrastructure. Flat guideways can also make use of electromagnetic directional switching [1] rather than mechanically moving guideways, and are less likely to accumulate debris and snow; they also create less aerodynamic drag forces. Two flat passive guideway topologies shown in Fig 1a & 1b are assessed in this paper. Using these guideways a vehicle would create the suspension and thrust forces by electromechanically rotating the magnetic rotors, also called electrodynamic wheels, shown in Fig 1a, 1b, above the split and dual split-sheet guideways. The forces are created by the induced eddy currents in the guideway, thus there is a slip speed defined as $s = \omega \cdot r - v$ (ω =rotor mechanical angular velocity, r =outer radius, v =translational velocity). A lateral re-centering force is created when the magnetic rotors are offset from the center. Numerous such wheels are needed for a full size vehicle and dynamic control is essential. An onboard power source or power transfer to the vehicle will be needed and the vehicle will need to run on wheels at very low speeds. High efficiency is possible when using multiple electrodynamic wheels in series [2]. This paper focuses on assessing the ability to create sufficient lateral re-centering guidance forces when the wheels are laterally off-center. The 3D A- Φ steady-state convective diffusion model presented in [3] is used to calculate the forces. The 4 pole-pair Halbach rotor shown in Fig 1c has been used. The re-centering split-sheet guideway force shown in Fig 1a is dependent on the split sheet current difference, as seen in Fig 2a and 2b. In contrast, the dual rotor and dual split-sheet topology create re-centering forces when offset onto the guidance sheets located on either side of the guideway (see Fig 2c). The full paper shows that the dual design creates greater re-centering guidance force. Due to limited space only an example of the split-sheet guideway forces are shown. The iso-field plot for the A- Φ model used to obtain the results is shown in Fig 3a and the resulting lift, thrust and lateral restorative forces are shown in Fig 3b-3d. The forces are small because the experimental setup parameters have been used (ie: Halbach rotor OD=0.1m, width=0.05m, guideway width=77mm etc). The results show that relatively high lateral forces can be created albeit at the expense of a reduced lift and thrust force. The lift and thrust force can be improved by using a greater rotor width (Fig 3e). More results given in the full paper.

The left-to-right ratio is defined as $L_z = F_{y1}/m \cdot g$ where F_{y1} is the left force and $m \cdot g$ is the mass and gravity of the Halbach rotor.

Magnetic levitation with minimum power consumption using disturbance compensation.

J. Ahn¹, S. Kim², J. Lee¹, J. Choi³

1. Electrical Engineering, Hanyang University, Seoul, South Korea; 2. Electrical Engineering, Yuhan College, Buchon, South Korea; 3. Industry Application Research Division, Korea Electrotechnology Research Institute, Changwon, South Korea

In the super clean process as semiconductor or LCD manufacturing process, magnetic levitation and transportation system without external power supply is suitable because there is no mechanical coupling between stator and mover, then it doesn't make any dust. However there is no external power supply, the power consumption has to be kept in its minimum, the zero-power levitation control must be adopted.[1] The internal non-linearity of magnetic levitation system makes itself unstable, the conventional control method cannot sustain its stability with disturbances. Luenberger observer, robust levitation controller and other non-linear control theories had been adopted for compensating its non-linearity. They were effective but difficult to implement because they had complex structure. Disturbance Observer(DOB) has been focused because of its simplicity and characteristics of frequency response which is suitable for electro-mechanical system.[2] Therefore the zero power controller with DOB is proposed in this paper. The disturbance is considered as load variance. The system non-linearity and parameter uncertainty are compensated by DOB, it is possible to implement relatively simple and robust zero power levitation controller. The proposed method is verified by simulation and experiment.

Introduction

The magnetic levitation (Maglev) train is one of the best candidates for new-generation transportation system because they are environment-friendly, compact, light-weight and suited to mass-transportation [1]. Therefore, the study on propulsion, levitation and guidance system for the Maglev train has been developed. Especially, in order to improve their reliability, particular attention to design and control of the levitation systems has been increased.

Typically, there are three types of levitation technologies: electromagnetic suspension (EMS), electrodynamic suspension (EDS), hybrid electromagnetic suspension (HEMS). The EMS is inherently unstable due to the characteristics of the magnetic circuit. Therefore, precise air-gap control is dispensable in order to maintain the uniform air-gap. However, EMS is easier than EDS technically and it is able to levitate by itself in zero or low speeds. Also, EMS requires a much smaller variation of the current's amplitude as compared with HEMS because the permeability of permanent magnet (PM) is unity [1-3].

Therefore, this paper deals with design and dynamic analysis of electromagnets having rectangular cross-section for levitation applications. First, by applying equivalent magnetic circuit (EMC) method to analysis model shown in Fig. 1(a), initial design for electromagnets is performed. And then, on the basis of the initial design results and 3-D finite element analysis (FEA) model shown in Fig. 1(b), detailed design for those is also accomplished. Second, as shown in Fig. 2, the testing apparatus including the electromagnet and a driver is manufactured. Finally, in order to confirm the validation of the designed electromagnet, this paper investigates using control concept of 1-axis suspension system shown in Fig.3 that the uniform airgap is maintained under required load weight conditions, and required levitation force is produced under rated current. In particular, the influence of temperature of windings on levitation control is investigated in detail.

Results and Discussion

Figure 4 shows the measured results for temperature of windings, current of the electromagnet and maintained air-gap in levitation system. It can be seen that current of the electromagnet is much affected by the temperature of windings, which results in the failure of the precise air-gap control due to variation of magnetic levitation force. It can be judged that this phenomenon is caused by the variation of the winding resistance according to temperature of windings. In order to solve this problem, the block diagram shown in Fig.3 should be modified to make the gain (K_p and T_d) have not fixed but flexible value considering windings temperature. More detailed results and discussion will be given in final paper. The mathematical expressions related to the EMC methods, state and output equation used in Fig.3 will be also given in final paper.

Basic Characteristics of an Active Thrust Magnetic Bearing with a Cylindrical Rotor Core.

K. Hijikata¹, S. Kobayashi¹, M. Takemoto¹, Y. Tanaka¹, A. Chiba², T. Fukao¹

¹ Mechanical Systems Engineering, Musashi Institute of Technology, Setagaya-ku, Japan; ²

Electrical Engineering, Tokyo University of Science, Noda-shi, Japan

Magnetic bearings (MBs) can suspend rotor shafts by electromagnetic force without mechanical contacts or lubrication. Therefore, the MBs have advantageous features such as high rotational speed, maintenance free, using in specific environments and low acoustic noise. Accordingly, the various types of MBs have been developed and commercialized for application to special blowers, LNG pumps, turbo-molecular pumps and all that [1-5]. In these MBs, thrust magnetic bearings (TMBs) with thrust disks are generally used for active suspension control of thrust direction [2-4]. However, the thrust disks, which have large diameter, have caused various problems such as worsening performance to assemble or to disassemble and limiting rotational speed. Accordingly, this paper proposes a novel structure of an active thrust magnetic bearing using a small cylindrical rotor core without the large thrust disk. It is shown with 3D-FEA and experiment that the proposed TMB with the cylindrical rotor core is effective in producing characteristic features.

Fig. 1 shows the structure of the proposed TMB. The proposed TMB has the simply cylindrical rotor core. The stator is composed of an E shape core and permanent magnets. In addition, suspension windings in two slots of the E shape core are wound in the same direction and are connected in series.

Fig. 2 shows the principle of the thrust force generation. The excitation flux ψ_{mag} is generated by permanent magnets. The cylindrical rotor core is magnetized at 3 pole of N-S-N by the ψ_{mag} . If the suspension current flows in the suspension winding, the suspension flux ψ_s is generated as shown in Fig. 2. It is evident that the flux density in the left-side air gap is increased. On the contrary, the flux density in the right-side air gap is decreased. Therefore, this superimposed magnetic field results in the thrust force acting on the rotor core toward the left direction.

Fig. 3 shows the relationship between the thrust force and the suspension current analyzed with 3D-FEA. The dimensions of the proposed TMB are shown in Table. 1. It is seen that the thrust force is almost linearly increasing according to the suspension current. In addition, when the current density of the suspension current is 6A/mm², the thrust force is 163.4N which is 2.5 times larger than the rotor-shaft weight of the experimental machine. Thus, it is found that the proposed TMB with the cylindrical rotor core is effective in producing the thrust force. In the full paper, other analysis results and experimental results of the experimental machine will be provided in order to make clear the basic characteristics of the proposed TMB.

Magnetically-Levitated Steel Plate Conveyance System Using Electromagnets and a Transverse-Flux Linear Induction Motor.

J. Choi, Y. Baek

Mechanical Engineering, Yonsei University, Seoul, South Korea

To maintain high-quality steel plates is very important to such processes as painting and coating in the steel industry. However, a roller-based steel plate conveyance method widely used is difficult to ensure the high quality of steel plates due to its scratches by friction. One of the solutions for this problem is to use magnetic levitation in conveying steel plates.

Magnetic levitation can maintain the high quality of steel plates during processes because of its noncontact characteristics. As a study on steel plate conveyance and magnetic levitation, Hayashiya et al.[1],[2] proposed two combined lift and propulsion systems using electromagnets and transverse-flux linear induction motors (TFLIMs). Their experimental results are focused on the effects of the levitation force of a TFLIM on the levitation behaviors of the systems, so the conveyance behaviors are not shown.

This study presents a novel-concept noncontact steel plate conveyance system. The novel concept is to use an unbalanced force generated by the deviation of the center-of-mass of a steel plate from the origin of a reference frame and a thrust force generated by a TFLIM for steel plate conveyance. These two forces are summed and used as a total thrust force in our conveyance system to enhance its conveyance performance. And also its experiment results are presented to show the behaviors during levitation and conveyance.

Fig. 1 shows the components of the system and its photograph. Also, the system responses during levitation and conveyance are shown in Fig. 2. Fig. 2(a) presents the z-axis position of the steel plate used in this study. After a conveyance experiment starts at 0.7 sec, the levitation forces by the TFLIM affect the levitation position of the steel plate to a constant level. We observed that the z-axis stability of the system is maintained. Figs. 2(b) and 2(c) are the roll and pitch motion data of the steel plate, respectively. The roll motion is bounded within the stable limit cycle and the pitch motion is changed due to the conveyance experiment right after 0.7 sec. The pitch motion at the initial state is negative because of the deviation of the initial position of the steel plate from the origin of the reference frame. So, this phenomenon affects the conveyance motion at a small movement of about -0.2 mm in the x-axis direction as shown in Fig. 2 (d). However, during the period of the conveyance motion, the pitch motion is changed to the positive direction and also the conveyance motion is directed to the positive x axis. We observed that the conveyance motion can be generated from a combined force of the thrust by the TFLIM and also the force due to the deviation of the center-of-mass of the steel plate. Fig. 2(d) has a lower-level position resolution due to the measuring resolution of the laser displacement sensor compared to Figs. 2 (a), (b) and (c) collected from the capacitance-type gap sensors.

This study proposed a noncontact steel plate conveyance system. The presented method to improve the ability of the conveyance movement of the system is to use the effect of the moment generated by the deviation of the center-of-mass of a rigid-body steel plate. This method was integrated with magnetic levitation and a transverse-flux linear induction motor. A prototype of the conveyance system was built and its experimental results were presented to verify the feasibility of the proposed concept.

Combination resonance of a rigid body levitated above a diamagnetic slab.

T. Sugiura, T. Hosono

Mechanical Engineering, Keio University, Yokohama, Japan

According to recent research, permanent magnet can be levitated stably in a static magnetic field by using a diamagnetic material[1]. This method of levitation has an advantage over other ones: intrinsic stability without control under room-temperature condition. Thus its industrial applications such as efficient rotary bearings or mass transportation can be expected. So far there have been some researches on static stability of diamagnetic levitation, but its dynamics has not been treated so much. This research investigates nonlinear dynamics of a rigid body levitated over a diamagnetic slab.

In our model shown in Fig.1, the rigid body consists of a bar and two permanent magnets attached at its both ends. This rigid body can be stably levitated without any control, only by an attractive force from a lifting magnet placed over the levitated body and also by a repelling force from a diamagnetic material placed under the levitated body. Now we consider that the lifting magnet is externally excited in the horizontal direction sinusoidally.

First, the equations of motion describing translation and rotation of the rigid body have been derived, using an analytical expression of nonlinear magnetic force. This expression can be obtained by magnetic dipole approximation of the attached magnets and by the mirror image method for evaluating diamagnetic response. These equations show nonlinear coupling between two eigenmodes: vertical translation and one of two modes caused by coupling of horizontal translation and rotation. This nonlinear coupling can lead to combination resonance of these eigenmodes.

Numerical results of motion of the rigid body have been obtained by the Runge-Kutta method. Figure 2 shows horizontal motion of the lifting magnet shaken externally and vertical motion and rotation of the levitated body, displaying their time histories and their spectra. It can be found that the nonlinearly coupled two eigenmodes mentioned above show their resonance at their eigenfrequencies, respectively, at the same time when the excitation frequency of the lifting magnet is the sum of those eigenfrequencies. This resonance is what is called combination resonance. Numerical results of frequency responses show that this combination resonance occurs only when the excitation frequency is in the neighborhood of the sum of those eigenfrequencies. Frequency responses also show a soft-spring tendency of this resonance.

Experiments have also been carried out, using a high-speed camera. Figure 3 shows experimental results of combination resonance, corresponding to Fig.2. Experimental results have verified our theoretical and numerical predictions.

Dynamic shielded room for biomagnetism.

D. Costandache, O. Baltag

University of Medicine and Pharmacy "Gr.T.Popa", Iasi, Romania

Abstract. The paper presents a shielded room made from nonferromagnetic materials used for biomagnetic studies and measurements in ambient electromagnetic environment. The shielded room is placed in the centre of a triaxial Helmholtz coil system of big dimensions for dynamic control and compensation of the natural geomagnetic perturbations and the fields produced by human activity. The technical solutions and the performances of the installation are presented.

I. INTRODUCTION

The paper presents a complex installation formed by a shielded room made from nonferromagnetic materials placed in a triaxial Helmholtz system for compensation and dynamic control of the external magnetic field. This installation is used for basic studies and researches in biomagnetism and biomedical diagnosis.

The aluminum material selection has been done after measuring the shielding coefficients to audio range frequencies (20 Hz \sqrt 20 KHz). The paper presents the method employed for shielding coefficient evaluation for different materials (Al, Copper, brass).

II. DESCRIPTION OF THE INSTALLATION

The room having the dimensions (3000 x 2000 x 2000)mm is made from aluminum sheets of 12 mm thickness. The room is mounted on a wood laminated structure in the centre of the triaxial Helmholtz system.

The triaxial Helmholtz system which allows the compensation on the three directions of the low frequency magnetic fields is realized from three pairs of large square Helmholtz coils, having the dimensions (4000 x 4000 x 4000)mm. The currents from the coils are controlled by a triaxial magnetometer. Each coil has two windings, one for manual compensation and the second for automatic control. The ratio of the two coils constants is 1/5.

The first coil allows the manual compensation of the continuous component of the magnetic field vector on the three directions (X, Y, Z).

The second coil allows the compensation of the alternative and slow variable components of the earth magnetic field using an automatic system controlled by a triaxial magnetometer. The magnetometer is working in a negative feedback system. The negative feedback loop is closed by the Helmholtz coils field where is placed the triaxial transducers block.

This structure presents the advantage of a flexibility and a high dynamic control of the magnetic field.

The manual control system consists from a current amplifier stage voltage controlled, using power operational amplifiers. A digital-analog converter gives the command voltage. The field programmed value is indicated (by means of an alphanumeric keyboard) on a digital display. The three channels for manual control are identically; the differences are the values of the coils constants, caused by different dimensions of the three coils.

The automatic control system is working in negative feedback loop on each channel. For each channel the feedback loop is closing in a chain made from: transducer – magnetometric channel – current source voltage controlled – Helmholtz coil – transducer. The three channels are independent calibrated. The response frequency of the channels is between (0 \sqrt 400) Hz.

III. RESULTS AND PERFORMANCES

Experimentally was determined the aluminum shielding coefficients for alternating fields by using a simple installation. The installation consists from a magnetic field generator coil supplied by an

audiofrequency generator and a search coil magnetometer. The measurements was performed for the frequency range (20 \sqrt 8000) Hz.

The compensation range of the earth magnetic field is \pm 5.10-5 T (50.000 nT). The compensation level is almost 10-9 T (1 nT) residual field. The field is homogenous (inhomogeneity 10-4) in a volume having the dimensions (0,8 x 0,8 x 0,8) m.

Magnetic shielding design for magneto-electronic devices protection.

W. Wang, Z. Jiang

Electrical Engineering, University of Wisconsin - Milwaukee, Milwaukee, WI

With rapid progress in Magnetic Random Access Memory (MRAM) development, shielding for MRAM and other magneto-electronics devices becomes more important. Traditionally, magnetic shielding is done by cylindrical shells with length to diameter ratio greater than one [1]. Such shielding shapes are not compatible with the form factor of electronic chips, boards or systems. Novel magnetic shielding designs with low length to diameter ratio are needed. In this paper, we introduce a shielding strategy and demonstrate a case study to achieve shielding factor above 1000 with cylindrical shell length to diameter ratio below 0.3 and end-cap openings for signal and power I/O connections.

Although the active shielding is an efficient shielding approach, it demands an always-on power supply. This limitation partially off-sets the advantage of non-volatility in MRAM and other magneto-electronic device. Therefore, the passive magnetic shielding is preferred.

Traditionally, the challenge on passive magnetic field shielding is in the trade-off between shielding efficiency and shell volume/mass. For magneto-electronics shielding, there are three new challenges: (1) form factor. Since the magneto-electronic devices often co-exist with other electronic devices, the shielding shell should maintain a form factor that compatible with other components in the system, i.e. a cylindrical shell with length to diameter ratio much less than one. (2) Openings for signal and power I/O paths. 64 bits or 128bits signal buses are common in today's systems. Openings for such wide bus can significant degrade the shielding factors. (3) Signal path performance impact. System performances rely on the link speed among its components. For example, computer system performances heavily depend on the bus speed between CPU and DRAM. The shielding should not increase the critical signal bus lengths so that the signal link performance gets degraded.

Magnetic shielding for magneto-electronics can be applied in chip, board or system level. Shielding entire system leads to large volume and mass penalty. In contrast, the chip level shielding may impact the signal link performance between shielded magneto-electronic device and other electronic devices outside the shielding volume. Therefore, the board level shielding is the practical solution, since the critical on-board signal bus performance is not affected. And the volume/mass impact is acceptable.

For board shielding, the design goals are: (1) low cylinder length to diameter ratio; (2) multiple openings on end caps for signal and power I/O connections. The opening size should be large enough to handle wide bus bundles.

We propose a multi-layer shielding with mis-aligned openings on one side of the end caps. The I/O bus paths are similar to the flip chip packaging used in semiconductor IC chips. Fig. 1 shows a two-layer shell structures. The openings on the end caps are mis-aligned so that there is no direct path for external magnetic field penetrates into the protected volume. Each pair of openings on end-caps forms a channel for signal bus bundle. In most of electronics system, the time delay skew among all the bits within a bus group should be minimized. All those bits should be connected to outside in the same bundle to minimize link length skew.

The shielding effects of the proposed design are simulated numerically by using Maxwell 3D simulator. In the simulation, the inner cavity diameter is set at 100mm with depths of 10mm, i.e., length to diameter ratio of 0.1. The shell material is 0.5mm thick mu-metal. Both axial and radial gap are 10mm. On one side, the end-caps have 15mm diameter openings, while the other side uses closed

end caps. The external magnetic field is set at 1 G. Since the axial shielding factors are much lower than radial shielding factors, we focus our efforts on axial shielding factors. Figure 2 shows axial shielding factor varies with the separation of the openings. Fig. 2 (a) shows angular dependency for two openings on the same circle with radius of 25mm. The axial shielding factor increased from 64 to above 1000 after 45 degrees, which is equal to center-to-center distance at 1.3x of the opening diameter. Fig. 2(b) shows the axial shielding factor dependency on the radial separation. The shielding factor reaches to 1000 after the separation of the 1.3x of opening diameter. Based above data, multiple pairs of openings can be simultaneously placed. Each pair provides a channel for one signal/power I/O bus bundle.

In summary, we proposed a novel shielding structure to protect the circuit board with the magneto-electronics devices. A numerical simulation based case study demonstrates the feasibility of the proposed shielding strategy.

Measurement and calculation of shielding performance of reinforced concrete structures.

M. Zhang, Z. Zhao, X. Cui

North China Electric Power University, Baoding, China

1. INTRODUCTION

Reinforced concrete constructions can be found everywhere. In substation, with the placement of protection devices into the switchyard, protection equipments may be destroyed seriously by the intense transient process for bad shielding performance of the reinforced concrete relay cell during the operation of switches. For example, as the power magnetic field more than $3\mu T$ is not allowed for CRT display, the shielding effect of reinforce concrete relay cell to magnetic field is important for the work of CRT display placed in relay cell. Therefore, it is necessary and significant to identify the shielding performance of reinforced concrete constructions. [1]

In this paper, a rigorous method with fewer unknown variables is proposed on the basis of method of moment and equivalent principle. And the shielding effectiveness of different concrete structures are measured and calculated.

2. DESCRIPTION OF THE APPROACH

Taking a general reinforced concrete building as an example, the considered space can be separated into three parts, namely the outside of the building, inside of the building and in the concrete. Surface cells with surface current are assumed on both the inner side and the outer side of the concrete. The outer field of the building is generated by the surface currents on the outer side of the building as well as the incident field. The field inside the building is generated by the surface currents on the inner side. While the field in the concrete itself comes from the surface currents on the inner side and the line currents distributed on the steel grid. Based on equivalent principle, the equations can be obtained on both sides of the concrete, from which the surface currents and the resulting electromagnetic fields can be obtained.

The equations can be solved by the Gauss elimination method to obtain the distribution of the electric and the magnetic currents on these surfaces. The electromagnetic fields inside and outside of the enclosure and the shielding effectiveness of the enclosure can be obtained as well.

3. MEASUREMENT AND CALCULATION OF SHIELDING EFFECTIVENESS

In order to obtain the shielding effectiveness of the reinforced concrete, several effect factors have been analyzed. Fig.1 and Fig.2 shows the electric and magnetic shielding effectiveness of concrete structure with metal grids, the steel conductor have diameter of 10mm and space of 200mm, the shielding performances of 0.2m from the center of $2m \times 2m$ single layer concrete and the conductivity of the concrete is $75.2\text{ohm} \cdot m$, the relative permittivity is 9.4, the thickness of the concrete is 0.2m.

It is obvious that at low frequency, the magnetic field shielding effectiveness is not obviously for the pure concrete. And for the reinforced concrete, at low frequency the shielding effectiveness is little different, but for the frequency more than 1MHz, the wire grid buried in the concrete shows its effect.

CONCLUSION

A method based on method of moments and equivalent principle suitable for estimation of the shielding effectiveness of reinforced concrete constructions is used. And the shielding effectiveness of different concrete structures are measured and analyzed.

Reduction of magnetic shaking flux leakage from loosely coupled cylindrical magnetic shield shells having active compensation.

I. Sasada, R. Takahashi

Applied Science for Electronics and Materials, Kyushu University, Kasuga, Japan

We have proposed a new method of magnetic shielding by combining sets of a coil to carry compensation current and a backing up magnetic thin plate [1]. In this method, a compensation current generates repulsive forces acting on the environmental magnetic fields and a magnetic thin plate provides a good magnetic pathway to the compensating magnetic fluxes so that they exist only on one side of the thin plate. We have demonstrated that magnetic shielding factor as large as 3000 can be obtained with a pair of magnetic shells not connected with each other (see Fig. 1). By applying magnetic shaking technique [2] to the magnetic layers in the shell, the thickness of the layer can be made thinner due to a large enhancement of the magnetic permeability.

Unlike a full cylinder, a separate magnetic shell does not have a closed magnetic path for shaking magnetic fluxes, therefore the shell is prone to leak shaking magnetic fluxes. In this paper, an efficient method for reducing shaking leakage from magnetic shells are investigated.

Fig. 1 shows a cross section of a separate magnetic shield (left half) whose size is one-third of that of a magnetic shield we have planned to use for the MCG measurement. m1~m3 are magnetic layers consisting of 11 stacks of Metglas amorphous tapes. m2 and m3 are equipped with a toroidal shaking coil whose conductors are indicated a1, a2 and b1, b2. Spacing between m2 and m3 is 2 mm and that between m1 and m2 is 4 mm. The number of turns of the outer shaking coil (a2 and b2) are 18 and that of inner ones (a1 and b1) are 19. All the components within a shell were fabricated in a single rigid body as a composite with glass fiber prepreg and carbon fiber prepreg [3]. An idea to reduce the flux leakage from the shaking process is that m2 and m3 are subjected to the magnetic shaking at the same time but in an opposite direction. There are two ways of magnetic flux path in the lower shell with respect to the upper one; the one is to circulate over the corresponding magnetic layers and the other is heading on in gaps between extended flat parts. We will call the former circular symmetry and the latter mirror symmetry.

When the outer shaking current $I_{s2}=20$ mA of 400 Hz and the inner shaking current $I_{s1}=0$, the leakage of the shaking flux observed at $x=0$ and $y=3$ cm along the x-axis is huge (214 nT) as shown in Fig. 2. We are interested mostly in the x component of the leakage, because the shielding system will be rotated 90 degree angle and coaxial SQUID gradiometers in a Dewar will be inserted through the gap space along the y-axis down to the center to measure MCG, which is sensitive to the x component of the magnetic field. Of course, large y component is harmful because the base line (coaxial line) of the gradiometer is not always kept parallel to the x-axis. When I_{s1} is properly adjusted ($I_{s1}=11.8$ mA for $I_{s2}=20$ mA), the leakage can be reduced to 4.1 nT for the mirror symmetry combination (Fig. 3) and slightly smaller for the circular symmetry combination. It should be noted that unsuppressed component is mainly consisting of the third harmonics of 400 Hz shaking frequency which becomes clear when the shaking currents are increased. This may be because small portion of the shaking magnetic field magnetized m1 layer weakly and generated the third harmonic. We expect this can be cancelled by properly adding a small 1200 Hz current to I_{s2} or I_{s1} . Other interesting phenomenon showing the important role of the magnetic shaking is shown in Fig. 4, where 10 μ T of 10 Hz external magnetic field is applied along the y-axis and the magnetic field (1st~10th harmonics) is observed along the y-axis at the same point ($x=0$, $y=3$ cm). The figure shows the shielding system in Fig. 1 can attenuate a y-axis impressed magnetic field below two

orders of magnitude smaller but limited by the odd harmonics emitted by shells when no magnetic shaking is applied. With the magnetic shaking, the odd harmonics are decreased to one seventh.

2. Department of Electrical Engineering and Computer Science, University of Liege, Liege, Belgium

This paper studies the effect on shielding performance of perforations in magnetic shields as a function of frequency, number of gaps, and dimensions of the gaps. The source is an axisymmetric induction heating device. The shield is an axisymmetric ring with 0.3 m radius and n perforations aligned in axial direction, repeated periodically along the circumference. The gap diameter is d . The considered geometry requires a 3D finite element model (FEM): a 2D approach such as in [1] is not possible. To optimize 3D shielding configurations without the computational burden of iteratively evaluating a 3D FEM, we use the aggressive space mapping (ASM) technique [2] that combines two models: a 3D time-harmonic finite element model where the shield is represented by a thin shell formulation [3], and a 2D axisymmetric FEM where the perforations are approximated by “axisymmetric air gaps” resulting in a segmented shield.

In Fig. 1, the two models are compared with each other and with measurements for an axisymmetric geometry (shield not perforated: 2D and 3D geometry are identical) at three frequencies: 100 Hz where the penetration depth is larger than the shield thickness, 10 kHz where the penetration depth is smaller than the thickness, and 1 kHz. The figure shows that both models correspond well with each other and with the measurements.

For several numbers of holes n with constant diameter d of 10 mm, Fig. 2 shows the shielding factor $s(r)$ - defined as the induction in a point divided by the induction in the same point without shields - for a frequency of 100 Hz. If there are no perforations, the 2D and the 3D model yield similar results (3D model predicts a 2.5 percent lower shielding factor on average).

In case of perforations, the 2D model is not able to predict the shielding factor well: the predicted shielding efficiency is underestimated because the circumferential air gaps in the 2D model act as flux barriers that are not present in the 3D model. In order to be able to use the 2D model for perforated shields, the circumferential air gap should be smaller than d . Better correspondence between 2D and 3D model is achieved by introducing in the 2D model an equivalent air gap, obtained from reluctance considerations. Fig. 2 shows for 12 holes that the modified 2D model behaves similar to the 3D model.

A numerical optimization is carried out with the following objectives: good shielding factor and minimal shield volume. The parameters to optimize are n and d . The ASM technique optimizes the shield in a more accurate way than the modified 2D model. The difference with the ASM version explained in [2] is that the parameter extraction is not based on function values but on gradients. Although for constant n the optimum of the 2D FEM for d differs from the optimum of the 3D FEM, the ASM finds the optimal solution after 4 evaluations of the 3D and 55 evaluations of the 2D model, compared to 12 3D optimizations using a gradient algorithm (GA). As the evaluation of the 2D FEM is approximately 10 times faster than an evaluation of the 3D FEM, it is clear that space mapping is faster. It was observed that the lowest objective value can be obtained both for a few big holes and for many small holes, all having the same total surface of the holes.

Induction norm in the $z=0$ plane as a function of the position r for $f= 100$ Hz - 1 kHz - 10 kHz, obtained by 2D FEM, by 3D FEM and by measurements for an unperforated shield (radius 0.3 m, height 0.19 m) or no shield (B_0)

For 100 Hz, shielding factor in the $z=0$ plane for a shield (0.3 m radius, 0.19 m height) with several numbers of holes n with diameter 0.01 m as a function of the position r , obtained by the 2D FEM, by the modified 2D FEM with equivalent air gap (2DM) and by the 3D FEM

Optimal Design and Analysis of Faraday Shield Used in High Frequency Coaxial Transformer.

X. Yang¹, J. Lu²

1. Province-Ministry Joint Key Laboratory of Electromagnetic Field and Electrical Apparatus Reliability, Hebei University of Technology, Tianjin, China; 2. School of Eng., Griffith University, Brisbane, QLD, Australia

Abstract— A numerical simulation and optimal design of a high frequency coaxial transformer (HFCT) employing a Faraday shield is presented. The magnetic flux and eddy current distributions for different winding configurations under both open circuit and short circuit conditions are discussed. The shield thickness should be less than two skin depths and the shield should be positioned approximately midway between the primary and secondary windings. The intra and inter capacitances of a HFCT with and without a shield were also numerically analyzed. The calculated coupling capacitance between the primary and secondary windings of the HFCT are in good agreement with the experimental results.

Index Terms—High Frequency Coaxial Transformer, Faraday Shield, Eddy current, Coupling capacitance

I. INTRODUCTION

Practical transformers have leakage inductances, intra-winding capacitances and an inter-winding capacitance between the primary and secondary windings. High frequency coupling noise between the primary and secondary windings can cause serious common mode noise problems. These parasitics can not be neglected if the operating frequencies are above 100 kHz. The problem of coupling noise is commonly addressed by introducing a Faraday shield between the primary and secondary windings. The purpose of this paper is to investigate the effects of a Faraday shield on the coupling capacitance, magnetic flux and eddy current distribution for a HFCT. The investigation considers the impact of different shield locations, shield thicknesses, and coil configurations on the total winding losses.

II. NUMERICAL ANALYSIS OF EDDY CURRENT LOSSES

Figure 1 shows the structure of the HFCT. The primary and secondary windings, and Faraday shield are threaded through four identical magnetic cores. Six turn coils are used for both the inner and outer windings with a 30 degree phase shaft between the inner and outer circumferential layers. Each coil is comprised of litz wire with 7 strands. The wires in each circumferential layer are placed in an equidistant fashion with respect to each other. Consequently, the current distribution in each winding exhibits symmetry and hence the total current in each winding is equivalent (optimal). Moreover, this configuration will minimize the temperature rise since the losses are the same and the distance between the lossy elements is maximized.

The Faraday shield is placed between the outer winding and inner winding. A FEM analysis was employed to calculate the magnetic field distribution. Power loss increases rapidly if the thickness of shield is larger than twice the thickness of the skin depth under both open circuit and short circuit conditions. A total power loss reduction, around 25% in the open circuit case, and 12% in the short circuit case were achieved using an optimized shield position (midway point between the primary and secondary layer).

Figure 2 (a) and (b) show the distributions of magnetic flux and current density in the HFCT with and without a Faraday shield under open circuit conditions with the outer winding representing the primary side. Comparing Fig. 2 (a) with (b), we can see that the power loss of the shield can be neglected and the magnetic flux distribution is not affected by the shield.

III. CAPACITANCE CALCULATION AND MEASUREMENT

A FEM electrostatic analysis and the theory of capacitances for multi-conductor systems are used to determine the inter and intra winding capacitances; $C_{ps}=19.96\text{pF}$ between the primary and secondary windings, $C_p=7.67\text{pF}$ between primary winding and ground and $C_s=3.55\text{pF}$ across the secondary winding. The following results are obtained with a grounded shield: $C_{ps}=0.08\text{pF}$, while $C_p=24.67\text{pF}$ and $C_s=22.50\text{pF}$. Measurements are in agreement with the calculations.

IV. CONCLUSION

The thickness of the Faraday shield should be less than twice the skin depth thickness, and its position should be approximately midway between the two windings but closer to the secondary winding in order to minimize the power loss. The optimized shield position leads to a reduction in the total power loss in the windings by approximately 25% for the open circuit case and 12% for the short circuit case. The outer winding should preferably be the primary winding due to the lower power loss. The inter-winding capacitance for a grounded optimized shield is reduced by a factor of 250.

Electromagnetic wave absorption properties of double layers absorbers made of hollow glass microspheres electroless plated with FeCoNiB and NiCoZn ferrites.

M. Han, F. Xiao, Y. Ou

State Key Laboratory of Electronic Thin Films and Integrated Devices, University of Electronic Science and Technology of China, Chengdu, China

With the advancement of electronic technologies, electromagnetic (EM) pollution has become a serious problem, and the demands to develop thinner, lighter, stronger EM wave absorbers with wider absorption bands are ever increasing[1, 2]. The commonly used absorber are the spinel ferrite and hexagonal ferrite, and some other absorbers, for instance, metal powders, microwires and nanotubes. However, both of them have a severe shortcoming: heavy weight. To overcome this problem, coating some low density materials with magnetic materials are suggested. In this contribution, light EM absorbers have been designed adopting a double-layers structure which are composed of a layer of $(\text{Ni}_{0.4}\text{Co}_{0.24}\text{Zn}_{0.36})\text{Fe}_2\text{O}_4$ ferrite and a layer of glass microspheres (low density) plated with FeCoNiB by an electroless chemical deposition technique. The NiCoZn ferrites were prepared by a traditional ceramic sintering route. XRD was employed to show that the FeCoSiB films coated on the hollow microspheres were in the amorphous state and the NiCoZn ferrites were in spinel structure. The microwave permittivity and permeability properties have been measured within the frequency range of 1 GHz – 18 GHz.

The uncoated glass microspheres are shown in Fig. 1(a). The hollow structure of glass balls is also clearly indicated in Fig. 1(a). The coated glass microspheres are shown in Fig. 1(b). Magnetic hysteresis loop of coated glass microspheres is shown in Fig. 1(c), the coercivity of FeCoNiB is about 330 Oe. The low saturation magnetization (4.6 emu/g) is due to the hollow structure, where the magnetic layer only accounts a small fraction of total weight.

If the absorbers are attached on a conducting metal plate, then the EM wave absorbing performance of a double-layers absorber, which is generally evaluated by the reflection loss (RL) in dB, can be calculated based on the following equations [3, 4]:

$$Z_{\text{in}(2)} = [Z_2(Z_{\text{in}(1)} + Z_2 \tanh(j(2\pi ft/c)(\mu_2 \epsilon_2)^{1/2}))]/[Z_2 + Z_{\text{in}(1)} \tanh(j(2\pi ft/c)(\mu_2 \epsilon_2)^{1/2})] \quad (1)$$

$$Z_{\text{in}(1)} = (\mu_1/\epsilon_1)^{1/2} \tanh(j(2\pi ft/c)(\mu_1 \epsilon_1)^{1/2}) \quad (2)$$

$$\text{RL} = 20 \log |(Z_{\text{in}(2)} - Z_0)/(Z_{\text{in}(2)} + Z_0)| \quad (3)$$

Where Z_0 is the impedance of free space, $Z_2 = (\mu_2/\epsilon_2)^{1/2}$, $Z_{\text{in}(1)}$ is the interface impedance between the bottom layer and the upper layer, $Z_{\text{in}(2)}$ is the interface impedance between the free space and the upper layer, t is the thickness of an absorber. If we suppose that an absorber is only made of glass microspheres/paraffin composite (weight ratio = 1: 2), and its thickness is 16 mm, then its EM wave absorption performance can be evaluated, as shown in Fig. 1(d). If the absorber is only made of NiCoZn ferrite/paraffin composite (weight ratio = 1: 2), its EM wave absorption performances are shown in Fig. 2(b) for two thicknesses (0.8 mm, 4.3 mm). Clearly, when only ferrites are used for absorbers, the absorption performance is bad. However, if we fabricate the absorbers with plated glass microspheres and NiCoZn ferrites by choosing a double-layers structure, the EM wave absorption properties can be enhanced significantly, as shown in Fig. 2(c) and (d). In Fig. 2(c), the t of hollow glass microspheres (bottom layer) and the ferrites (upper layer) are 2.2 mm and 4.3 mm respectively. In Fig. 2(d), the t of hollow glass microspheres (upper layer) and the ferrites (bottom layer) are 2.5 mm and 0.8 mm respectively. Especially, in Fig. 2(d), since the density of hollow glass microspheres are much lower than those of ferrites. Therefore, with the double-layer absorber structure, the total weight of absorbers can be greatly reduced, and this is very important for some application, such as aircraft.

1. Nippon Steel corporation, Chiba, Japan; 2. Nippon Steel Engineering Co., LTD., Tokyo, Japan; 3. Kajima Corporation, Tokyo, Japan

To obtain the degree of freedom in designing the magnetic shield room, we propose a new type of magnetic shielding structure named “open-type” [1]. Here, magnetic shielding performance of open-type is compared with that of conventional “closed-type”.

Example of proposed open-type shield structure is shown in Fig.1. The unit magnetic paths are placed with some openings and surround the needed spaces. The path consists of magnetic strips that are overlapping with their terminal edge in the direction of sheet thickness.

Top view of the magnetic path of open-type shield is illustrated in Fig.2 (A). The grain-oriented electrical steels (GO) were used to form the path. Thickness, width and length of GO are 0.35mm, 30mm and 300mm respectively. The rolling direction of GO is parallel to magnetic path directions. In case of closed-type shield, since the magnetic sheets are parallel to the wall, the equivalent magnetic path is considered to be Fig.2 (B). And flux leakage at the corner usually becomes problem in closed-type shield, we also consider the revised closed-type, which is shown as Fig.2 (C). Fig.3 shows the DC magnetization curve of the three types of magnetic path. The open-type magnetic path (A) has higher magnetic permeability than the closed-type (B), (C) have. It is considered that difference in the contact of the sheets in the paths affect the permeability. So, the Open-type shield is considered to have an ability of high-level shield performance.

How to suppress the flux leakage from the opening part is an important problem for the open-type shield. Since the width of magnetic material strip W and opening space between strips d are thought to affect the shield performance, the performance of the structure shown in Fig.1 was measured with changing W and d . The weight of GO materials is constant in this measurement. Using Hermhorz coil, which size is 2000mm square, forms the uniform field, frequency of 50Hz and peak of 100mT. The performance of the closed-type shield, which consists of 4 L-shape sheets of GO; 900mm width, 600mm length, bended in the center at the longitudinal direction, was also measured. Fig.4 shows the average leakage flux at the center part in the shield body as a function of opening size factor d/W . The leakage of the open-type shield decreases with decreasing d/W , and reaches 4mT at d/W of below 1. It is half of the case of closed-type that is 8mT. The open-type shield structures have good shield performance if the d/W is selected appropriately.

Introduction

In recent years, the studies to make good use of the electromagnetic steel are being developed.[1,2] And one of its utilization for the MAGNETIC SHIELD has just started, which can reduce the level of low frequency magnetic noise (leak magnetic flux) released from large power equipments, such as trains, power transmission wires (cables), transformer substations, etc. The above shield has to be installed to decrease the level of the magnetic noise in order to prevent the electronic devices and the precision instruments from various kinds of error caused by the magnetic noise. In particular, almost all the hospitals are required to install MRI in a magnetic shielding room because MRI, large power equipment, is usually set up near some precision instruments in such place.

It would be important to design shield structures, considering not only to apply GO (Grain Oriented steel sheet), which has superior magnetic characteristic, but also to make sure the setting direction of GO with the easily magnetized axis against the direction of the magnetic flux to be shielded, in order to improve the shield capability of the mentioned room.

It is suggested in this paper that the setting direction of GO affects the shield capability of a magnetic shielding room based on the estimation with the electromagnetic field analysis, using homogenization method for thin steel plate (so called Equivalent BH method).[3]

Construction of the magnetic shielding room with GO

The analysis model is shown in Fig.1 as a bird's-eye view. Assuming the actual location, MRI, regarded as a direct current coil (DC-coil), is placed close to D-wall, where the operation of MRI is done, and to F-wall, floor side. The magnetic shielding room is composed of the side-walls of GO, laid out like grids and of the top/bottom walls of laminated GO. As the all side-walls have the see-through structures in the mentioned room, which is invented by Kajima Corporation [4], it can reduce the mental pressure of the patients. In addition to it, this shielding room has such an advantage that there is no construction work to keep some gaps from the top/bottom walls to the ceilings and the floors because the top/bottom walls are completely flat.

In the case of the conventional design for shielding rooms, laminated GO is usually laid out regardless of the direction of the magnetic flux. This design, which lay out GO to cross the easily magnetized axis of GO each other like the top/bottom walls shown in Fig.1(a), aims at giving the equal shield capability to all walls of them.

However, it is proposed by the writers to lay out GO with easily magnetized axis, agreeing with the same direction of the released magnetic flux from MRI(DC-coil), in order to improve the shield capability of the room. Because MRI(DC-coil) always releases the magnetic flux with the fixed direction, which goes from MRI to D-wall at first, and next goes to A/C-walls and R/F-walls separately, and finally gets together to pass through B-wall. Then the indicated model shown in Fig.1(b) is proposed, which consists of GO with the easily magnetized axis laid out to agree with

the same direction of the magnetic flux. And the shield capability of GO with the given model is estimated with Equivalent BH method.

Estimation result with Equivalent BH method

The distribution of the leak magnetic flux density at a height of DC-coil center in each wall is shown in Fig.2, using the electromagnetic field analysis with Equivalent BH method. According to the above result, the shield capability of the proposal model at A/C-walls is better than the conventional one although the shield capability of both models at B/D-walls is almost same.

It indicates that laying out GO with easily magnetized axis, agreeing with the same direction of the magnetic flux, improves the shield capability of such rooms as the shown proposal model.

When a magnetic shielding room is designed, it is definitely necessary to lay out GO based on the direction of easily magnetized axis of it and of the magnetic flux.

Introduction

In order to reduce the leakage flux density to less than 0.5 mT outside the room and shield an electro-magnetic field at high-frequency for operating, an magnetic resonance imaging (MRI) scanner is usually installed in a magnetically shielded room (MSR) surrounded by a wall with magnetic and conductive layers. The small space enclosed by the wall causes patients a great deal of stress and discomfort because they are isolated from the operators and from the scenery outside. In order to improve amenity for patients in hospitals, open type MSRs for MRI, which use magnetic bars [1], canceling coils [2] instead of magnetic walls, and double-layered electro-magnetic shielded glasses instead of conductive walls, have been developed. However, these MSRs can't provide a sufficiently open feeling because of the lack of transparency and optical moiré pattern of the glass. Moreover, the electro-magnetic shielded glasses are expensive compared with magnetic and conductive walls. We have therefore developed a new open-type MSR using a combination of a square cylinder (147 x 147, $t=1$ mm) made of a magnetic material, silicon steel, placed inside a second square cylinder (150 x 150, $t=3$ mm) made of a conductive material, aluminum. The cylinders are piled up instead of a wall in order to provide open feeling. The conductive cylinder prevents the deterioration of magnetic property of magnetic cylinder due to stress. The cylinders piled up have also the effect of electro-magnetic shield by the electrical contact between square cylinders of aluminum. Therefore, the number of panes of shielded glass can be diminished and it improves the open feeling for the patient. In this paper, the optimal design of an open-type MSR for MRI combining square cylinders made of magnetic and conductive materials is discussed using 3-D magnetic field analysis and experimentally using a small model.

Method of Analysis and Measurement

First, from the standpoints of the leakage flux density (LFD) outside MSR, the optimal design of square cylinders made of magnetic materials is discussed using 3-D magnetic field analysis with a simple cubic MSR shown in Figure 1. LFDs along line O-P varying with the length and number of division of cylinders and width of the gap between cylinders were calculated. The relative permeability of silicon steel was assumed to be 3,000 and the current of the MRI magnet model is 87,500 AT. Next, the validity of the analysis and the practical realization of the designed MSR were investigated using a small experimental model shown in Figure 2. Sixty units composed of square cylinders of aluminum ($t=3$ mm) and silicon steel ($t=1$ mm) were accumulated on the opening of the model MSR. The relative permeability of the silicon steel of the cylinder and wall, and of the aluminum were assumed to be 1000 and 1, respectively. The current of each of the four circular coils as the MRI model is 1,485 AT. The contour of LFDs at a surface 100 mm away (A) from the opening obtained from calculation and experiment were compared and the effect of the division of cylinders was confirmed. Finally, the electro-magnetic shielding effect at frequencies from 60 to 180 MHz of models of some combinations of electro-magnetic shielded glass and square cylinders (300 mm, 450 mm of length) made of aluminum was measured using horizontal biconical antennas in an experimental electro-magnetic shielded room.

Results

Figures 2 and 3 show the LFD dependency on the length (l) of the cylinders and the width of gap. The optimal length is $l=300$ mm which is around two times width, because the LFD for $l=300$ mm is smaller than those of $l=50$ and 100 mm, and almost the same as those of $l=450$ mm and 600 mm shown in Figure 2. The effect of the increase of gap between magnetic layers due to conductive layers on the LFD can be neglected because there is small difference between the LFD of gap=6 mm and 1 mm shown in Figure 3. Figure 5 shows the comparison of the distribution of LFDs obtained from calculation and from measurement at surface A using small model as shown in Figure 4. The figure shows that the tendency of the calculation is in good agreement with the measurement. In both measurement and calculation, the LFD of a cylinder divided into three parts by gaps of 30 mm is lower than that of a cylinder without gaps. This is because the flux reaching outer cylinder is reduced due to the gaps. On the other hand, the measured shielding effects of the combination of single electro-magnetic shielded glass and the square cylinder of aluminum, 300 mm of length, were higher than 100 dB at frequencies from 60 to 180 MHz, so that the MRIs could be operating (Figure is omitted). Consequently, as the optimal design of open-type MSR for MRI, we have developed the combination of single-layered electro-magnetic shielded glass together with a unit composed of cylinders, 150 mm x 150 mm and 300mm long, with aluminum ($t=3$ mm) outside and silicon plate ($t=1$ mm) divided into three parts inside.

Shield Duct to Prevent Magnetic Field Leakage through Openings in Double-layered Magnetically Shielded Rooms.

K. Yamazaki¹, Y. Hatsukade², S. Tanaka², A. Haga³

1. Takenaka Corp., Chiba, Japan; 2. Toyohashi University of Technology, Toyohashi, Japan; 3. Tohoku-Gakuin University, Miyagi, Japan

Introduction

Magnetically-shielded rooms (MSR) made of multi-layered ferromagnetic materials such as μ -metal are used for electron beam lithography systems (EBLS) and biomagnetic measurements [1] [2]. However, a number of openings must be provided in the walls, ceiling and floor of such rooms for air conditioning and cables [3]. In the case of EBLs, especially, large sized openings (such as 500 mm x 500 mm²) are required as the number of air changes increases depending on highly specific requirements for cleanliness, temperature and relative humidity. On the other hand, for biomagnetic measurements, large openings for windows and transparent doors are required to communicate with the outside and to provide comfortable atmosphere for subjects and patients. Usually, short shield ducts are attached around the openings to prevent leakage of magnetic flux through the openings [4]. This paper reports an optimal structure of short shield ducts to prevent the leakage of magnetic flux through the openings of a double-layered MSR, as investigated experimentally using a small model of an MSR and 3-D magnetic field analysis with the finite element method (FEM).

Model and Method of Measurement and Analysis

Figure 1 shows a one-tenth scale model (Magnetically Shielded Box: MSB) of a double-layered MSR with ducts connected to its inner and outer layers, investigated by experiment and analysis in this study. The thickness of the magnetic wall is 1 mm and the openings are 60 mm x 60 mm² on the inner layer and 70 mm x 70 mm² on the outer layer. Almost uniform magnetic noise, ΔB_0 , of 8 μ T at 0.1 Hz was applied to the MSB in the vertical direction to the opening by three-layered large sized coils. Leakage magnetic field ΔB_i ($\sqrt{\Delta B_x^2 + \Delta B_y^2 + \Delta B_z^2}$) at the point P, 60 mm (the same length as the width of the inner layer opening) from the opening in the MSB, was measured by a fluxgate magnetometer with short shield ducts (SSDs) which lengths were half, same, twice and three times as long as the width of the opening, attached to the inner and outer layer, respectively. Dividing ΔB_i by ΔB_0 , the normalized leakage flux ratios (LFR= $\Delta B_i / \Delta B_0$) under numerous conditions, depending on the SSDs attached around the openings, were obtained. The optimal combinations of lengths of the attached SSDs with inner (L_{in}/D_{in}) and outer (L_{out}/D_{out}) openings were investigated. Next, the distributions of the magnetic fields inside the MSB were evaluated by 3-D FEM with the finite element method, which employed the magnetic vector potential when ΔB_0 was 8 μ T and the relative permeability of μ -metal was 12,000. LFRs at point P obtained by the FEM were compared with those from the experiment. The distributions of magnetic vectors inside and outside the opening were analyzed to clarify the optimal combination of ducts attached around the inner and outer opening.

Results

Figure 2 shows the measured relationships between L_{in}/D_{in} , L_{out}/D_{out} and LFR. The minimum and optimal combinations of L_{in}/D_{in} and L_{out}/D_{out} for LFR were 0.5 and 1.0. SSDs with inner and outer layers should not be overlapped, and the L_{out}/D_{out} should not be larger than 1. This tendency of the leakage flux ratios, LFRs shown in Figure 1 was almost in agreement with that obtained from 3-D FEM (figure omitted), verifying the validity of the analysis method. Figure 3 shows the analyzed distributions of magnetic flux inside and outside the opening. As shown in (b), the duct attached to

the inner layer was saturated by magnetic flux from the duct with the outer layer at the overlapping space A, so that the duct at the inner layer could not absorb magnetic flux inside the duct to reduce leakage of the magnetic field through the opening. As shown in (c), extending the duct with an outer layer larger than twice L_{out}/D_{out} resulted in absorbing too much magnetic flux not only from inside, but also from the outside, so that magnetic flux inside the duct could not be reduced except near opening B. Near point C, magnetic flux was exhausted into inside from the duct attached to the outer layer. Therefore, an optimal combination of short shield ducts with inner and outer layers to prevent the leakage of magnetic flux through the openings of a double layered MSR is to not overlap ducts and to make the length of the duct attached to the outer layer no larger than the width of the opening (shown in (a)). Our manuscript discusses the optimal structure on a lattice made of magnetic materials installed at the opening.

Features of a Wall with Open-type Magnetic Shield.

T. Saito

Kajima Corporation, Tokyo, Japan

It has been commonly believed over 100 years that magnetic materials should be arranged without any space between them to achieve a sufficient magnetic shielding effect [1]. However, it was newly found that the aligned strips with gaps could achieve almost the same effect of magnetic shielding as conventional method which is complete plate without any gap [2]. Furthermore, sufficient magnetic shielding effect can be achieved with sizable gaps. Here this study reports the features of a wall with this “open-type” magnetic shield by some experiments about interval between strips, layers and rotation of strips.

1. Open-type magnetic shield

Fig. 1(a) illustrates the case in which the magnetic field/flux is generated by electric current and a plate like magnetic shielding material. To shield magnetic field for reducing the leakage to the front, we have generally put a plate like high permeability material, because magnetic flux go into it and make detour [3]. In contrast to this conventional method, open-type magnetic shielding method aligns strips like high permeability material with gaps as shown in Fig. 1(b). It can be air or vacuum in the gaps. The advantage that light and air can pass through this magnetic shielding wall will create wide range of applications.

2. Experimental System

Fig. 2 indicates the part of experimental system which is simply composed of two electric wires and magnetic strips. In fact, this part consecutively repeated to 15m in length. The two electric wires carry +50A and -50A direct currents. Magnetic shielding material was made of grain-oriented electrical steel sheet with 0.35mm in thickness. All strips for open-type magnetic shielding method are 900mm×20mm in size. The rolling direction of the electrical steel sheets/strips is vertical to the ground. The height of two wires and measuring points are same as those of the center of sheets/strips.

3. Features of wall with open-type magnetic shield

Fig. 3 shows the experimental result about the leakage of magnetic field when the gaps between strips are changed. It tells us the magnetic shielding efficiency with open type method of 25mm gap is not so worse in comparison with conventional method in the area more than 600 mm far from electric wire. Fig. 4 represents the effect of layers for each strip. It tells us that double layers for each strip with 50mm gap can achieve almost the same performance as single layer with 25mm gap. Fig. 5 indicates the effect of rotation for each strip. It tells us that almost same shielding performance can be achieved at 0 and 90 degree of rotation on the center axis of each strip.

Analysis of the shielding effectiveness of rectangular enclosure of metal structures with apertures.

M. Zhang¹, Z. Zhao¹, C. Gao¹, S. Wang²

1. INTRODUCTION

The problem of electromagnetic field penetration into rectangular enclosures with apertures has received considerable attention in the power system because many relay cells in substations have been built in switchyards in recent years. Modern electronic circuits generally have weak signal levels and are sensitive to various kinds of electromagnetic disturbances. The shielding effectiveness of the relay cell should therefore be analyzed so that the electromagnetic field does not exceed acceptable levels [1].

The interaction between the inner and the outer surfaces of the enclosure which is not easily predictable is modeled by introducing magnetic currents on the apertures. In this paper, the cavity and the apertures are modeled by rectangular surface patches. The roof-top basic functions are used to expand the unknown electric and magnetic currents on the surfaces of the cavity and the apertures.

2. DESCRIPTION OF THE APPROACH

The model consists of a metallic box with a rectangular aperture excited by a source out of the enclosure. The wall of the enclosure is infinite thin screen.

By applying the equivalence principle, the aperture can be metallized. So the original problem can be divided into two simple independent problems. (1) the radiation of the source out of the enclosure; (2) the radiation of the source in the enclosure.

A set of equations can be obtained by means of the continuity of the tangential components of the electromagnetic field at the aperture. The pertinent boundary conditions at the surface of the enclosure can be described using the electric field.

3. VALIDATION

To verify the proposed approaches, electromagnetic shielding effectiveness at the center of a 55cm*55cm*60cm rectangular box with nine 8cm*8cm rectangular apertures located at the front size is measured, as in Fig. 1. The test is carried out in a compact anechoic chamber with three-meter method. The cavity is located on a desk 0.8m high.

The box is excited by a plane wave with normal incidence. Three different cases of the electric field shielding effectiveness at the center of the box are calculated using the above method and measured. In the first case, aperture 5 is open and the other eight apertures are closed. The results are shown in Fig. 2. In the second case, apertures 4, 5 and 6 are open and the other six apertures are closed. The results are shown in Fig. 3. In the last case, apertures 2, 4, 5, 6 and 8 are open and the other four apertures are closed. The results are shown in Fig. 4.

From the above result, we can see that the results calculated with the method presented in this paper are in agreement with the measurement results.

4. CONCLUSION

A rigorous method based on method of moments suitable for estimation of the shielding effectiveness of rectangular enclosures with apertures is presented. The comparison between the calculation results and the measurement results shows that the method is effective.

Effect of La-substitution on magnetic and ferroelectric properties of $\text{Bi}_{(1-x)}\text{La}_x\text{Dy}_{0.3}\text{FeO}_3$ system.

P. Kovur, S. P. Duttgupta, V. R. Palkar

Electrical Engineering, Indian Institute of Technology Bombay, Mumbai, India

Multiferroics are the materials having coexistence of magnetic and ferroelectric properties with coupling between two order parameters. These materials therefore find novel applications like multiple memories apart from MEMS sensors and actuators etc. However, there are very few materials which exhibit such properties at room temperature. The perovskite BiFeO_3 (BFO) belongs to this class of multiferroic materials and has recently emerged as a promising magnetoelectric material. It exhibits antiferromagnetic behavior with a Neel temperature of 380°C and ferroelectric behavior with $T_c \approx 810^\circ\text{C}$. We were successful in inducing ferromagnetism in this system without disturbing ferroelectric properties by doping with Dy at Bi site ($\text{Bi}_{0.6}\text{La}_{0.1}\text{Dy}_{0.3}\text{FeO}_3$) [1]. La was used to stabilize the ferroelectric perovskite phase and to reduce leakage current [2]. Now it has been observed that in the presence of Dy, addition of La is not essential for the above purpose. Interestingly, the removal of La not only leads to orders of magnitude enhancement in magnetic properties but also improves the ferroelectric properties. In this paper, we are reporting the multiferroic properties of Dy modified BFO with and without La. Powder samples of $\text{Bi}_{0.6}\text{La}_{0.1}\text{Dy}_{0.3}\text{FeO}_3$ (DL1) and $\text{Bi}_{0.7}\text{Dy}_{0.3}\text{FeO}_3$ (DL0) were synthesized by using a newly developed wet chemical route. The reacted samples have been characterized by various techniques (X-ray powder diffraction, neutron diffraction, ferroelectric loop tracer and vibrating sample magnetometer). XRD patterns obtained for DL1 and DL0 samples are shown in Fig.1. * indicates the presence of $\text{Bi}_2\text{Fe}_4\text{O}_9$ and $\alpha\text{-Bi}_2\text{O}_3$ as impurity phases. The impurity phases are neither magnetic nor ferroelectric at room temperature, so their presence could at the most reduce overall percentage of ferromagnetic and ferroelectric component from the system. From Fig.2, it is clearly evident that in the presence of Dy, La is not required to control the leakage current. In fact, both magnetic as well as ferroelectric properties improve to a large extent in the absence of La in the system (Fig.3 & Fig.4). The enhancement in properties could be explained on the basis of neutron diffraction results (Table 1). Removal of La from the system is found to decrease the lattice cell volume, Fe-Fe and Bi-Fe bond distances also Fe-O-Fe bond angle. The decrease in bond distances and bond angle helps to enhance the magnetic properties as typically one finds in oxide systems with indirect interactions. The scaling up in lattice distortion and cell parameter c with removal of La leads improved ferroelectric properties as reported by Wang et al. [4].

Recently, Jain et al. [1] have studied the effect of partial substitution of Ni by Cr in CeNi₅ intermetallic compound. Their study of the pressure-composition isotherms for CeNi_{5-x}Cr_x (x = 0, 1, 2) have been motivated by search for hydrogen storage materials. It was shown that all the compounds crystallized in the hexagonal CaCu₅ type of structure. Compounds of this structure have been in the focus of our interest in recent years [2,3], mainly from the point of view of the magnetic, transport, thermodynamic, structural and electronic properties. Therefore, in this paper we present these types of characterization for the CeNi₄Cr representative. Figure 1 shows the result of the magnetic susceptibility measurements as a function of temperature. The reciprocal susceptibility did not show any distinct linear region, therefore we employed the modified Curie-Weiss law ($\chi_{dc}(T) = \chi_0 + C/(T - \theta)$) to fit directly the $\chi_{dc}(T)$ dependence. The corresponding parameters' values are displayed in the figure. The striking results is the small value of the effective paramagnetic moment. Assuming that only Ce ions contribute to the moment one could expect the theoretical value of $2.54\mu_B/f.u.$ This reduction can be caused by the mixed valence behavior of this compound, which is suggested also by the x-ray photoemission studies to be shown in the full paper. We will also discuss the magnetic susceptibility measured at low magnetic field, which seems to indicate an importance of the magnetism of chromium known from its antiferromagnetic nature. In Fig.2 the specific heat divided by temperature is plotted as a function of the temperature square for changing magnetic field strength. The extrapolation to T=0 provides directly the value of the electronic specific heat coefficient γ . It drops from 90 to 60 Jmol⁻¹K⁻² for H increasing from 0 to 9T.

I. INTRODUCTION

It has been known that a pure HoMn₂O₅ compound can only be formed in a pure oxygen environment with an oxygen pressure as high as three atmospheres. [1,2] The pure HoMn₂O₅ compound has an orthorhombic structure of space group Pbam [3] and undergoes an antiferromagnetic (AFM) transition at a Neel temperature (TN) ranging from 39 to 45K. In this study, we found that by doping 20% of La at the Ho site the pure Mn_{0.8}La_{0.2}Mn₂O₅ phase may be formed in one atmosphere. An unexpected ferromagnetic (FM) phase appears at 150K and changes back to AFM phase at lower temperature. This FM phase was examined by the superconducting quantum interference device (SQUID) and Neutron Diffractometer and is found to be a two dimensional ferromagnetic cluster.

II. EXPERIMENT

The precursors Ho_{1-x}La_xMn₂O₅ were formed by a standard sol-gel method [1,2]. The sample was formed at 1000°C for 12 hours under one atmosphere of flowing Oxygen. The crystal structures of compounds were examined by standard X-ray diffractometry (XRD) from which the data were analyzed by a Generalized Structure Analysis System (GSAS) with Rietveld method. Their magnetic property was then measured using a SQUID magnetometer. Neutron diffraction was taken in NIST to explore the lattice and magnetic structure.

III. RESULTS AND DISCUSSION

The crystal structure of Ho_{1-x}La_xMn₂O₅ compound was examined by a commercial 4-axis X-ray diffraction and a high resolution X-ray diffractometer in National Synchrotron Radiation Research Center, Taiwan. It is found that Mn_{0.8}La_{0.2}Mn₂O₅ is a pure phase with no trace of an impurity phase up to the limitation of within reasonable accuracy of XRD. The AFM transition in Mn_{0.8}La_{0.2}Mn₂O₅ compound can be more clearly understood from the 1/M vs. temperature plot where the linear extrapolation of the high temperature paramagnetic part of the curves intersect with the temperature axis at a negative intercept. An unexpected FM transition appears at 150K, as shown in Figure 1. By measuring the ZFC and FC magnetization as a function of temperature and the hysteresis loops at various temperatures, the FM phase is indeed contributed to the formation of ferromagnetic clusters. The magnetic structure explored by Neutron diffraction at temperature lower than the Neel temperature reveals the compound is an incommensurate AFM phase. At the temperature where FM phase is initiated, the appearance of asymmetric broad neutron diffraction peaks, as shown in Fig. 2, indicates the formation of small portion of two-dimensional FM clusters in the paramagnetic matrix.

IV. CONCLUSIONS

A pure Mn_{0.8}La_{0.2}Mn₂O₅ phase can be stabilized by doping 20% of La at Ho sites under one atmosphere of pure oxygen. A FM phase appears at 150K and can be attributed to the formation of two dimensional FM clusters

The field of molecular magnetism has known, in the last decade an important outburst, triggered by the need for new materials with multifunctional properties. Beside the molecular ferri- and ferro-magnetic compounds, the spin transition complexes based on the existence of two accessible states of different spin multiplicity rounds up the field. These complexes are inorganic solids characterized by two states: low spin (LS) and high spin (HS) with different magnetic properties (LS is diamagnetic while HS is paramagnetic), change of color, vibrational properties, molecular volume and dielectric constant. The crossover between these two states can be triggered by various external constraints like temperature, pressure, magnetic field or light intensity. Depending on the elastic interaction strength, the spin crossover between LS and HS can vary from gradual to a first order transition with hysteresis. In fact, this bistability is envisaged in potential applications like ultra high density and fast access storage data medium, sensors or displays.

Simultaneous with designing new materials showing enhanced properties at room temperature an equal effort is made in developing new characterization tools and understanding of switching behavior. As a static investigation tool, we have introduced the First order Reversal Curve (FORC) diagram method [1,2]. Another approach is to record the response of the system under fast perturbation, i.e. dynamical methods [3]. Till now, as fast perturbation was used a high magnetic field, pressure pulses [4] and laser pulses [5]. The fastest perturbation is obtained with the laser (nanoseconds), then magnetic field (0.1 seconds) and in the end pressure pulses (minutes). In fact, several years ago, a pressure pulse experiment was made in order to compare it with the magnetic field pulse, concluding that the pressure and magnetic field are inducing "mirror effect" [4].

In this paper, we present a series of systematical experiments to study the piezo switching of the [Fe(PM-BiA)2(NCS)2] complex. Compared with other types of perturbations, here we were able to shift the reference line from atmospheric pressure to 500 bars allowing a 400 bars negative and positive variation. In the first experiment, we have started from high spin saturation (high temperature phase), the temperature was decreased till the system is brought in the bistability zone. At a given temperature the pressure is increased with 400 bar and after that reduced back to its initial value (see Fig. 1). To get the full image of the switching in the bistability zone we were repeating the experiment for several temperatures. The results are presented in Fig. 2. In our second experiment, the pressure was first decreased and after that increased back to 500 bars (see Fig 3).

The response of the system to the pressure stimulus in the experiments indicated above can be understood easily recalling that the high pressure favors the LS states and the low pressure the HS states. Also, the major hysteresis loop limits the metastability region. The spin crossover system can be brought outside the major hysteresis loop, but when the perturbation is removed, the system drops to the closest stable state, which is on the major hysteresis loop.

In conclusion, we obtained the switching from the cooling branch of the thermal hysteresis loop to the heating branch of the same hysteresis and vice versa. Also, we have shown that in order to obtain a piezo-switch we have to correlate the pressure variation with the actual state of the system on the thermal hysteresis loop. In the full paper, we shall indicate and explain the differences

between our results and the ones reported in the first experiment of this kind. Also, the link with the magnetic and laser pulses will be explored.

Magnetic Properties of $\text{Zr}_9\text{Ni}_{11}$ Intermetallic Compound.

V. Provenzano¹, R. D. Shull¹, R. M. Waterstrat¹, L. H. Bennett^{1,2}, E. Della Torre^{1,2}, H. Seyoum³
 1. Magnetic Materials Group, NIST, Gaithersburg, MD; 2. Physics Department, George Washington University, Washington, DC; 3. Physics Department, University of the District of Columbia, Washington, DC

As part of a study of transition metal₉-transition metal₁₁ intermetallic compounds, we carried out some exploratory magnetic measurements on a number of these compounds. Unexpectedly, in one of these compounds (the $\text{Zr}_9\text{Ni}_{11}$ compound), we observed an unusual magnetic behavior. The neutron diffraction results on the same $\text{Zr}_9\text{Ni}_{11}$ compound provided valuable insight on two aspects of this unusual magnetic behavior: (i) spin-glass behavior that had not been previously seen in this 9-11 family of compounds, and (ii) oscillations in magnetization versus temperature curves. Here we report on the magnetic measurements that were carried out on the $\text{Zr}_9\text{Ni}_{11}$ intermetallic compound. Though the main focus of the present study is on the magnetic property measurements, we shall also make brief reference to a parallel crystal structure study conducted on the same $\text{Zr}_9\text{Ni}_{11}$ compound and whose results have been recently submitted for publication [1].

The samples used for both studies were prepared by arc melting the appropriate elements, using a water-cooled copper hearth, in an argon atmosphere. The purity of the starting constituents was 99.9 wt. % or better. After arc melting, the compound was homogenized in vacuum at 1030°C for one week and then water quenched. After the homogenizing treatment, in the temperature range from 2 K to 320 K, the magnetization of the $\text{Zr}_9\text{Ni}_{11}$ compound was measured both as a function of temperature at constant field values and as a function field at constant temperatures, using a SQUID magnetometer. Figure 1(A) shows the temperature dependence of the zero field cooled magnetization (M_{ZFC}) and the field cooled Magnetization (M_{FC}) of the compound in a dc field of 100 Oe. The M_{ZFC} shows a peak centered at 36 K, whereas the M_{FC} shows an upturn at low temperatures. From 100 Oe to 400 Oe, the magnetization dependence with temperature of both M_{ZFC} and M_{FC} is similar to that at 100 Oe, except that the M_{ZFC} peak temperature (T_p) shifts to lower temperatures with increasing field. Above 400 Oe, there is no discernible difference between the M_{ZFC} and M_{FC} vs. T plots; both plots show the same trend and are essentially superimposed on each other. However, for the $\text{Zr}_9\text{Ni}_{11}$ compound of particular interest are the characteristics of M_{ZFC} and M_{FC} vs. T plots for field values below 100 Oe down to 2 Oe. In this field range, T_p increases with increasing field. The peak temperature T_p of M_{ZFC} curves versus applied field are shown in Figure 1(B). The temperature dependence of the magnetization of the $\text{Zr}_9\text{Ni}_{11}$ compound for field values of 100 Oe and above is typical of a spin glass. In fact, in the region between 100 Oe and 400 Oe, the decrease in T_p is proportional to H^b , where H is the applied field and $b < 1$. The value of the exponent ("b") is found to be 0.61, which is close to the de Almeida-Thouless 2/3 power law that applies to spin glasses. However, the behavior of the magnetization below 100 Oe is not typical of a spin glass, in that T_p decreases with decreasing field [Fig. 1(B)].

The temperature dependence of the M_{ZFC} and M_{FC} vs. T plots at 400 Oe is shown in Figure 1(C). Consistent with a spin glass behavior is the shape of the M_{FC} vs. T plot, where the M_{FC} values deviate and reside above the corresponding M_{ZFC} values. Of particular interest is the presence of deviations with varying amplitudes (small peaks) in the M_{FC} vs. T plot at various temperatures, whereas, by contrast, the M_{ZFC} vs. T plot is smooth over the entire temperature range. These deviations are believed to arise from the Dzyaloshinskii-Moriya interactions occurring in the $\text{Zr}_9\text{Ni}_{11}$ compound. In fact, it was the presence of these small peaks that helped explain the unusual variation in the neutron spectrum observed in the compound while collecting the spectral data. The crystal

structure study conducted on the $\text{Zr}_9\text{Ni}_{11}$ compound by TEM and neutron diffraction in the temperature range of 4 K to 1273 K revealed that the compound had a $\text{Zr}_9\text{Pt}_{11}$ -type tetragonal structure plus columnar atomic chains of alternating Zr and Ni atoms lying along the c-axis. These spectral variations are consistent with deviations seen in the M_{FC} vs. T plot at 400 Oe. The small peaks seen in the M_{FC} vs. T plot at 400 Oe are believed to be the result of movements of the atoms along the chains over short distances [1].

First-Order Reversal Curve Analysis of Spin-Transition Thermal Hysteresis Under Pressure in Terms of Physical-Parameter Distributions and Their Correlations.

A. Rotaru^{1,2}, J. Linares¹, E. Codjovi¹, F. Varret¹, A. Stancu²

1. Physique, GEMAC-Versailles University, Versailles, France; 2. Physique, Alexandru Ioan Cuza University, Iasi, Romania

The study of the elastic domain distributions as well as the parameters characterizing these distributions are of paramount importance in spin transition materials, as they are directly determining their general hysteretic properties. In order to evidence the elastic domain distribution the experimental First Order Reversal Curve (FORC) diagram method was proposed [1].

The FORC diagram method was proposed by Mayergoz [2] for the identification of the Classical Preisach Model and its use was extended to virtually any hysteretic system, as an experimental characterization tool, by Pike [3]. The experimental FORC diagram method was initially mainly used in ferromagnetic materials but it proved its efficiency also for the characterization of ferroelectric materials [4,5] and thermal and light induced thermal hysteresis in spin transition materials [6,7].

Recently, it has been shown that First Order Reversal Curves (FORC) diagrams for the spin crossover compounds can be interpreted in terms of distributions of physical parameters such as the energy gap Δ between low spin (LS) and high spin (HS) states and the mean field interaction parameter J of Ising-like model [7].

In this contribution we present the pressure effect on these two distributions. We recorded the FORC curves of the spin transition solid $[\text{Fe}_0.6\text{Zn}_{0.4}(\text{btr})_2(\text{NCS})_2]\text{H}_2\text{O}$ at several pressures. The derived FORC distributions are shown in Figure 1 in the bias-coercivity c - b and in Δ - J axes. With respect to the previous work at ambient pressure [7] we observed an unexpected splitting of the distribution with a “quasi-reversible” component on most of the diagrams. This additional contribution might be due to kinetic effects with remain to be cleared up and mastered by further investigations. We have removed this extra-contribution for the plot in Δ - J axes and for the following.

Following [7] we analysed the joint probability distributions in terms of standard deviations σ and the dimensionless correlation parameter r defined as usually $r = \text{cov}(b, c) / \sigma(b)\sigma(c)$. Detailed expressions can be found in [7]. As noticed by Tanasa et al. [7] the correlation factor can be associated with a rotation of the contour plots (ellipses in case of Gaussian distribution) by an angle α (defined modulo $\pi/2$) expressed through $\tanh(2\alpha) = 2\sigma(b)\sigma(c) / [\sigma^2(b) - \sigma^2(c)]$.

The statistical analysis data of the corrected distributions are listed in Table I.

These statistical data can be discussed as follows :

- pressure induces an overall increase in the equilibrium temperatures, expressed as $db/dP \sim 22 \text{ KBar}$, in excellent agreement with previous investigations of the major loops and simple thermodynamic expectations [8].
- pressure also induces an overall increase in the interaction parameter values, which can be understood as the enhancement of elastic interactions by a stiffer lattice.
- the widths of the distributions are not significantly modified by pressure. This result support the assumptions made in [7] that these factors were due to crystal size effects and internal stresses which should not remain, irrespective of the external pressure.
- the correlation parameter also remains little affected by the external pressure. In [7] we assigned it to a distribution of the dilution parameter, which also cannot be affected by the effect of external pressure.

Thermodynamic and electronic properties of DyNi₄Si compound.

M. Falkowski¹, A. Kowalczyk¹, M. Reiffers², T. Tolinski¹, E. Gazo², M. Zapotokova², G. Chelkowska³

Intermetallic compounds formed between rare earth and transition metals have been intensively investigated both from the theoretical and experimental point of view. This is because they often present promising materials for practical applications, especially as powerful permanent magnets and hydrogen storage.

Heat capacity of the DyNi₄Si compound has been studied in the temperature range 1.8-150 K in various applied magnetic fields. The specific heat was measured from pumped helium up to room temperature by employing the relaxation method, using the specific heat option of the Quantum Design PPMS system. The X-ray photoemission (XPS) spectra were obtained with monochromatized Al-K α radiation with photon energy of 1487.6 eV using a PHI 5700/660 Physical Electronics Spectrometer. The energy spectra of the electrons were analysed by a hemispherical mirror analyzer with the energy resolution of about ~0.3 eV. The Fermi level, $E_F = 0$, was referred to the gold 4f_{7/2} binding energy at 84 eV. All emission spectra were measured immediately after breaking the sample in a vacuum of 10⁻¹⁰ Torr.

DyNi₄Si compound crystallize in the hexagonal CaCu₅-type structure, space group P6/mmm. R atoms occupy the (1a) site, Ni(1) the 2c site and Ni(2) and Si are statistically distributed on the 3g positions. Our magnetic measurements indicate that DyNi₄Si is ferromagnetic with the saturation moment of 7.9 μ_B /f.u. at 4.2 K (in $H = 9$ T) and Curie temperature $T_C = 15.6$ K [1].

Studying the specific heat is a powerful tool for obtaining information on magnetic properties and phase transitions. The total specific heat consists of electronic, phonon and magnetic contributions. The electronic specific heat coefficient γ was determined in the region, where the application of the Debye law $C = \gamma T + BT^3$ was physically acceptable providing $\gamma = 72$ mJ/mol \cdot K⁻² (Fig. 1). Zero field heat capacity of the DyNi₄Si compound reveals a peak close to the magnetic ordering temperature, which eventually gets suppressed after application of the magnetic field (inset of Fig. 1).

The experimental photoemission spectrum (solid line) of the valence band region of DyNi₄Si is shown in Fig. 2. The valence band spectrum at the Fermi level exhibits the domination of the Ni(3d) states below 3 eV. The multiplet structure of the Dy 4f state is visible in the energy range from 4 eV to 13 eV. The positions of the peaks are consistent with the metallic dysprosium (Fig. 2, dash line). The slight shift of peaks' positions towards the higher binding energy by about 0.3 eV in respect to the pure Dy is probably due to the different crystalline field for Dy in the DyNi₄Si compound.

We present the synthesis and characterization of $\text{Sr}_2\text{TiMnO}_6$ (STMO), which is a new manganite-like material, that evidence dielectric and magnetic behaviors. Magnetic measurements show the ferromagnetic feature and polarization hysteresis curves reveal the ferroelectric character of STMO. Density Functional Theory (DFT) calculation, by means of wien2k software, reveals a half-metallic nature. Samples were synthesized by means the solid state reaction. The SrO , TiO_2 and MnO_2 (Aldrich 99.9%) powders, were stoichiometrically mixed according to the chemical formula. Mixture was ground to form a pellet and annealed, then regrinded, repelletized and sintered. X-Ray diffraction was performed with a PW1710 diffractometer. Zero Field Cooling (ZFC) and Field Cooling (FC) measurements of magnetization were carried out by using a MPMS Quantum Design SQUID and electric polarization curves by means a Radiant Ferroelectric Tester, which include a ± 10 kV source. Rietveld refinement permitted to establish that the space group is $I4/m$ and lattice parameters are $a=5.4858$ Å and $c=7.7518$ Å. From DFT, the results are $a=5.508(2)$ Å and $c=7.792(8)$ Å, which are more than 99% in agreement to our experimental results.

The magnetic properties have been investigated by measuring the DC magnetization in the temperature range 5 K to 300 K and at an applied magnetic field of 0.2 T. Temperature dependence of the DC magnetization as a function of temperature for STMO was measured by using the ZFC and FC recipes. We use the minimum observed in $d\chi/dT$ as a function of temperature to determine the critical temperature $T_C = 44.8$ K. It is very interesting the irreversibility observed in the ZFC and FC curves. This separation of ZFC and FC magnetization as a function of temperature is a characteristic of magnetic ordered frustrated systems. Hysteresis curve evidences a ferromagnetic behavior with finite magnetization saturation value (0.2 emu/cm^3 , approximately). From the magnetization saturation and crystallographic parameter of cell it is possible to determine an effective magnetic moment $5.01 \mu_B$.

Measurements of polarization as a function of applied voltage were performed in order to establish the multiferroic behavior of STMO material. Figure 1 shows hysteretic loops of the material in a capacitor configuration, under several applied voltages, which reveal the characteristic ferroelectric response of STMO. Due the bulk characteristic of samples, in figure 1 we do not observe a well-saturated polarization up to the maximum applied voltage. On the other hand, the experiments show the possible occurrence of a non-conventional polarization effect, which is observed as an anomaly in the hysteretic behavior showed in figure 1. For hysteresis curves of polarization as a function of applied voltage a small asymmetry is systematically evidenced. Particularly, it is observed that the system is smoothly positively polarized.

Figure 2 shows the total and partial Density of States (DOS) due to the d-like atomic orbital of Mn atom. For the total magnetic moment, the most important orbitals are x^2-y^2 and $xy+yz$ of Mn. The total calculated magnetic moment was $3.0 \mu_B$, which is an integer number of Bohr magneton that characterizes the half-metallic behavior. A detailed study of figure 2, shows that the material behaves as a half-metallic, because the total spin-up density of states across the Fermi Level is $\sim 0.04 \text{ eV}$. The conductor nature of spin up channel is majority due the x^2-y^2 and $xy+yz$ orbital of Mn. The conductor character of the spin up configuration and the theoretically determined magnetic moment of cell are in agreement with the ferromagnetic experimental response of material.

In conclusion, $\text{Sr}_2\text{TiMnO}_6$ presents a magnetic ordering transition with the presence of a typical irreversibility of ferromagnetic frustrated materials. The DOS shows that is a half-metallic. Experimental and theoretical magnetic moment is an integer value, which is else characteristic of half-metallic systems. Our results permit to infer that is possible produce multiferroic complex perovskites from the mixture of ferroelectric and ferromagnetic simple perovskites. On the other hand, our work suggests that several half-metallic perovskites could be evidence coupled magnetoelectric response.

Physical Properties in Powder, Bulk and Thin Films of $\text{La}_{2/3}\text{Ca}_{1/3}\text{Cr}_x\text{Mn}_{1-x}\text{O}_3$ with Low Doping.

D. L. Quintero, D. Girata

Physics Institute, Universidad de Antioquia, Medellin, Colombia

The manganites are of scientific and technological interest due to their physical properties and because for their applications in spin valves and systems based on the phase control. In this work we prepared $\text{La}_{2/3}\text{Ca}_{1/3}\text{Cr}_x\text{Mn}_{1-x}\text{O}_3$ (LCMCrO) with $x=0, 0.06, 0.07$ and 0.08 , in thin films by DC-magnetron Sputtering and in powder and pellets synthesized by solid state reaction, the characterization was made measuring magnetic, transport and structural properties. The characterization of the pellets and powder was performing as preliminary study in order to know the physical properties of the targets used for the thin films preparation. Since Rivadulla work we already know that the doping with Cr at low concentrations lead an increase in the magnetoresistance, MR, in a critical concentration of Cr 7% [1], that is way we decide to work around this concentration. In different works report that the only ion that replaces Mn is Cr^{3+} , which is isoelectronic with Mn^{4+} [2-4], additional, due to the preparation technique the Cr can occupy any of the two places of the manganese ions, in a random way.

We found changes in the values of the MR, metal-insulator transition temperatures, TMI, Curie temperatures, TC, and magnetization, so the magnetic behavior is strongly dependent on the composition of the samples. For the XRD and EDX we found that all the samples are single phase and that the Cr is into the manganite structure, the powder samples are not homogeneous because the nature of the reaction while the thin films have uniform concentration and topology.

In figure 1 the results of resistance in function of the temperature confirm the metallic-insulator transition; which is an expected result for lanthanum manganite with calcium at 33%. The Cr doping increase the resistance peak and reduce the TMI, this temperature is not so low for thin films. The magnetization reduces by the Cr doping but the magnetization value is not as low like other concentrations ($T_c = 250\text{K}, 220\text{K}$ and 222K for Cr 0%, Cr6% and Cr 7%, for the samples in bulk at 2kOe), the TC also reduces but not significantly as TMI. There are a range of temperatures to which the sample is ferromagnetic but remains insulating, this region is getting bigger with the Cr concentration and we have not found evidence of this behavior in others reports. The figure 2 shows the MR in function of the magnetic field at TMI, we can noticed that for 7% of Cr the MR is higher than for others concentration, the MR value is appreciably high (more than 10%) for thin films; this result has not reported for other authors since until now we have not found works with manganite doped with Cr at low concentrations in thin films. For measurements of magnetic moment in function of the magnetic field for different temperatures, we had observed from the hysteresis loops that the coercive field does not change significantly with the Cr addition.

In this work we discuss the Cr-Mn coupling and the influence of this coupling in the transport and magnetic properties of these doped manganites, we empathized in the evidence of the strongly correlated behavior of these materials and in the fact that all of the properties improve with the production of thin film rather that the powder and pellets material. The changes in the critical temperatures are not due to the variation of the fraction of the different valence Mn ions because we are doping with a very low levels of Cr. The increase of MR in the critical concentration could be explained by a FM coupling of the Mn and Cr ions, likewise as postulated exchange interaction between Mn ions.

Observation of colossal magnetoresistive (CMR) effect in thin films of mixed-valence Mn perovskite renewed interest for these materials studied since the 1950s [1]. Potential applications of noted materials require a serious study of their structure, transport and magnetic properties which are closely related. Last years much attention was also paid for the long time relaxation effects in perovskite manganites (e.g., see works [2-3] and references therein). We here present the first observation of short time magnetic relaxation in perovskite manganites.

$\text{Nd}_{0.5}\text{Sr}_{0.5}\text{MnO}_3$ samples were synthesized by the conventional solid state reaction and characterized by powder x-ray Cu K α analysis. Magnetization measurements were performed with a SQUID magnetometer (Quantum Design MPMSXL) in the temperature region of 10-300 K. AC susceptibility measurements were carried out with AC7000 LakeShore susceptometer in temperature region of 77-300 K, frequency of 85 Hz and effective ac magnetic field of 10 Oe.

According to x-ray analysis results, samples were single phase and exhibited an orthorhombic cell in accordance with previous report [4]. The temperature dependence of magnetization for $\text{Nd}_{0.5}\text{Sr}_{0.5}\text{MnO}_3$ manganites is presented in Fig. 1. In accordance with the phase diagram [4], sample of this composition is antiferromagnetic insulator at low temperatures; at the temperature $T_{CO} \approx 150$ K the manganites undergoes a charge-ordering - charge-disordering phase transition and becomes ferromagnetic metal, and in the temperature interval of 180-270 K it undergoes a ferromagnetic paramagnetic (FM-PM) transition with Curie temperature $T_C \approx 270$ K.

Figure 2 shows temperature dependence of real (χ'_{ac}) and imaginary (χ''_{ac}) components of ac susceptibility for $\text{Nd}_{0.5}\text{Sr}_{0.5}\text{MnO}_3$ sample. Large negative χ''_{ac} peak is observed in the FM-PM transition region and kink at χ'_{ac} is also observed at the noted temperature interval. No anomaly at M - T curve and its derivative are observed at the temperature region of 250-275 K where the imaginary part of ac susceptibility is negative. According to Palacio et al. [5], the negative χ''_{ac} can be observed if $\omega \ll \tau^{-1}$ (ω is a frequency of ac magnetic field, τ is the characteristic magnetization relaxation time). The negative χ''_{ac} was also observed in $\text{Gd}_5(\text{Si}_2\text{Ge}_2)$ alloy [6] and, following to Ref. [5], explained by domain wall anomalous relaxation motion under the alternating magnetic field. Other reasons for the negative imaginary component of ac susceptibility will be also discussed.

Synthesis and characterization of multiferroic polycrystalline transition metal doped BiFeO₃ thin films.

P. Kharel¹, S. Talebi^{2,1}, C. Sudakar¹, M. B. Sahana¹, V. M. Naik², R. Naik¹, G. Lawes¹

1. Department of Physics and Astronomy, Wayne State University, Detroit, MI; 2. Department of Natural Sciences, University of Michigan-Dearborn, Dearborn, MI

Multiferroic materials, which exhibit simultaneous ferromagnetic and ferroelectric order, offer enormous potential for developing novel magnetoelectronic devices. BiFeO₃ is a widely studied multiferroic oxide because it develops both magnetic and ferroelectric order at high temperatures, making it attractive for devices. While BiFeO₃ orders antiferromagnetically at ~640 K, thin film samples have been shown to exhibit a sizeable ferromagnetic moment. There have been some studies on enhancing the multiferroic properties of BiFeO₃ films by adding transition metal dopants to the samples. Doping by Cr has been especially well studied, both theoretically and experimentally. However, there has been no systematic investigation to determine how different transition metal dopants affect the dielectric and magnetic properties of BiFeO₃ films. In the following, we discuss some of our results on BiFeO₃ samples doped with a range of transition metal ions (Cr, Co, Cu, Fe, Mn, V, Zn).

We have synthesized the thin film samples using metalorganic decomposition. Bismuth 2-ethylhexanoate, Iron (III) 2-ethylhexanoate, and transition metal organic precursor solutions were mixed in appropriate ratios and the mixtures were deposited onto silicon substrate, which was spun up to 5000 rpm for 15 s to ensure a uniform film. The organic residue was evaporated by heating at 550 °C for 90 seconds and the process was repeated to build up the final film thickness of ~1 μm. The samples were then annealed in nitrogen at temperatures between 500 and 600 °C for ~1 hour. X-Ray Diffraction patterns showed only the peaks expected for BiFeO₃, with the exception of the V and Co doped samples, which also showed secondary impurity phases. We confirmed that the dopant concentration was approximately 3 at% for all samples using EDAX.

We have measured the temperature dependent magnetization for both pure and doped samples using a Quantum Design MPMS SQUID magnetometer. Representative data are plotted in Fig. 1. The magnetic susceptibility for several of the transition metal doped films was enhanced relative to the undoped samples. The magnetization of the pure BiFeO₃ film was approximately 0.3 emu/cm³ over the entire temperature range, with a small paramagnetic Curie tail at low temperatures. The transition metal doped samples exhibit increasing susceptibility with decreasing temperature and show much larger magnetizations, reaching 7.5 emu/cm³ for the Cr doped sample. Additionally, certain samples showed splitting between the field cooled (FC) and zero-field cooled (ZFC) magnetization curves, which indicates the freezing of the net magnetic moment at low temperatures, possibly due to exchange bias coupling or superparamagnetic effects.

We have also investigated the dielectric response of these samples, in order to determine whether adding transition metal dopants could improve the ferroelectric properties by reducing the dielectric loss in the films. The temperature dependence of the dielectric loss is plotted in Fig. 2. The pure BiFeO₃ film (upper curve) shows a loss tangent (tan δ) ~1, indicative of a lossy dielectric material. On doping with transition metals, the dielectric properties of the samples improved substantially, with the dielectric loss being reduced by an order of magnitude for the Co, Cr, and Zn doped films.

In summary, we found that doping these polycrystalline BiFeO₃ films with transition metal ions substantially improved the dielectric characteristics of samples for almost all dopants, and

improved the magnetic properties for several different transition metals. The Cr doped films showed the most significant improvements among all transition metal doped films.

Fig.1. Magnetization of (a) pure BiFeO₃, (b) Cr doped BiFeO₃, and (c) Zn doped BiFeO₃. The open circles show the field cooled data, the filled circles show the zero field cooled data. All measurements were done with an applied field of 1 kOe.

Fig. 2. Dielectric loss component as a function a temperature for different transition metal doped BiFeO₃ samples, as labeled. The curve labeled “Fe” represents pure BiFeO₃. Note the logarithmic scale.

Influence of current induced magnetic inhomogeneities on spin wave propagation.

T. Neumann¹, A. A. Serga¹, M. P. Kostylev², B. Hillebrands¹

1. Fachbereich Physik und Forschungsschwerpunkt MINAS, TU Kaiserslautern, Kaiserslautern, Germany; 2. School of Physics, University of Western Australia, Crawley, WA, Australia

We present the first comprehensive experimental study of the frequency dependent reflection and transmission of dipole-dominated backward volume magnetostatic spin waves (BVMSW) through the localized inhomogeneity created by a dc-current induced Oersted field. A resonant behaviour of the reflected and transmitted signal intensities was observed. The results build a foundation for the understanding of the spin-wave propagation in current induced periodic magnetic structures and are important for the design of dynamic magnonic crystals.

Dynamically controllable periodic magnetic structures, so called dynamic magnonic crystals, possess a large potential in the field of microwave signal processing on a nanosecond time scale. Such crystals can be realized with the help of dc-current carrying wires placed on the surface of magnetic films. By changing the dc-current the local bias magnetic field and thus the spin wave propagation is altered. Depending on the direction of the current w.r.t. the external magnetic field two principally different kinds of magnetic inhomogeneities occur: a magnetic hill (local increase of bias magnetic field) or a magnetic valley (local decrease).

In order to determine the influence of dc-current induced magnetic inhomogeneities on the dynamics of spin waves we have studied the propagation of BVMSW pulses in a 5 μm thick yttrium iron garnet (YIG) film through a single inhomogeneity.

The measurements were performed in the pulse regime in order to avoid overheating the sample as a result of the applied dc-current between -2 A and +2 A. The BVMSW pulses were excited by 280 ns long microwave pulses with a carrier frequency $\omega/2\pi$ between 7.01 GHz and 7.115 GHz in a bias magnetic field $H=1800$ Oe. The dc-current pulses were 180 ns long and thus only affected part of the corresponding BVMSW pulses. By comparing the unaffected part it was possible to verify that the experimental conditions remained the same. Figure 1 shows a sketch of the experimental setup. During the measurement the reflected and transmitted signal were detected simultaneously. The main results are displayed in Figure 2. The two upper panels contain the reflected intensities while the lower panels show the transmitted signal levels.

For a magnetic valley, which corresponds to the left panels in Figure 2, a barrier for the spin-wave propagation is created from which the spin wave pulses are reflected. The intensity of the reflected signal increases monotonically with increasing valley. This situation is associated to the so-called spin wave tunneling phenomenon [1].

In the case of a magnetic hill the behaviour proves to be more complex as resonances of the spin-wave intensity are observed. Minimal reflectivity is obtained when the dc-current is switched off and at a current of 1.02 A.

The reflection is maximal for currents of 0.52 A and 1.74 A. This behaviour was observed for all considered frequencies (and hence spin-wave wave vectors) with no significant wave vector dependence of the current values corresponding to the mentioned extrema. However, the maximally reflected intensity normalized w.r.t. the unperturbed level of the transmitted pulse with the same carrier frequency strongly depends on the wave vector. While close to the frequency of ferromagnetic resonance (FMR) the signal is almost completely reflected, the reflection is only partial for lower frequencies.

We interpret the existence of extrema in reflection as evidence of a resonant scattering [2].

By comparing the results obtained in reflection and transmission we can deduce that the spin wave energy is conserved and practically no energy is lost inside the barrier. Measurements at other bias magnetic fields from 800 Oe to 2200 Oe confirm the described observations.

In conclusion, we note that the spin wave propagation is significantly different for a magnetic hill and valley. In the first case the intensity depends non-monotonically on the current and is - for small current values - influenced strongly by current changes. Together with the described, strong resonance effects close to the FMR this must be kept in mind when designing dynamic magnonic crystals.

A YIG/GGG/GaAs-Based Magnetically Tunable Wideband Microwave Band-Pass Filter Using Cascaded Band-Stop Filters*.

G. Qiu¹, B. T. Wang², C. S. Tsai^{1,3}

1. Dept of Electrical Engineering and Computer Science, and Institute of Surface and Interface Science, University of California, Irvine, CA; 2. Wang, NMR Inc., Livermore, CA; 3. Institute of Electrooptics Engineering, National Taiwan University, Taipei, Taiwan

Electronically tunable microwave devices are essential in military and long-distance communications applications [1]. For example, tunable band-pass filters are used in the scanner receiver of electronic support measures systems. Yttrium iron garnet / gadolinium gallium garnet/gallium arsenide (YIG/GGG/GaAs)-based magnetically tunable band-stop filters with large bandwidth were realized recently [2].

In this paper, a microwave band-pass filter with large tuning ranges in center frequency and bandwidth using a pair of aforementioned band-stop filters in cascade is reported. Fig. 1 shows the basic band-stop filter utilized [2]. A YIG-GGG layer is laid upon the GaAs-based microstrip meander-line. An incoming microwave is coupled into the YIG/GGG layer and the maximum coupling and, thus, peak absorption of the microwave power occurs when its carrier frequency coincides with the ferromagnetic resonance (FMR) frequency of the YIG/GGG layer. A Y-direction bias magnetic field, H_{ext} , with non-uniform distribution along the X-axis is applied. The different bias magnetic fields at the four segments of the meander-line would result in a large widening of the resultant bandwidth in the stopband. Such band-stop filter has demonstrated a large tuning range in peak absorption frequency of 5.0 to 21.0 GHz and an absorption level of 35.5 dB together with a corresponding 3 dB bandwidth as large as 1.70 GHz[2]. Clearly, a band-pass filter with large tuning ranges in both the center frequency and the bandwidth can be realized using a pair of such basic band-stop filters in cascade in which different bias magnetic fields ($H_{02} > H_{01}$) are applied (Fig. 2). In modeling and simulation, the band-pass filter was modeled as a series connection of the lumped-element equivalent circuit [3][4] for the two basic band-stop filters each with a four-segment meander-line. The combined equivalent circuit was then simulated using *Microwave Office* software. The simulated results on the transmission characteristics of the resulting band-pass filter are shown in solid line in Fig. 3.

The band-pass filter was constructed using a pair of wideband band-stop filters in cascade each with a YIG/GGG layer (YIG film 6.8 μm thick and 6.5 \times 8.0mm² in the Y and X directions) laid upon a 4-segment microstrip meander-line. The microstrip meander-line with segment length of 5.7 mm was fabricated on a 350 μm thick GaAs substrate. The non-uniform bias magnetic field was facilitated by a pair of *NdFeB* permanent magnets [2]. The measured transmission characteristics of the band-pass filter (shown in circles in Fig. 3) at 2,750 Oe (H_{01}) and 4,150 Oe (H_{02}) shows a 3dB bandwidth of 1.73 GHz, out-of-band rejections of 33 dB, and an insertion loss of -4.25 dB. A good agreement between the measured and the simulated results in the tuning ranges of center frequency in the passband and the peak absorption frequency in the two guarding stopbands has been achieved. Note that the large difference between the simulated and the measured absorptions in the two stopbands was due to the limitation in the dynamic-range of the power sensor used. Finally, the insertion loss in the passband can be reduced using an optimized microstrip meander-line. In conclusion, a wideband band-pass filter with tunable center frequency of 5.9 to 17.8 GHz and bandwidth of 1.27 to 2.08 GHz as well as large bandwidth in the two guarding stopbands has been realized using a pair of band-stop filters in cascade. By optimized design such magnetically-tun-

able microwave band-pass filters with even larger tuning ranges in both center frequency and bandwidth as well as smaller insertion losses can be realized.

Bistable control of ferromagnetic resonance frequencies in ferromagnetic trilayered dots.

Y. Nozaki, K. Tateishi, S. Taharazako, S. Yoshimura, K. Matsuyama
Dept. of Electronics, Kyushu University, Fukuoka, Japan

In programmable microwave filters, it is essential to tune the frequency where the transmitted microwaves are strongly attenuated. In our previous study, we have numerically [1] and experimentally [2] examined that the ferromagnetic resonance (FMR) frequency f_{FMR} of NiFe/Cu/NiFe trilayered dot can be discontinuously changed by switching the relative orientation of magnetization from parallel (P) to antiparallel (AP). This is attributed to that the magnetostatic fringe-field exerted on each NiFe layer changes its polarity from negative to positive in relation to the magnetization direction. In this paper, to understand the influence of the fringe-field coupling on the FMR properties quantitatively, we have investigated the dependence of f_{FMR} on the aspect ratio of the dot. Figure 1 shows the scanning electron micrograph of the magnetic trilayered dots consisting of NiFe(18 nm)/Cu(9 nm)/NiFe(18 nm) fabricated on a microfabricated coplanar waveguide. The length L of the dot is varied from 0.5 to 2.5 μm , while the width w is always 0.3 μm . The variations of the FMR spectra of the dots during the magnetization reversal process was measured using a microwave probing system combined with a vector network analyzer. The external magnetic fields were applied at an angle θ_H to the long axis of the dot. Figure 2 shows the variation of f_{FMR} of the dot ($L=2.5 \mu\text{m}$) measured with sweeping the magnetic fields ($\theta_H=0$) from 600 to -550 Oe. The f_{FMR} shows rapid increase at -92 and -397 Oe, where the magnetic configuration switches from P to AP and AP to P , respectively. In the case of AP , the increase of f_{FMR} with the magnetic field is smaller than that of the P configuration. This is attributable to the conflicted dependences of f_{FMR} on the magnetic field in top and bottom NiFe layers with AP configuration of magnetization [2]. Figure 3(a) shows the aspect ratio L/w dependence of f_{FMR} . The closed and open circles indicate the results for P and AP , respectively. In the case of P , the f_{FMR} decreases with decreasing the L/w because the shape anisotropy is suppressed. When L/w becomes smaller than 3.7, the metastable P configuration is no longer appeared at the remanent state by dominating the antiferromagnetic fringe-field coupling. It is interesting that the f_{FMR} of the dot with AP configuration shows little dependence on the aspect ratio. The decrease of L/w causes not only the suppression of the shape anisotropy but also the increase of the fringe field exerted on each NiFe layer. In the case of AP , the fringe field is positively applied to the magnetization in each NiFe layer so that the increase of the fringe field enhances the f_{FMR} . It is considered that the decrease of f_{FMR} owing to the suppression of shape anisotropy is compensated by the increase of the fringe field. Finally, we have tried to control the f_{FMR} at the remanent state by choosing the magnetized angle of the dot. Figure 3(b) shows the f_{FMR} at the remanent state as a function of θ_H . The strength of the magnetic field used to magnetize the dot is 1.4 kOe. It is obviously observed that the high- f_{FMR} state implying the AP configuration appears at θ_H in the range from 88 to 92 degrees, while the low- f_{FMR} state suggesting the P configuration is preferentially realized as $\theta_H < 88$ degrees. The opposed rotation of magnetization resulting the AP configuration at large θ_H is occurred to decrease the magnetostatic coupling energy of the dot. In the demagnetizing process along the in-plane hard axis of the dot, there is no energy barrier on the way to the AP configuration. As a consequence, the complete AP configuration can be realized even if the switching field of each magnetic layer is distributed in the multilayer. It is considered that this method is very useful to create the AP configuration especially for the multilayered dot with a large stacking number.

An Electric Field Tunable Millimeter-Wave Ferrite-Piezoelectric Phase Shifter.

A. S. Tatarenko, G. Srinivasan

Physics, Oakland University, Rochester, MI

Abstract

A novel electric field tunable phase shifter with a barium ferrite-lead zirconate titanate (PZT) bilayer is designed and characterized. The 50-GHz phase shifter is based on ferromagnetic resonance (FMR) in barium ferrite. An electric field applied across PZT produces mechanical deformation that manifests as a shift in FMR, and therefore, a differential phase shift. Estimates of the phase shifts are in agreement with data.

Introduction

Ferrites are materials of choice for tunable microwave devices. The magnetic field (H) tuning of such devices could be achieved over a very wide frequency range, but is slow and requires high operating power. A similar, but rapid tunability and low-power requirements could be accomplished with ferroelectrics and electric fields (E). A combination of ferrite and ferroelectrics, therefore, could provide simultaneous E and H-tuning and the advantages of both methods [1].

This work is on an electric field controlled mm-wave barium hexaferrite-lead zirconate titanate (PZT) phase shifter operating close to FMR. In the presence of E, the piezoelectric deformation in PZT will result in an internal field $\delta H = -A E$ (A is the magneto-electric coupling coefficient) in the ferrite, leading to a frequency shift $\delta f = -2.8 \text{ GHz/kOe } \delta H$ in FMR [2] and a differential phase shift $\delta \phi$. Here we discuss the performance characteristics of a 50 GHz barium ferrite-PZT phase shifter.

Experiment

First we measured the ME effect induced shift in FMR profiles. A bilayer of ferrite-PZT was prepared by bonding a single crystal ferrite slab to a PZT plate and it formed the short of a coaxial-to-wave guide adapter. Absorption vs f profiles were obtained for E and H perpendicular to the bilayer plane and parallel to the magnetic easy axis of the ferrite. Several peaks due to magnetostatic forward volume waves were observed and representative data in Fig.1 shows the E-induced frequency shift for the dominant mode. As E was increased from 0 to 8 kV/cm, a down-shift in frequency of 30 MHz was measured. The shift reversed sign with the reversal of direction of E.

The phase shifter studied consisted of a $3.5 \times 1.6 \times 0.1 \text{ mm}^3$ bilayer placed on the narrow side a rectangular waveguide. Phase vs. f characteristics as in Fig.2 were obtained as a function of H and for E=0 and 8 kV/cm. One observes a near-linear variation in the phase shift with E. Theoretical estimates of the phase shift are in good agreement with the data, as seen in Fig.2. The insertion loss was quite high, on the order of 15-20 dB.

The work was supported by grants from the Office of Naval Research and the Army Research Office.

Design of Scandium and Indium doped hexaferrite microstripline phase shifters for X-band applications.

T. Sakai, C. Chinnasamy, V. Ilanchelian, S. Yoon, C. Vittoria, V. G. Harris
Electrical & Computer Engineering, Northeastern university, Boston, MA

Tunable ferrite phase shifters are widely used as a basic component of microwave circuits in communication and radar systems. To meet the industry requirements in communication and radar systems, the new generation of ferrite phase shifters should be able to work at K-band and higher frequencies. However, at such high frequencies, ferrite phase shifters using spinel or garnet need high biasing field (5 kOe), applied over the length of the device, which is too excessive for practical devices. The solution to this problem in ferrite is to use self-biased hexaferrite, which is inherent of large anisotropy field with self biasing properties either in-plane or out-of-plane orientation. (Sc) and Indium (In) substituted hexaferrite materials are candidates for the ferrite substrate in the next generation of planar tunable ferrite phase shifters operating at millimeter-wavelength frequencies. We have synthesized, self-biased, designed, fabricated, measured, and modeled such a phase shifter operating at 10 GHz that utilizes a (Sc) and Indium (In) substituted hexaferrite crystals.

Scandium ($\text{BaFe}_{12-x}\text{Sc}_x\text{O}_{19}$, $x = 0.5, 1$) and Indium substituted ferrites ($\text{BaFe}_{12-y}\text{In}_y\text{O}_{19}$, $y = 1, 2$) have been prepared by using the modified coprecipitation technique followed by sintering at moderate temperature. XRD patterns in Fig. 1 confirmed the formation of single phase Sc/In doped Ba-hexaferrite with the magnetoplumbite structure. Scanning electron micrograph (Fig. 2) of the $\text{BaFe}_{11}\text{In}_1\text{O}_{19}$ sample sintered at 1150°C shows the formation of larger grains, which are micrometer size and have better intergrain connectivity. After ball milling the samples were screen printed on alumina substrates and applied with high magnetic field (1.5 T) parallel to the surface of alumina substrates. All in-plane oriented thick films were annealed at certain temperatures and are measured with X-ray diffractometer, SEM (Scanning Electron Microscope), VSM (Vibrating Sample Magnetometer), and FMR (Ferromagnetic Resonance). The annealed in-plane oriented samples are substituted in a phase shifter design as shown in (Fig. 3). The design and modeling combined the conjugate method of microstripline on dielectric substrate and magnetostatic mode calculation in ferrites. This combination of a substantial phase shift and a relatively small external biasing field makes the Sc and In substituted hexaferrites as promising materials for low frequency (X-band) phase shifters. The results will be discussed in detail in the paper.

Propagation characteristics of magnetostatic surface waves in a YIG-based one-dimensional magnonic crystal composed of rubber magnets.

K. Togo¹, K. Hatafuku¹, M. E. Dokukin¹, J. Kim¹, K. Shin², M. Inoue¹

On the analogy of photonic crystals, where light traveling is modified via photonic bandgap and localization of waves originating in the spatial periodicity of propagation media, magnonic crystal is indeed an attractive medium for controlling the propagation of magnetostatic surface waves (MSSWs) [1]. In fact, Tkachenkoa et al. recently reported that the propagation and manipulation of spin waves in a magnonic crystal with an internally structured defect [2]. The propagation mechanism of MSSW is due to the dipole-dipole interaction of magnetization, and hence the magnetic periodicity such as a magnetic domain alignment inherently attributes to the interference effect of MSSW, leading to the bandgap nature in MSSW propagations. In this respect, we here demonstrate the propagation characteristics of MSSW in a YIG-based one-dimensional magnonic crystal whose magnetic periodicity was formed with rubber magnets.

The one-dimensional magnonic crystal and the measurement system of MSSW are illustrated in Fig. 1. A YIG film (14 μm thickness) grown epitaxially on a GGG substrate was used as a base propagation medium of MSSW, on which rubber magnets (0.5 mm width and 0.8 mm thickness) were placed at 0.5 mm spatial interval, so as to form the one-dimensional magnetic periodicity. For exciting and detecting MSSWs, a pair of Cu microstrip lines (150 μm width and 18 μm thickness) formed on a Teflon substrate by photolithography was used. An external magnetic field H_0 ranging from 100 Oe to 700 Oe was applied in plane perpendicular to the propagation direction of MSSWs. The propagation characteristics of MSSWs were examined with a network analyzer.

Figure 2 shows the transmission spectra of MSSWs observed in the magnonic crystal (solid curve) and the YIG film without the rubber magnets (broken curve). It is clearly seen at around 2 GHz that a stop band appeared for the case of magnonic crystal. The wavelength λ of MSSW is given by $\lambda = 4\pi d / \ln(\omega_M^2 / (2\omega_H + \omega_M)^2 - 4\omega^2)$ with and, where γ is the gyromagnetic constant, H_0 is the external magnetic field, ω is the angular frequency of MSSW, while d and M_s are, respectively, the YIG film thickness and the saturation magnetization (1735 G). When $f = \omega/2\pi = 2$ GHz and $H_0 = 200$ Oe, λ is evaluated to be 1 mm, whose value quantitatively coincides with the periodicity of rubber magnets (0.5 mm interval), suggesting that the magnetic periodicity is effective for obtaining the artificial controllability of MSSWs. This is also confirmed by evaluating the center frequency of stop band as a function of the external magnetic field H_0 . As shown in Fig. 3, by increasing the intensity of magnetic field, the stop band frequency increased monotonically, where good quantitative agreements among the experimental and theoretical values were obtained.

A magnetosensitive microwave absorption characterization of terbium.

G. Alvarez¹, H. Montiel², R. Zamorano³, R. Valenzuela¹

1. Departamento de Materiales Metálicos y Cerámicos, Instituto de Investigaciones en Materiales de la Universidad Nacional Autónoma de México, Ciudad de México, Mexico; 2. Centro de Ciencias Aplicadas y Desarrollo Tecnológico de la Universidad Nacional Autónoma de México, Ciudad de México, Mexico; 3. Departamento de Ciencias de los Materiales, Instituto Politécnico Nacional, Ciudad de México, Mexico

We report on the effects of temperature and dc magnetic field on magnetosensitive microwave absorption measurements at 8.8-9.8 GHz (X-band), in powder samples of terbium. We have recently implemented two novel experiments to measure the magnetosensitive non-resonant microwave absorption [1-4], known as magnetically modulated microwave absorption spectroscopy (MAMMAS), and the low-field microwave absorption (LFA). In the MAMMAS measurement, the sample is subjected to a constant dc field, and its microwave absorption behavior is obtained as a function of temperature [1,3,4]. LFA measurement refers to the non-resonant microwave absorption around the zero DC field, in otherwise typical electron paramagnetic resonance setup [2,4-6].

Figure 1 shows that the MAMMAS signal increases as temperature decreases from 300 K to $T_N=227$ K. In this temperature range the material is paramagnetic (PM)[7], and the paramagnetic microwave absorption increases [3,4] with the decrease in temperature. MAMMAS response reaches a maximum at T_N , associated with the onset of an antiferromagnetic (AFM) helical ordering [8]. The absorption then decreases from T_N and about $T_C=220$ K, a change in slope points to another microwave energy-absorbing process that changes the previous behavior; this feature is associated with a subsequent order-order transformation [8]. After that, the microwave absorption decreases with decreasing temperature until $T_F=214$ K is reached. Below T_F , the microwave absorption slowly increases and we can attribute this behavior of the MAMMAS profile to the presence of a ferromagnetic (FM) structure, where the magnetic moments lie in the plane perpendicular to the hexagonal axis [8] of the crystalline lattice.

A frozen-strain model has been proposed [9] to take into account the influence of magneto-elastic interactions in the microwave absorption of Tb. This model predicts a non-resonant microwave absorption (LFA) at about 10 GHz and $T=230$ K, which has not been observed [10,11]. In this work, however, we report the existence of such LFA signal at X-band, see inset in Fig. 1, in good agreement with the frozen-strain model. We discuss all the obtained results to give a new look, based on novel techniques, to an old problem.

Magnetic tuning of surface acoustic wave devices within high frequency range.

C. Cavaco¹, L. A. Francis^{2,1}, L. Lagae¹, G. Borghs¹

1. IMEC, Leuven, Belgium; 2. Université catholique de Louvain, Louvain-la-Neuve, Belgium

Surface Acoustic Wave (SAW) devices play a key role in wireless communication and sensor applications. SAW devices are e.g. commonly used in signal filtering for their small size, small power consumption and costs, although their frequent lack on tunability of acoustic wave velocity restricts their usefulness in crucial areas such as time delay and tuneable filter applications [1]. Several approaches have been used to address this problem [1-3], but until now tunable SAW devices working at frequencies above 1 GHz where never attained.

In this research a magnetic method was used to induce a variation in the acoustic velocity of SAW devices in a high frequency range. More specifically, we exploited the magnetoelectric effect defined as the induction of magnetization by an electric field or of electrical polarization by a magnetic field [4]. This effect usually originates in a magnetoelastic coupling, i.e., interaction between the magnetization and the strain of a magnetic material and has recently been applied to obtain electrical control over the system magnetic properties or vice-versa [5,6].

The used devices, as shown in Fig. 1, essentially comprise a $\text{Co}_{50}\text{Fe}_{50}$ magnetostrictive thin film sputtered in between two gold interdigital transducers (IDTs), i.e., in between two interpenetrating finger shaped electrodes over a piezoelectric substrate, LiNbO_3 .

In this method surface acoustic waves are generated at the free surface of the piezoelectric substrate by applying a voltage to an input metal-film IDT which converts the voltage signal into mechanical waves, the second IDT works as an output transducer converting back the mechanical waves to an output voltage.

Since the thin $\text{Co}_{50}\text{Fe}_{50}$ film is magnetostrictive, its effective elastic modulus changes as the film is magnetized. Thus, a variation of the applied external magnetic field induces changes in the acoustic wave velocity, which can be measured through the phase shift created in the SAW delay line.

These phase shifts, as well the frequency spectrum, were measured using a HP 8753D Network analyzer (transmission parameter S_{21}). The induced phase shift across the device is converted to a variation on the acoustic velocity by:

$$\Delta v = \Delta\theta \lambda v_0 / 360^\circ L_{\text{film}};$$

where Δv is the SAW velocity variation, $\Delta\theta$ is the phase variation induced by the magnetelastic coupling, λ is the SAW wavelength that corresponds to four times the width of one of the IDT fingers, L_{film} is the magnetostrictive thin film length and v_0 is the substrate SAW velocity that is obtained through the relation $v = f \times \lambda$, where f is the center frequency of the SAW device.

The typical frequency response for a fabricated SAW device working at 1.49GHz and its phase and corresponding relative velocity changes in function of the applied external magnetic field are shown in Fig. 2.

The verified 0.11% variation of the SAW device acoustic velocity with an external magnetic field of 80mT, proves that it is possible to magnetically achieve a similar tunability to the one obtained through well know methods like voltage tuning methods. These voltage tuning methods work at lower frequencies (e.g. 660MHz [1]) or require extremely high voltages (e.g. 6kV [2]) to achieve a 0.62% or 0.1% variation of the SAW device acoustic velocity, respectively.

In conclusion, we have achieved a reproducible magneto-electric tunability over the acoustic velocity of a SAW device using the magnetostrictive and piezoelectric properties of $\text{Co}_{50}\text{Fe}_{50}$ thin films and LiNbO_3 substrates, respectively. The achieved tunability is similar to what was previously

obtained through voltage induced methods but with higher operation frequencies for the magnetic method.

Microwave Absorption Properties of The Hierarchically Branched Ni Nanowires Composites.

L. Qiao, J. Wang, X. Han, B. Gao, F. Wen, F. Li

Lanzhou University, Institute of Applied Magnetism, Key Laboratory for Magnetism and Magnetic Materials of Ministry of Education, Lanzhou, China

The microwave absorption properties of the ferromagnetic metal-based materials draw much attention due to their advantages of higher saturation magnetization than ferrites^{[1][2][3]}.

In this work, the hierarchically branched Ni nanowires are fabricated by the electrodeposition within the branched nanoporous of anodic aluminum oxide (AAO) templates.

We fabricated the large area of branched nanoporous of AAO templates with $20 \times 20 \text{ cm}^2$ by reducing the anodizing voltage multiple times in the anodization^[4]. Initially, the anodizing voltage is 80 V, during the anodization, the anodizing voltage was reduced by a factor of 1/2 to form Y-branched pores. Ni was deposited in the pores by ac electrolysis in an electrolyte consisting of NiSO_4 (120g/L), boric acid (45g/L). Branched Ni nanowires were liberated from the AAO film by dissolving the alumina layer with 0.1 mol/L NaOH solution.

Fig. 1 shows the SEM micrographs of the hierarchically branched Ni nanowires, large-scale nanowires with 100 nm in diameter and 10-15 μm in length were prepared. The diameter of each wire is below 1 μm , which would decrease skin effect.

The composite samples were prepared by mixing the branched Ni nanowires with epoxy resin with 30% volume concentration of the particles. Fig.2 shows the frequency dependence of the relative complex permittivity of the sample. It can be found that the values of the real part of permittivity is about 9, and the imaginary part is about 0.5 over the 1-12 GHz frequency range.

Fig. 3 shows the complex permeability of the composites. It is note worthy that the maximum value of the imaginary part of permeability appearing at 9 GHz implies that the natural resonance. According to the Kittel's equation, the natural resonance of nanowire is : $f_r = \gamma(H_a + 4\pi M_s/2)$, where $\gamma = 2.8 \text{ GHz/kOe}$ is the gyromagnetic ratio, the theoretical natural resonance frequency should be around 8.6 GHz. The skin-effect criterion is related to expression^[5]: $\mu''(\mu')^{-2}f^{-1} = 2\pi\mu_0 d^2 \sigma/3$. Fig. 4 shows the value of $\mu''(\mu')^{-2}f^{-1}$ for the sample is markedly changed over 2-15 GHz, and the change extent is bigger than 0.03 ns. Therefore, it means that the magnetic loss in branched Ni nanowires is mainly caused by the natural resonance.

The reflection loss R (dB) of the branched Ni nanowires/epoxy resin composites were calculated, as shown in Fig. 5. It is shown that the maximum reflection loss reaches 13 dB at 8 GHz with 3 mm in thickness.

The discovery of giant magnetoresistance (GMR) in Fe/Cr multilayers[1] has attracted considerable scientific interest. Since then, many efforts have been devoted to studying the magnetization and magnetoresistance (MR) of multilayered systems. MR has also been observed in Fe/ZrO₂ discontinuous multilayers[2] and Co-ZnO inhomogeneous magnetic semiconductor films[3] *etc.* However, the mechanism of the presence of MR in transition metal doped semiconductor films is far from being fully understood.

In this work, a series of [Co(0.6 nm)/ZnO(x nm)]₆₀ (x=0.3~3) multilayer films were prepared on glass substrates by magnetron sputtering at room temperature. After deposition, the samples were annealed under the pressure of 2×10⁻⁴ Pa at 400 °C for 120 min.

Fig. 1 shows the variation of MR ratio of [Co(0.6 nm)/ZnO(x nm)]₆₀ films measured at room temperature with ZnO layer thickness. Here the MR ratio was calculated by $MR = [R(H) - R_0] / R_0 \times 100\%$, where R(H) and R₀ are the resistances with/without an applied magnetic field. When ZnO layer thickness is increased from 0.3 nm to 3 nm, MR ratios of the as-deposited Co/ZnO films are gradually decreased and MR ratios of the annealed films are increased. Fig. 2 shows the typical dependence of MR ratio on the magnetic field, which clearly reflects that MR ratios are strongly dependent on the ZnO layer thickness and the post-annealing process.

ZnO layer thickness also strongly affects R₀ values of Co/ZnO films (as seen in Fig. 3). With increasing ZnO layer thickness, R₀ values of both the as-deposited films and the annealed ones are increased, which is attributed to the increase of ZnO semiconductor fraction. The as-deposited films may behave the multilayers structure, whereas the post-annealing deteriorates the multilayers structure and leads to granular films. The granular structural [Co(0.6 nm)/ZnO(0.3~3 nm)]₆₀ films after annealing can be divided into three distinct structural regimes. (1) ZnO layer thickness ≤ 0.7 nm: The large MR ratios of the as-deposited Co/ZnO films may come from the coupling between the magnetic Co layers mediated by the non-magnetic ZnO layers. Whereas, when the films were annealed at 400 °C for 120 min, Co grains could be grown and touched each other. This leads to the remarkable reduction of both R₀ and MR ratios. (2) ZnO layer thickness ≥ 1 nm: The thicker ZnO layer in the as-deposited films makes the coupling between Co layers very weak, which causes MR ratios small. Co grains can be grown and dispersed in ZnO semiconductor host after annealing. Spin related tunnelling takes place between isolated Co grains under applying a magnetic field, this is the main reason for the increase of MR ratios in the annealed Co/ZnO films as compared with the as-deposited ones. (3) 0.7 nm ≤ ZnO layer thickness ≤ 1 nm: This is the regime in which ZnO fraction is suitable to form labyrinth structure after annealing.

In summary, a series of [Co(0.6 nm)/ZnO(x nm)]₆₀ multilayers were systematically investigated. We found a large MR ratio of 10.4% in as-deposited Co/ZnO films. MR ratios and R₀ are strongly dependent on the ZnO layer thickness and the post-annealing process.

<p>Introduction

Advances in diluted magnetic semiconductors (DMS) has opened up new perspectives for realizing spintronics devices which combine microelectronics with spin-dependent effects that arise from the interaction between spin of the carrier and the magnetic properties of the material. The application of non-equilibrium growth methods such as molecular beam epitaxy (MBE) has been demonstrated to offer doping in excess of the thermodynamic solubility limit [1,2]. However for many semiconductor materials, the bulk solid solubility of magnetic or electronic dopants is not favorable for the coexistence of carriers and spins in high densities. In this aspect, IV-VI ferromagnetic $\text{Ge}_{1-x}\text{Mn}_x\text{Te}$ is an interesting material to study because it has been reported to have a high solubility limit of more than 95% Mn in GeTe and a highest Curie temperature of $T_c = 140\text{K}$ [3]. So far, a comprehensive understanding of the magneto-transport behavior of this material has not yet been achieved. In this work, we conduct the temperature dependent magneto-transport studies on a $\text{Ge}_{1-x}\text{Mn}_x\text{Te}$ film with high Mn composition of $x = 0.98$ prepared on BaF_2 (111) substrate using a MnTe buffer layer by solid source MBE technique.

</>>

Experimental Results

Figure 1 shows the M-H curves of the $\text{Ge}_{0.02}\text{Mn}_{0.98}\text{Te}$ film measured at 5 K with field applied in-plane ($H \parallel$ plane) and perpendicular to plane ($H \perp$ plane). We did not observe distinct magnetic anisotropy for different applied-field directions as the difference in coercivity is very small. The ratio of $M_r(\parallel)/M_r(\perp)$ increases from 1.44 at $T = 5\text{K}$ to 2.58 at $T = 90\text{K}$, where $M_r(\parallel)$ and $M_r(\perp)$ are the in-plane and perpendicular remanences, respectively. Our temperature dependence of coercive fields in the two cases is nearly the same. The result indicates that the magnetic moments are not all in-plane but part of them are out of plane. The existence of the out-plane magnetic moments could be due to surface roughness which may induce spin disordering in the film surface. As the temperature increases, the disordered spins are randomized, therefore the out-plane magnetic moments are attenuated at near the T_c . Magnetoresistance (MR) measurements were performed with ($H \parallel$ plane) and ($H \perp$ plane) from 20 to 120 K as shown in Fig. 2. A negative MR was observed for all temperature range for ($H \parallel$ plane) [Fig. 2(a)]. Figure 2(b) shows the MR behavior of the ($H \perp$ plane). The MR is entirely negative for $T < 75\text{K}$. The disappearance of the negative MR above $T > 95\text{K}$ could be represented as a transition from ferromagnetism to paramagnetism at $T_c = 95\text{K}$ which is consistent with our M-T curve results.

Exponential decrease of neutral dangling bonds density in rare-earth doped amorphous Si films.

W. Iwamoto¹, P. G. Pagliuso¹, C. Rettori¹, A. R. Zanatta²

1. DEQ, IFGW - Unicamp, Campinas, Brazil; 2. Instituto de Física de São Carlos, USP, São Carlos, Brazil

Amorphous silicon films doped with rare-earth elements ($a\text{-Si:RE} = \text{Y, Gd, Er, and Lu}$) have been prepared by co-sputtering and studied by means of electron spin resonance (ESR). It was found that the rare-earth doping exponentially depletes the neutral dangling bonds D^0 density. The reduction of D^0 is significantly larger for the magnetic REs (Gd^{3+} and Er^{3+}) than for the non-magnetic ones (Y^{3+} and Lu^{3+}). These results are interpreted in terms of a RE volumetric effect and an exchange-like interaction, $\sim J_{\text{RE-DB}} S_{\text{RE}} S_{\text{DB}}$, between the spin of the magnetic REs and that of the D^0 . All films were prepared in a high vacuum chamber (base pressure $\sim 2.0 \times 10^{-6}$ Torr), by radio frequency (13.56 MHz) sputtering a Si

(99.999% pure) target covered at random with small pieces of metallic RE (99.9% pure) elements. For the whole series of films the nominal RE concentration was estimated by the relative RE-to-Si target area ($A_{\text{RE}}/A_{\text{Si}}$). The ESR experiments were carried out at room- T in a Bruker X-band (9.47 GHz) spectrometer using a room- T TE₁₀₂ cavity. The density of the dangling bonds species D^0 was determined from the ESR intensity as compared to a strong KCl-pitch standard sample. Room- T Raman scattering and X-ray diffraction measurements were performed in order to analyze the atomic structure of the $a\text{-Si:RE}$ films.

Figure 1 shows the room- T D^0 ESR signal of $a\text{-Si}$ and $a\text{-Si:RE}$ films doped with magnetic (Gd^{3+} and Er^{3+}) and non-magnetic (Y^{3+} , and Lu^{3+}) RE elements. For these films RE ~ 0.2 at.%. The ESR signal of quartz substrate is shown for comparison. According to these data the RE-doping reduces the ESR signal intensity of the D^0 states and the reduction produced by Gd^{3+} and Er^{3+} is remarkably greater than that caused by Y^{3+} and Lu^{3+} . In this work it is shown that, as a function of the RE concentration, the D^0 density decreases exponentially.

Introduction

Nitrides semiconductor doped with Mn, such as Mn-AlN and Mn-GaN, have been investigated as promising diluted magnetic semiconductors, because some groups have suggested that these materials show ferromagnetism at room temperature (RT) [1]. On the other hand, other groups have suggested that these materials do not exhibit ferromagnetism at RT [2, 3]. Thus, whether these materials exhibit ferromagnetism above RT remains to be elucidated. In this study, we investigated the magnetic behavior and structure of Mn-AlN ($\text{Al}_{1-x}\text{Mn}_x\text{N}$: $x = 0.05 - 0.24$) films fabricated by reactive DC magnetron sputtering, and report the absence of ferromagnetism at RT in these films. In addition, we discuss the origin of magnetic behavior in these films from the structural point of view. Results and Discussion

Figure 1 shows the temperature dependence of DC susceptibility at a magnetic field of 10 kOe for 250-nm-thick $\text{Al}_{1-x}\text{Mn}_x\text{N}$ films with various Mn concentrations. For $x = 0.05$ and 0.10, each DC susceptibility markedly decreases with increasing temperature, which is considered to obey Curie-Weiss law. Neither remanent magnetization nor coercivity is observed at 10 and 300 K (It is not shown here.). These reveal that the magnetic behavior is paramagnetic in the temperature range of 10 – 300 K. For $x = 0.17$, the DC susceptibility increases up to 20 K and decreases above 20 K. At 10 K, both remanent magnetization and coercivity are observed as shown in inset of Fig. 1. These suggest that the magnetic behavior changes from ferromagnetic to paramagnetic near 20 K. Furthermore, for $x = 0.24$, the DC susceptibility increases up to 40 K and decreases above 40 K. However, the DC susceptibility is relatively low and the change in DC susceptibility with temperature is small. Neither remanent magnetization nor coercivity appears at 10 and 300 K (It is not shown here.). The magnetic behavior of the film with $x = 0.24$ cannot be determined using only the results from this study. Thus, these results demonstrated that these films have no room-temperature ferromagnetism and that the magnetic behavior depends on the Mn concentrations.

In order to clarify the origin of the magnetic behavior in the $\text{Al}_{1-x}\text{Mn}_x\text{N}$ films from the structural point of view, we observed grazing-incidence X-ray diffraction profiles and selected area diffraction (SAD) patterns of these films. Here, SAD patterns of 50-nm-thick $\text{Al}_{1-x}\text{Mn}_x\text{N}$ films with various Mn concentrations are shown in Fig. 2. For $x = 0.05$ and 0.10, only the diffraction rings derived from wurtzite-type AlN are observed. These results suggest two possibilities as the origin of paramagnetic behavior; one is Mn ions incorporated into wurtzite-type AlN and the other is Mn-rich particles with superparamagnetism [4] below the detection limit of TEM. For $x = 0.17$, not only the diffraction rings derived from wurtzite-type AlN but also a diffraction ring is observed. This ring is considered to originate from a secondary phase such as Mn-N and Al-Mn. From this result, it is revealed that the change in the magnetic behavior with temperature is caused by the secondary phase. Furthermore, for $x = 0.24$, diffraction rings derived from ThH_2 -type Mn_3N_2 as well as those derived from wurtzite-type AlN are observed. These results suggest that the magnetic behavior is attributed to that of ThH_2 - Mn_3N_2 which is antiferromagnetic below 925 K. Accordingly, it is considered that the change in magnetic behavior with x is caused by the change of film structure.

Summary

The magnetic behavior and structure of $\text{Al}_{1-x}\text{Mn}_x\text{N}$ ($x = 0.05 - 0.24$) films have been studied. It is found that all films with $x = 0.05 - 0.24$ have no room temperature ferromagnetism; a paramagnetic behavior for x below 0.10, a magnetic behavior with remanent magnetization only at 10 K and a paramagnetic behavior above 20 K for $x = 0.17$, and a magnetic behavior with a weak temperature dependence of DC susceptibility for $x = 0.24$. These magnetic behaviors are mainly considered to be due to the film structure.

Growth parameter dependence of structural characterization of diluted magnetic semiconductor (Ga,Cr)As.

J. Lu, J. Bi, W. Wang, G. Gan, H. Meng, H. Zheng, J. Zhao

State Key Laboratory for Superlattices and Microstructures, Institute of Semiconductors, Chinese Academy of Sciences, Beijing, China

The earlier theoretical work predicted (Ga,Cr)As with higher Curie temperature (T_c) than that of (Ga,Mn)As [1]. However, recent theoretical progress indicates that it is difficult to increase T_c to room temperature even with Cr content x up to 0.15 [2]. Experimentally, (Ga,Cr)As epitaxial films grown on GaAs have been synthesized by several groups. Unlike the theoretical prediction, superparamagnetic behavior with short-range ferromagnetism for $x = 0.1$ and ferromagnetic behavior for $x = 0.11$ have been reported by different groups [3,4]. Recently, we obtained (Ga,Cr)As films with intrinsic ferromagnetic order by molecular-beam epitaxy (MBE) [5]. We found that the crystalline quality and magnetic property were very sensitive to the growth condition. In this digest, we report the influence of growth temperature (T_s), arsenic pressure and post-growth annealing on the structural and magnetic characterizations of (Ga,Cr)As films.

All the (Ga,Cr)As films were grown on epi-ready GaAs (001) substrates by low-temperature MBE. A 100 nm GaAs buffer layer was first grown at $T_s = 560$ °C, then three sets of (Ga,Cr)As films (set A, B and C) were grown. The detailed growth parameters are shown in Table I.

Clear streaky (1x1) RHEED patterns were observed during growth of (Ga,Cr)As films in set A except the film grown at 400 °C, which had a spotty pattern of the second phase, as shown in Fig. 1(a) and (b). Also, clear streaky (1x1) RHEED patterns were observed for the films in set B with Cr content $x < 0.1$, but a spotty RHEED pattern without the second phase appeared when $x = 0.1$, as shown in Fig. 1(c) and (d). RHEED patterns of the films in set C were broken streaky, not shown here. From the changes in RHEED patterns, the tendency of Cr-As clustering is enhanced with increasing both T_s and x . The difference is that hexagonal Cr-As compounds are obviously formed at high T_s , but this second phase is not seen in samples with higher x grown at low T_s from RHEED patterns. This tendency is also verified by double-crystal x-ray diffraction (XRD) curves and atomic force microscopy (AFM) images. One can see from Fig. 2(a) that the peaks of (Ga,Cr)As films in set A shift from the left of the GaAs substrate peak to the right. The same phenomenon is also seen in set B. With increasing Cr content, the peak of (Ga,Cr)As film disappears as shown in Fig. 2(b). To understand the phenomenon of the peak shift, we also grew a (Ga,Cr)As film at 250 °C, and then followed by annealing at 650 °C. We found that the peak of (Ga,Cr)As film is also on the right of the substrate peak. Therefore, we may deduce that the peak shift might originate from the compressive strain caused by Cr-As clusters inhomogeneously embedded in the epilayer. The roughness also increases with increasing T_s and x obtained from AFM images, not shown here.

Magnetic circular dichroism (MCD) measurements proved that all the samples with the intrinsic ferromagnetism. However, compared with (Ga,Mn)As, T_c of (Ga,Cr)As is lower than 30 K, known from both MCD and SQUID measurements. For the samples grown above 250 °C in sets A and B, the ferromagnetic signal at room temperature may be associated with Cr-As clusters inside the (Ga,Cr)As matrix. Therefore, a lower T_c is expected for the homogeneous (Ga,Cr)As alloy. More homogeneous (Ga,Cr)As films (set C) have been synthesized at lower T_s .

In summary, we systematically investigated the growth parameter dependence of structure and magnetic properties of (Ga,Cr)As films. The optimized growth condition at lower growth temperature may be the key to get the homogeneous (Ga, Cr)As films with higher T_c .

Gallium nitride doped by manganese belongs to a family of wide band gap dilute magnetic semiconductors which have been recently intensively studied as candidates for spintronic applications. The main potential of these materials is viewed in their ferromagnetic state persisting well above room temperature, which has been theoretically predicted and experimentally evidenced on thin films prepared by diverse techniques.

From the chemical point of view, Mn replaces Ga in wurtzite structure forming a substitutional solid solution. As predicted by our thermodynamic calculations, the Mn solubility in bulk $\text{Ga}_{1-x}\text{Mn}_x\text{N}$ is as low as a few per cent (2-3 at %) and decreases with increasing T and decreasing p_{N_2} . This suggests that a number of results reported as yet has been obtained on samples whose composition ($x > 0.05$) and synthesis condition (MBE and ion implantation in particular) were far from equilibrium. Hence the tendency of nanoscopic phase separation was high enough in such cases and might be one of the reasons for still significant discrepancies in magnetic and transport properties. In this respect, MO VPE is considered as a close to equilibrium method with a capability to provide high quality homogeneous thin films. However, only few reports [1-2] have appeared on MOVPE synthesis and characterization of $\text{Ga}_{1-x}\text{Mn}_x\text{N}$ so far.

In this paper we present a study of magnetic properties carried out on thin films deposited on sapphire substrates (0001 orientation) by MO VPE. The samples were prepared in a horizontal inductively heated reactor at $T = 1050^\circ\text{C}$ from $\text{Ga}(\text{CH}_3)_3$, NH_3 and $\text{Mn}(\text{MCp})_2$ precursors transported in N_2/H_2 carrier gas. The active $\text{Ga}_{1-x}\text{Mn}_x\text{N}$ layer was either deposited on a pure GaN buffer layer or directly on substrate. A typical thickness was 0.25 and 2.7 μm , respectively. The X-ray diffraction proved the wurtzite phase without any secondary phase related to Mn. The Mn concentration detected by electron microprobe and PIXE was well below the solubility limit, ranging from 0.2 to 0.7 at %, i.e. rather far from the value of 5% considered as optimal for ferromagnetism. The Hall measurements conducted at room temperature revealed n-type charge carriers reaching typical concentrations $1 \times 10^{18} \text{ cm}^{-3}$ and mobilities $230 \text{ cm}^2/(\text{Vs})$. From the isothermal magnetization data recorded on SQUID magnetometer, three main components can be separated – a strong diamagnetic signal from the substrate (and undoped GaN) as well as two weak contributions from the $\text{Ga}_{1-x}\text{Mn}_x\text{N}$ film – a paramagnetic (PM) component characterized by Brillouin $M(H)$ dependence at the lowest temperatures and a nearly temperature independent ferromagnetic (FM) component persisting above 300 K. The $M(H)$ curves show clear hysteresis with coercivities less than 80 Oe and relative remanent magnetizations ≈ 0.1 .

In order to analyze the magnetization data we assume that unlike GaMnAs, Mn occurs in trivalent state in GaMnN contributing by four spins to magnetic moment. This assumption is supported by electron spectroscopy and electronic structure calculations. According to our APW+lo calculations (Wien2k) performed within GGA+U (Mn-3d on-site repulsion $U = 3 \text{ eV}$) for $\text{Ga}_{0.875}\text{Mn}_{0.125}\text{N}$, the partially filled majority spin states of Mn- t_{2g} character form an impurity band centered 1.3 eV above the valence band maximum (VBM), which evolves into deep acceptor levels in the localized regime. In contrary, the filled Mn- e_g states are dipped into VB and strongly hybridized with N-2p, whereas all minority Mn-3d states are empty and pinned to conduction band minimum (CBM). Although a slight spin polarization is observed at both CBM and VBM, the electron and holes induced by doping would not substantially contribute to total magnetic moment. Hence, we can

directly recast the magnetic data to Mn concentration (expressed as x in $\text{Ga}_{1-x}\text{Mn}_x\text{N}$) provided a careful analysis of PM component is done.

The Brillouin fit applied on the $M(H)$ curves after subtracting a constant FM part (and indeed a diamagnetic addenda) revealed characteristic temperature Θ_p around 0 K and concentrations of paramagnetic Mn $x_{\text{PM}} = 0.5\text{--}0.9 \times 10^{-2}$. By contrast, the FM part x_{FM} amounts only $0.02\text{--}0.2 \times 10^{-2}$ i.e. 3.5-20% of the total Mn content. A reasonable agreement between magnetically and chemically determined Mn concentrations was found. Surprisingly, the highest FM/PM ratio was achieved for samples with lowest Mn concentration. This is difficult to explain in terms of percolation between bound magnetic polarons formed around donor impurities [3], unless a significant reduction of the polaron size with increasing x is considered. Despite this discrepancy, we can conclude that within the above mentioned model [3], the current concentrations of magnetic impurities (less than 1 at %) and possibly also the donor concentrations (2.5×10^{-3} at %) in the $\text{Ga}_{1-x}\text{Mn}_x\text{N}$ system under study fall below the percolation limit of metallic ferromagnetism. As a result, a mixed state of FM clusters dispersed in PM matrix is apparently established.

Introduction:

By patterning microstructures on a thin layer of GaMnAs, it is possible to partially relax the strain in this ferromagnetic film caused by the lattice mismatch with the underlying GaAs buffer layer. This technique can be used to modify the magnetic anisotropy and the transport properties of the GaMnAs structures[1,2,3]. We focus on the latter aspect by studying the influence of the patterning-induced strain relaxation on the anisotropic magnetoresistance (AMR) effect.

AMR is an effect emerging from the competition of the spin-orbit interaction and other symmetry-lowering terms (magnetization, anisotropic crystalline environment, strain) and it consists in the change in resistance of a ferromagnet depending on the orientation of the magnetization vector \mathbf{M} . For macroscopic Hall bars, the phenomenological description of the relative change in resistance dR_{xx} allows to identify non-crystalline and crystalline components[4,5] in the bulk AMR, represented by terms depending on the angle between \mathbf{M} and the crystallographic axes and \mathbf{M} and the current direction[5].

For a microscopic bar, an additional term accounts for the effect of the strain relaxation induced by lithographical patterning. The aim of the present study is to identify the contribution of the strain coefficient to the AMR as a function of temperature.

Materials and methods:

Four 1 μm -wide bars, aligned along the main crystallographic directions [100], [010], [110] and [1-10], are patterned in series with a 40 μm -wide bar along the [010] (see diagram in Fig.1a, with a picture of R2, R3 and R4) with two electron beam lithography steps: the mesa is defined by 500 nm trenches etched by reactive ion etching, then Cr/Au bond pads are evaporated.

The device was fabricated on a 25 nm GaMnAs layer, grown by low-temperature molecular beam epitaxy under compressive strain on a GaAs (001) substrate. The nominal Mn concentration is 5%. From SQUID magnetometry, the Curie temperature T_c of the as grown wafer is 60 K, at 5 K the easy axes are along the [100] directions while at $T > 25$ K the [1-10] direction becomes the easy axes.

In transport measurements, the longitudinal resistance of the five bars is measured simultaneously with lock-in amplifiers while an external magnetic field of 4 T (much larger than the anisotropy field in order to saturate the sample) is applied in the plane of the sample, and the sample is rotated in the plane by 360°. Measurements are performed in a range of temperature from 4 to 70 K (the AMR effect is observable at 70 K because of the increase in T_c due to fabrication processes).

Results and discussion:

The polar plots in Fig. 1b,c,d show dR_{xx} of the five studied bars as a function of the angle ϕ between the field and the [100] direction, at 4, 30 and 70 K respectively. The plots on the left show dR_{xx} for the microbars patterned along the [100] (green line) and [010] (dark-blue line) and the macrobar along the [010] (light-blue line) axes. The plots on the right show dR_{xx} for the microbars patterned along the [110] (black line) and the [1-10] (red line) axes.

By direct comparison of the light-blue and dark-blue lines in Fig. 1b(left), a remarkable reduction of the signal is observed due to the patterning-induced strain relaxation in the microbar. This effect is comparable to the uniaxial contribution along the [010] axis, found by comparing the dark-blue and green lines. The unusually strong uniaxial component along the [010] direction may be the result of strain induced during the growth, which relaxes when the sample is patterned, giving rise to such a big effect. Also, dR_{xx} for the bars along the [110] direction is noticeably smaller than for those along the [100] direction, suggesting a relatively large contribution of the cubic term.

As the temperature increases, the magnitude of dR_{xx} decreases for all the studied bars as T approaches T_c . By looking at the evolution of the black and red lines in Fig. 1b,c,d (right), it is clear that the relative strength of the uniaxial and cubic coefficients is changing.

Because of the limited number of data set with respect to the number of relevant phenomenological AMR coefficients we could not extract unambiguously the values for these coefficients. Further investigation of the effect of strain relaxation as a function of temperature will be carried out on samples with both macro- and microbars aligned along the main crystallographic directions and in samples with different film thickness and after annealing at 200°C to obtain better quantitative understanding of the effect of strain relaxation on the AMR.

1. Introduction

Carrier-induced ferromagnetism is a distinguish feature of Diluted Magnetic Semiconductors (DMSs), which enable to manipulate the magnetic order by external parameters such as irradiating light or applying electric field like FET. These experiments have been done in III-V DMSs such as $\text{In}_{1-x}\text{Mn}_x\text{As}$ and $\text{Ga}_{1-x}\text{Mn}_x\text{As}$.¹⁾⁻³⁾ The first experimental study of carrier-induced ferromagnetism was performed on $\text{Pb}_{1-x-y}\text{Sn}_y\text{Mn}_x\text{Te}$.⁴⁾ though the Cuire temperature T_C was of helium temperatures. So far we have successfully grown IV-VI DMS $\text{Ge}_{1-x}\text{Mn}_x\text{Te}$ films up to Mn composition $x=0.96$ by using ionized cluster beam (ICB) technique.⁵⁾ We have also demonstrated that the ferromagnetic properties of $\text{Ge}_{1-x}\text{Mn}_x\text{Te}$ such as the spontaneous magnetization and Cuire temperature can be controlled by the hole concentration, preparing the films with various carrier concentrations from 10^{19} to 10^{21} cm^{-3} by controlling Te composition.⁶⁾ Another carrier control method is that Ge is substituted by Pb. Crystal structure of PbTe is a NaCl while bulk GeTe has rhombohedral distorted lattice. Therefore, $\text{Ge}_{1-x}\text{Pb}_x\text{Te}$ is interesting for ferroelectric phase transition.⁷⁾ In $(\text{Ge}_{1-y}\text{Pb}_y)_{1-x}\text{Mn}_x\text{Te}$, ferroelectric transition temperature could be dependent on Pb and Mn composition. From a crystalline viewpoint for a spin-polarization source in IV-VI heterostructures, a NaCl type DMS is superior due to surface smoothness.

In this study, we have prepared various $(\text{Ge}_{1-y}\text{Pb}_y)_{1-x}\text{Mn}_x\text{Te}$ films by ICB methods and suggested that the carrier concentration can be controlled by Pb composition. Dependences of electrical and magnetic properties on Pb composition have been studied. Exchange integral J_{pd} between Mn ions and holes is discussed based on RKKY interaction. An increase of Mn composition in $(\text{Ge}_{1-y}\text{Pb}_y)_{1-x}\text{Mn}_x\text{Te}$ has also been tried.

2. Experimental

$(\text{Ge}_{1-y}\text{Pb}_y)_{1-x}\text{Mn}_x\text{Te}$ were grown onto air-cleaved BaF_2 (111) substrates. Molecular GeTe , MnTe and PbTe were used as source materials. After thermal cleaning of a BaF_2 substrate (400 °C, 30 min.), $(\text{Ge}_{1-y}\text{Pb}_y)_{1-x}\text{Mn}_x\text{Te}$ layer was grown at 280°C. The chemical composition was checked by electron probe microanalysis.

3. Results and Discussion

Each crucible temperature was controlled to be Mn composition $x \approx 0.1$ due to the solubility limit of $x=0.11$ in bulk $\text{Pb}_{1-x}\text{Mn}_x\text{Te}$. The x-ray diffraction pattern of (111) plane was observed in the films with $y=0$ and $y \geq 0.58$ while the no other diffraction pattern of BaF_2 substrate was observed in the films with $0.04 \leq y \leq 0.52$. The lattice constant linearly increased in proportion to y . Figure 1 shows the carrier concentration as a function of Pb composition in $(\text{Ge}_{1-y}\text{Pb}_y)_{1-x}\text{Mn}_x\text{Te}$ with Mn composition $x \approx 0.1$. Carrier concentration can be controlled from 10^{18} to 10^{21} cm^{-3} by Pb composition.

In order to investigate the electrical and magnetic properties, magnetotransport measurements were performed on hall bar pattern. Assuming that side jump scattering is dominant in the anomalous hall term, the magnetization M_{trans} is thus defined as $M_{\text{trans}} \propto (\rho_{\text{hall}} - R_0 B) / \rho^2$, where R_0 is the ordinary hall coefficient, B is the magnetic induction, ρ_{hall} is the hall resistivity and ρ is the resistivity. The ordinary hall term $R_0 B$ is deduced from the hall measurement at room temperature. Figure 2 shows a typical M_{trans} -H curve at 9 K in $(\text{Ge}_{1-y}\text{Pb}_y)_{1-x}\text{Mn}_x\text{Te}$ ($y=0.39$). The inset shows the magnetization curve at 5 K measured by SQUID. The curves clearly demonstrate ferromagnetism

and the similar behavior observed in both results. T_C was estimated by Arrot-plots using M_{trans} measured at various temperatures. Dependence of T_C on Pb composition as shown in Fig.3. T_C drastically decreases with increasing Pb composition. Ferromagnetic behavior is not observed in magnetotransport measurement at 9 K for the films with $y \geq 0.58$. Bulk $\text{Pb}_{1-x}\text{Mn}_x\text{Te}$ is paramagnetism while $\text{Ge}_{1-x}\text{Mn}_x\text{Te}$ is ferromagnetism. Therefore, exchange integral J_{pd} between Mn ions and holes in each sample has been calculated based on RKKY interaction. It was confirmed that the J_{pd} also decreased with increasing y , which made for the drastic decrease of T_C .

We have tried to increase the Mn composition in $(\text{Ge}_{1-y}\text{Pb}_y)_{1-x}\text{Mn}_x\text{Te}$ films with $y=0.47$. Figure 4 shows T_C as a function of Mn composition. Carrier concentrations are $p=1.27 \times 10^{20}$ for $x=0.08$, $p=1.84 \times 10^{20}$ for $x=0.15$, $p=6.41 \times 10^{20}$ for $x=0.22$ and $p=2.71 \times 10^{21} \text{ cm}^{-3}$ for $x=0.29$, respectively. As shown in the figure, T_C successfully increases till $x=0.22$.

Properties of ternary rare earth REXY compounds with 18 valence electrons.

F. Casper, C. Felser

Institute for inorganic and analytical chemistry, Mainz, Germany

Ternary rare earth compounds REXY, where RE is a lanthanide element, Y a transition element and Z is an sp element, offer a large variety of structure types. Our research focuses on compounds LiGaGe and MgAgAs (half-Heulser) structure which all have 18 valence electrons. The f-electrons are localized and therefore not count as valence electrons. Magnetic and resistivity measurements were used to examine some of these compounds. Most of the compounds order antiferromagnetic at low temperatures. While compounds with LiGaGe structure are metallic, many of the compounds with MgAgAs structure are semiconducting. Additionally for some of these compounds a metal-insulator transition was found. The metal - insulator transition temperature depends strongly on the preparation conditions.

Some of these compounds show a negative giant magnetoresistance (GMR) above the magnetic ordering temperature in the paramagnetic temperature regime. Except for a weak deviation, this magnetoresistance scales roughly with the square of the magnetization in the paramagnetic state, and is related to the metal-insulator transition.

For inhomogeneous compounds (REYZ with metallic impurities) a positive contribution to the magnetoresistance was found. The nonmagnetic inhomogeneous semiconducting LuNiBi compound shows a large positive MR effect of 25% at room temperature (figure 1). The positive MR may be due to metallic bismuth impurities in the sample that cause an extraordinary magnetoresistance (EMR).

Effect of local magnetic field on the transport properties of GaMnAs.

J. Suh^{1,2}, J. Chang¹, E. Kim², M. Sapozhnikov³, A. Fraerman³

II-IV DMS (diluted magnetic semiconductor) is reported to show an enormous Zeeman splitting and have the giant g-factor up to 500 [1] so that external magnetic field can significantly adjust the energy of the charge carriers. Assuming that the III-V DMS such as GaMnAs have the same level of large g-factor, the authors presumed that the localized inhomogeneous magnetic field essentially affects the transport properties of GaMnAs and even forms effective traps for spin polarized carriers. [2] Since giant g-factor was expected in GaMnAs, [3] it is very interesting to investigate the spin transport of DMS under the influence of such local field induced by an array of ferromagnetic nanodots. Controllable source of localized inhomogeneous field can be obtained with placing ferromagnetic nanodots on the top of GaMnAs microbridge. [4,5]

In this paper, we introduce novel device consisting of patterned Co nanodot on GaMnAs micron-sized channel in order to explore a new functionality to control the transport properties of GaMnAs. 100 nm thick Ga_{1-x}Mn_xAs layer ($x = 0.05$) was grown on a semi-insulating (001) GaAs substrate by molecular beam epitaxy (MBE, Riber) system. The standard UV photo lithography and Ar ion milling were used to fabricate 1 μ m wide and 10 μ m long GaMnAs microbridge parallel to [110] direction with four contact probes from the GaMnAs film. Van der Pauw and magnetoresistance (MR) measurements were carried out under applying magnetic field up to 1 kOe in the temperature range of 4.2 K.

Figure 1 presents the scanning electron microscopy (SEM) image of a fabricated device. The device is designed to measure resistance change of GaMnAs channel as a function of applied field with four probe measurement. Periodic single array of Co nanodots formed on the bridge is expected to produce local magnetic field. Long axis of elliptical Co dot is perpendicular to the bridge through which current flows. MFM observation clearly shows single domain is a stable state for Co dots. Figure 2 shows MR of the pure GaMnAs bridge without a chain of Co nanodots measured at 4.2 K. It clearly shows the typical anisotropic MR (AMR) of GaMnAs which is similar to those reported elsewhere for GaMnAs thin films and yield information concerning the magnetic anisotropy. Figure 3 presents both longitudinal and transverse MRs in the narrow field range of ± 600 Oe to search the effect of Co nanodots on the resistance. It is noted that additional steps marked by arrows were found in the longitudinal MR curves when applying longitudinal magnetic field. Such steps appeared only when magnetization of the sample was reversed. If we magnetize the sample in the same direction for a second time, no steps are observed as there is no magnetization reversal in the system.

Structural and magnetic properties of Co-doped ZnO thin films.

M. Fonin¹, G. Mayer¹, S. Voss¹, E. Goering², U. Rüdiger¹, R. Schneider³, D. Gerthsen³

Ferromagnetic oxides combine electronic and magnetic properties and thus gained much interest in recent years. These materials are usually fabricated by doping a non-magnetic semiconductor with 3d metal ions. In a theoretical work, Dietl *et al.* [1] showed that a stable ferromagnetic phase with Curie temperatures above room temperature is possible in wide gap semiconductors such as ZnO. Experimentally ferromagnetism above room temperature has been observed in different diluted magnetic semiconductors (Co:TiO₂, Mn:TiO₂, Co:ZnO, Mn:ZnO, Mn:SnO₂, etc.) [2] during the last years. Nevertheless, the origin of this ferromagnetism is still under debate.

Co-doped ZnO has been prepared by rf magnetron sputtering from a composite ZnCo target (90:10 wt.%) with pure Ar on the one hand and a mixture of Ar and O₂ on the other hand as sputtering gases. Al₂O₃ and SiO₂/Si have been used as substrates. The Co content was estimated by energy dispersive x-ray analysis (EDX) to be 3 at.% in the samples. X-ray diffraction (XRD) showed a *c*-axis oriented growth for both preparation conditions, which could also be confirmed by high resolution transmission electron microscopy (HRTEM). However, the latter showed the formation of Co-rich clusters in films on SiO₂/Si which were grown in a mixture of Ar and O₂ and post-annealed in pure O₂. The Co-rich clusters go together with Zn depletion, while oxygen is homogeneously distributed. The formation of a possible crystalline secondary phase such as CoO or Co₃O₄ has still to be examined. Films grown in pure Ar show a homogeneous Co distribution. For magnetic characterization, a superconducting quantum interference device (SQUID) and x-ray magnetic circular dichroism (XMCD) were used. X-ray absorption spectroscopy (XAS) reveals that Co is incorporated as Co²⁺ into the ZnO host lattice and thus substitutes Zn at the lattice sites. In SQUID measurements, all films gave a paramagnetic signal superimposed by a small ferromagnetic contribution. Figure 1 shows SQUID measurements of sample grown in pure Ar and post-annealed under vacuum at 750 °C. To obtain these results, a subtraction of an as treated pure sapphire substrate was taken into account. However, the non linearity around $\mu_0 H = 0$ T in the SQUID measurements may be not only due to the ferromagnetic contribution of ZnCoO but also due to the substrate. The Co-rich clusters do not enhance ferromagnetism, underlining the HRTEM results, that the clusters are not composed of pure Co. Figure 2 shows XMCD measurements at 15 K for different applied external fields. A clear XMCD signal can be seen at the Co *L*₃ edge (778.5 eV). In the inset of figure 2, the maximum XMCD signal is plotted versus the applied field. The dependence is clearly linear, as indicated by the fitted line. Thus XMCD measurements confirm the SQUID measurements, as they also show a linear dependence of the TEY-signal from the external applied magnetic field. XMCD measurements on Co-doped ZnO of other groups [3;4] also showed a pure paramagnetic contribution of Co to the magnetization of the sample, although they could see a large ferromagnetic component in SQUID measurements.

SQUID measurement of Zn_{0.94}Co_{0.06}O at 10 K and 300 K, respectively after the subtraction of an as treated (evaporation excluded) pure substrate.

XMCD measurement of Zn_{0.94}Co_{0.06}O for different applied external fields. A clear signal at the Co *L*₃ edge (778.5 eV) is visible. The inset shows the maximum XMCD signal as a function of the applied field. The dependence is linear as illustrated by the linear fit.

Ferromagnetism observed in transition metal doped high K oxides.

Q. Wen, H. Zhang, Y. Song, Q. Yang, Y. Liu

State Key Laboratory of Electronic Films and Integrated Devices, University of Electronic Science and Technology of China, Chengdu, China

Diluted magnetic oxides (DMO) with Curie temperature (T_c) above room temperature have attracted much attention. However, the presence and absence of ferromagnetism (FM) were alternatively reported for semiconducting oxides system by different research groups, which cast a shadow on the carrier-mediated ferromagnetic mechanism. Very recently, several researches reported large magnetic moment with high T_c in transition metal (TM) doped high-k oxides such as HfO_2 [1] and CeO_2 [2]. The FM in these insulating oxides challenges the carrier-induced FM mechanism and strongly support the F-center mediated exchange mechanism for diluted ferromagnetism. In the later mechanism, oxygen vacancy (V_o) traps an electron to constitutes an F center. The trapped electron occupies an orbital which overlaps the d shells of both TM neighbors, constituting a ferromagnetic polaron. The radius of the electron orbital is given as $a_0\epsilon$, where a_0 is the Bohr radius and ϵ is the dielectric constant.

For typical high-k oxides such as HfO_2 , La_2O_3 and CeO_2 , V_o is a typical defect [3,4] and the k constant is large. Therefore, it is anticipated that a RT FM can be generally obtained in TM doped high-k oxides. In present report, Co doped La_2O_3 and CeO_2 samples were fabricated by the solid-state reaction method with a high sintering temperature of 1200 °C and 1400 °C in air, respectively. Complex magnetic behaviors were observed in both insulating oxides and their dependence on Co concentration is discussed.

X-ray diffraction spectroscopy of $\text{La}_2(1-x)\text{Co}_x\text{O}_{3-\delta}$ and $\text{Ce}_{1-x}\text{Co}_x\text{O}_{2-\delta}$ with Co content from $x = 0$ to 0.08 were studied. It can be found that all samples have a single -phase structure, and none of the samples showed any evidence for impurity phases. A slight shift for most of the peaks can be seen with increasing Co ions concentration due to part of La or Ce atoms are substituted by Co atoms. XPS studies shows that the Co 2p_{3/2} and 2p_{1/2} core levels for Co-O bonding were at 780.38 eV and 796.92 eV, which, to an extent, eliminates the possibility of Co metal cluster.

The magnetization versus field curves (MH) for Co:La₂O₃ with different Co content were measured by vibrating sample magnetometer (VSM), as shown in figure.1. From the MH curves we found that: (i) undoped and very slightly Co doped (0.1%) samples show no FM signal but diamagnetic signal; (ii) well-defined hysteresis loops are observed in relatively heavily doped samples ($x \geq 0.5\%$); (iii) when x increase beyond 1%, the ferromagnetism become dominating and no diamagnetism was detected; (iv) a surprisingly soar of the FM signal was observed in the 2% Co doped La₂O₃ with a M_s of 0.05emu/g, and (v) when $x > 2\%$, an inverse correlation between the magnetization and Co content was observed. A similar magnetic behavior was observed in Co doped CeO_2 . Undoped or slightly doped samples show no ferromagnetic signal, while relatively larger Co doping ($x \geq 1\%$) gives rise to distinct RT FM which steeply increases with x up to 2% and then drops with further increasing x . It is interestingly that the largest magnetization was also appeared at about 2% Co doped sample.

When x is very small, Co ions are far apart from each other and their spins are free, with no contribution to FM. As x increasing, magnetic polarons form since the concentration of both Co and V_o increase, and the F center mechanism become dominating. However, small Co content is not sufficient to produce a net magnetization in each magnetic polaron. Once x reaches to a critical value, i.e. 2%, a net moment on each polaron was developed, leading to the sudden soar of magnetic

moment. When x increases beyond 2%, the decrease of M_s with Co is ascribed to the antiferromagnetic interactions between Co ions.

In conclusion, we reported that an M_s as large as 0.05emu/g and a Curie temperature above RT in Co doped La_2O_3 and CeO_2 , rendering them candidate DMOs for RT applications. Our results also confirm the oxygen-vacancy (F-Center) mediated FM mechanism for TM doped high-k oxides.

Evidence of oxygen vacancies enhancing the room temperature ferromagnetism in CeO₂ nanopowders.

M. Li, S. Ge, Y. Zuo, X. Zhou, L. Zhang, S. Yan
Lanzhou University, Lanzhou, China

Recently, ferromagnetism in nanoparticles of Al₂O₃, ZnO, SnO₂, CeO₂ has been observed by Sundaresan et al [1], and assumed to be the exchange interactions between unpaired electron spins arising from oxygen vacancies at the surfaces of the nanoparticles. In this study, we synthesized pure CeO₂ nanopowders by sol-gel method. Anneal studies were performed on samples to investigate the effect of oxygen vacancies. The products were characterized by X-ray diffraction (XRD), Raman spectroscopy and vibrating sample magnetometer (VSM).

Cerium nitrate and citric acid were dissolved in the mixture of distilled water and ethanol. Then the solution was stirred constantly at 65°C for 4 h during circumfluence and dried at 65°C in air to get the precursors. As-prepared samples were obtained by calcining the precursors at 320°C for 2 h in air. After the anneal in air or in the reducing forming gas, the hydrogenated, oxygenated and rehydrogenated samples were prepared respectively. In order to avoid the magnetic impurities, all the processes of experiment were carried out very carefully. Only the high pure reagent and gas source, and agate mortar were used, and all the tools used for handling the samples were non-magnetic and plastic based.

All of the samples' XRD patterns matched well with the fluorite structure of ceria, without any impurity phases. After the anneals, the crystalline quality is improved, and the particle size increases from about 10nm (by Scherrer formula) for as-prepared samples to about 14nm for rehydrogenated samples. Fig.1 shows the room temperature magnetic properties of the samples. Hysteretic behavior is observed and the loops have small coercivities in the range from 50 to 100Oe. The saturation magnetization Ms of the samples is weak, only 10⁻⁴–10⁻³emu/g, this order of magnitude is consistent with previous report [1]. Further more, the hydrogenated sample has much larger saturation magnetization than the as-prepared sample does. Fig.2 shows the Raman spectra performed at RT of as-prepared and hydrogenated samples. Two broad peaks can be observed near 442 and 590cm⁻¹, arising from the fluorite structure of ceria and the presence of O vacancies respectively [2]. The decrease of the intensity of 442cm⁻¹ feature and the increase of 590cm⁻¹ feature after the annealing in the reducing atmosphere indicate that there are more O vacancies in the hydrogenated CeO₂ nanopowders. Thus, with combination of the VSM and Raman data, it can be concluded that adding more oxygen vacancies can enhance the ferromagnetism of CeO₂ nanopowders. In addition, the saturation magnetization of rehydrogenated samples is smaller than hydrogenated ones', which can be understood in terms of the specific surface area of nanopowders decreases by crystal growth after the reanneals, if one considers that the ferromagnetism arises from the O vacancies at surface of nanopowders.

The above results show that the oxygen vacancies are essential to produce ferromagnetism in pure CeO₂ nanopowders. The force-field calculations suggest that the O vacancy is more stable at the surface than in the bulk [3], so the origin of ferromagnetism in pure CeO₂ nanopowders is close related to oxygen vacancies at the surfaces of CeO₂ nanopowders.

Much interest has been put into developing new materials that utilize the spin of electrons, since the theoretical predictions of room temperature ferromagnetism in transition metal (TM) doped ZnO [1]. Although many efforts have been done on the magneto-transport of Co-doped ZnO, poor reproducibility and contradictory results make it still worth to be further studied. Recently, p-type TM doped Cu₂O joined the group of researched materials for its wide applications in optoelectronics and solar cells [2]. In this work, we compare and discuss giant positive magnetoresistance (PMR) obtained in Co-doped ZnO and small PMR of Co-doped Cu₂O nanoparticles.

Samples studied here are prepared by sputtering-gas-aggregation cluster source [3]. Electrical transport properties are measured using SQUID by four wire method with the applied magnetic field parallel to both the film plane and the current flow. MR is defined as

$MR = 100 \cdot (R_{(H)} - R_{(0)}) / R_{(0)}$, where $R_{(H)}$ and $R_{(0)}$ are the resistance with and without applied magnetic field, respectively.

Figure 1 shows the giant PMR in Co-doped ZnO nanoparticle films with different Co doping concentration. The PMR increases with increasing Co doping. It shows linear dependence on applied field in the low field limit and turns to saturate quickly in the high field limit. It is known that carriers in Co-doped ZnO are mainly produced by oxygen vacancies which lie close to the bottom of conduction band and act as a shallow donor level. Doping Co atoms can interact strongly with these weakly localized carriers due to s,p-d exchange interactions. Strong exchange interaction leads to large Zeeman splitting. When double occupation is allowed, two types (Type A and Type B) of sites contribute to the transport [4]. Type A has energy close to Fermi energy. Type B has one electron at a deep level, and the second electron also closes to Fermi energy. When magnetic field was applied, the suppression of spin dependent hopping between single occupied A and double occupied B sites, which leads to a large PMR with $\ln(R_{(H)}/R_{(0)})$ appearing a linear dependence on applied field H in the low field limit. At high field, transition between A and B sites cannot occur. Therefore, MR is independent of applied field and shows saturation behavior [5].

Figure 2 shows the PMR of 5% Co-doped Cu₂O nanoparticles. It can see that it shows similar behavior as the PMR found in Co-doped ZnO except for the much smaller MR amplitude. The most remarkable property for the Co-doped Cu₂O is that it has a vanishing density of states at Fermi level for both spin channels [5]. For spin up channel, E_F is no longer inside the conduction band, and for spin down channel E_F is situated inside a crystal field gap, separating the occupied orbitals from the empty ones. As the electrical transport properties are mainly decided by the carriers near the Fermi level, the observed small PMR should be a result of this.

In conclusion, we report here a giant PMR in Co-doped ZnO nanoparticles is caused by giant Zeeman splitting effect and a small PMR in the Co-doped Cu₂O is related to the vanishing density of states at the Fermi level.

ZnO is an interesting direct wide band gap (3.37eV) semiconductor with large exciton binding energy (60meV) whose properties make it very suitable material for optoelectronics applications, and potential ZnO-based devices. In addition, ZnO is a particularly promising candidate for applications in spintronics since it could exhibit ferromagnetic characteristics at room temperature when doped with selected transition elements to form novel materials [1].

Studies on Co-doped ZnO prepared by different methods have been reported along the last years [2-3]. In this work, ZnO:Co films have been obtained through a novel technique by high temperature annealing of ZnTe/Co/Si structures. Co films were first sputtered on Si substrates and then ZnTe thin films were grown by Isothermal Closed Space Sublimation (ICSS) technique [4] using Zn (99.99 %) and Te (99.999 %) as starting elemental sources. Finally, the multilayered samples were annealed at 823 K for 6 hours under Ar atmosphere. As a consequence of a non-negligible Oxygen content in the Ar flow and the high temperature kept during the annealing process, a thermally stimulated chemical reaction took place removing Te atoms from ZnTe films previously grown and then hexagonal ZnO crystalline phase was formed as it is confirmed by X-ray diffraction patterns showed in figure 1. From RBS studies it could be concluded that, no significant amount of Te remain in the annealed films and, on the other hand, Co atoms diffused almost homogeneously in such ZnO films.

Magnetic measurements have been performed by a SQUID magnetometer with a maximum applied field of 1.5T in the temperature range from 4 to 300 K. Figure 2a and 2b show the hysteresis loops at two selected temperatures, confirming the presence of ferromagnetic behavior even at the highest measurement temperature.

In conclusion, the ICSS technique combined with sputtering technique in such experimental conditions has been proved to be a reliable way to achieve Co doped ZnO thin films, whose ferromagnetic behavior has been confirmed at room temperature. Other studies to determine the formation of new very interesting diluted magnetic semiconductors by these procedures are in progress.

Carrier-induced ferromagnetism and dilute magnetic semiconductors (DMS) are of much interest from the industrial viewpoint, because of their potential applications as new functional materials, opening a way to introduce the spin degree of freedom into semiconductor devices. Current technologies require a continuous information exchange between semiconductors (controlling the logic) and the magnetic material that stores the information. High-speed semiconductor technologies are nowadays the base of a large amount of devices. The energy consumption and the high volatility of the information are disadvantages of these technologies. In magnetic materials the information storage relies on the magnetization orientation within the ferromagnetic material, being non-volatile devices. From the engineering point of view, materials combining both the semiconducting and the magnetic properties are of great interest. $\text{Co}:\text{TiO}_2$ has been one of the most studied DMS systems because of the interesting optical properties of TiO_2 (wide direct band-gap) [1] and one of the first systems showing room temperature ferromagnetism. [2]. However, many doubts arise about the real origin of the magnetism in this system, with some works claiming that the FM was due to secondary segregated phases.

Here we report on the properties of Ti-Co-O system prepared by milling and thermal annealing of TiO_2 and Co_3O_4 .

$\text{TiO}_2\text{-Co}_3\text{O}_4$ samples with Co_3O_4 content of 0.05%, 0.1%, 0.2%, 0.5% were prepared by mechanical milling using agate balls. Samples were subsequently annealed in air for 24h at temperatures ranging between 500C and 900C. Samples were prepared using TiO_2 in both anatase and rutile phases.

Result shows that partial reaction between both phases leads to room temperature ferromagnetism (RT FM). The magnetic properties strongly depend on the TiO_2 phase; RT FM is favoured using anatase TiO_2 (although the magnetic signal is very weak) while using rutile TiO_2 did not show magnetic properties different to those of Co_3O_4 . Those results indicate that the RT FM is due to a partial reaction of the oxides and can not be ascribed simply to Co_3O_4 nor segregated metallic Co. However, none of the phases presents can explain the RT FM. Therefore, the results suggest the interface between the oxides as the responsible for the RT FM. The particular crystallographic ordering in this interfaces after partial reaction can lead to a structure for which exchange forces arise ferromagnetism as previously demonstrated for the Zn-O-Mn system.

Following the first experimental observation of room temperature (RT) ferromagnetism (FM) in the Mn-Zn-O system in bulk samples¹, Kundaliya et al.² claimed that the FM found was not attributable to a DMS but to a secondary $\text{Zn}_x\text{Mn}_{2-x}\text{O}_3$ -y phase. Moreover, Lawes et al.³ found no ferromagnetism down to 2 K in bulk samples prepared by chemical methods, and we attribute the FM observed to the double-exchange mechanism taking place between Mn^{3+} and Mn^{4+} ions⁴. In an attempt to achieve deeper understanding of the origin of FM in this system, this work focuses on the study of the influence of Mn oxidation states and the kinetics of Zn diffusion into MnO_2 on the magnetic properties of Mn-Zn-O bulk samples.

2%MnO₂-98%ZnO (named ZM samples) pellets were prepared following the method described by Sharma et al.¹.

From the XANES spectra of the samples, it is possible to obtain a quantitative estimation of the Mn oxidation state, averaged for all the Mn atoms of the sample. In fact, the energy shifts on the absorption edge are directly related to the mean oxidation state of the absorbent atom^{5,6}. The obtained mean oxidation state of Mn in each sample is shown in figure 1.

From the XANES spectra it is inferred that Mn^{4+} and Mn^{3+} coexist in the FM samples. Although this condition is necessary, it is not sufficient. The two oxidation states also coexist for non-FM compounds (ZM annealed at 800 °C). The analysis of the oxidation state of Mn indicates that FM arises only when a small fraction of the Mn^{4+} atoms of MnO_2 reduce to Mn^{3+} , since the mean oxidation state of the FM compounds is approximately 3.9 and 3.8. We attribute the FM behaviour of this system to a double-exchange mechanism between Mn^{4+} and Mn^{3+} taking place at the Zn diffusion front in the surface of the MnO_2 grains⁴. Zn stabilizes the two Mn oxidation states in its surrounding, presumably supplying the appropriate geometry for this mechanism to take place. At 500 °C, two processes, both necessary for the appearance of FM in this system, are competing: the diffusion of Zn into MnO_2 , and the reduction of MnO_2 to Mn_2O_3 . The conditions for FM are thus very subtle: Zn atoms must diffuse superficially into MnO_2 while a small amount of MnO_2 has reduced to Mn_2O_3 . There should be a determined value of the mean oxidation state of Mn and of the amount of Zn that has diffused onto MnO_2 for which the FM reaches a maximum. From these conditions, further diffusion of Zn and/or a greater reduction of MnO_2 yield the decay of FM, as the ZnMn_2O_4 paramagnetic spinel begins to appear, and the number of Mn^{4+} atoms becomes not sufficient. The Raman and XANES experiments indicate that changing the dynamics of the two competing processes, the reduction of MnO_2 and the diffusion of Zn onto MnO_2 grains, tunes the FM in the system.

In summary, we have experimentally shown that Mn^{4+} and Mn^{3+} coexist in bulk ferromagnetic Mn-Zn-O, confirming the hypothesis of double-exchange as the responsible for FM at RT. FM appears when only a small fraction of Mn^{4+} has reduced to Mn^{3+} . Although the coexistence of the two oxidation states is a necessary condition for FM, the kinetics of the Zn diffusion into MnO_2

also plays a crucial role in the magnetic properties of the system. The double-exchange mechanism between Mn ions is tuned by the competition between these two linked processes.

The search for Diluted Magnetic Semiconductors (DMS) with Curie temperature above room temperature (RT) has recently attracted much attention. In particular, considerable work has been carried out using ZnO. However, the origin of ferromagnetism (FM) in these systems is still a matter of discussion. For the Co-Zn-O system, the situation is still more complicated as segregation of small metallic Co clusters can lead to RT FM¹. Fitzgerald et al. claim also that the FM observed is mediated by carriers, thus intrinsic². However, Lawes et al.³ prepared bulk samples confirming the substitution of the magnetic ions in the semiconductor matrix and found no magnetic ordering in this system down to 2K. In this work we will focus just on bulk samples prepared by the ceramic method.

ZnO_{1-x}(Co₃O₄)_x samples with x=0.01, 0.05 and 0.25 (named ZC1 ZC5 and ZC25 respectively) were fabricated following the low temperature procedure of Sharma et al.⁴. The magnetic characterization of the as cast starting powders revealed the typical diamagnetic behaviour for ZnO and a paramagnetic component over a small FM contribution for Co₃O₄ at RT. The small FM observed (0,001 emu/g(Co₃O₄Oe)) was attributed to the presence of small metallic cobalt clusters in the samples.

The samples were then attrition milled in water medium. The structural characterization of the samples by means of X-ray diffraction (XRD) revealed only the presence of Co₃O₄ and ZnO, no secondary phases were found. The magnetization dependence with the applied magnetic field at RT showed a ferromagnetic component superposed to a paramagnetic behaviour for all the samples. After subtracting the paramagnetic contribution, the samples present the hysteresis loops shown in fig. 1.a.

The FM signal increases over an order of magnitude its value after the mixing procedure, the largest saturation magnetization corresponding to the ZC1 sample. The initial Co₃O₄ powder alone was also milled and in this case the milling process did not modify the magnetic properties of the sample (red curve). The increase of the FM signal after milling for samples containing ZnO indicates that some kind of interaction between ZnO and Co₃O₄ grains is taking place during the mixing process.

The samples were then in a third step exposed to thermal treatments in the 400 C to 1000 C range. The XRD revealed again only the presence of ZnO and Co₃O₄. The maxima corresponding to Co₃O₄ disappear at 800-900 C for all the samples, and only the maxima from ZnO remain. We suggest that a solid solution Zn_{1-x}Co_xO with a wurtzite type structure is forming at these T explaining the fact that only peaks from the wurzite structure of ZnO are observed in the diffraction patterns. Annealing yields the decrease of FM for all the samples (see fig. 1.b.).

For Co₃O₄, the FM vanishes after annealing at 400 C, while it is still present for Zn containing samples after annealing up to 800 C. The different behaviour observed for the ZnO containing samples confirms that the FM signal observed in these samples is not related to any metallic Co cluster, which should disappear after annealing at about 400 C. It is worthy to note that for ZnO containing samples the FM signal is present up to 800 C, the same temperature at which Co₃O₄ is still present in the sample according to X-ray diffraction patterns. Thus, we can conclude that the wurtzite type solid solution formed in this reaction is not the responsible for the FM. The decrease of FM

with the subsequent anneals suggests that the origin of these magnetic properties is not associated with carrier-mediated mechanisms in a DMS.

We propose that during alloying Co₃O₄ and ZnO electrostatically attract each other. The presence of ZnO at the Co₃O₄ surface promotes an electronic modification that leads to the reduction of the Co³⁺ atoms to Co²⁺ in the octahedral positions of Co₃O₄. This reduction changes the electronic configuration and atomic distances at the Co₃O₄ surface. The consequence of this modification is that superexchange interactions are substituted by exchange interactions between Co atoms at the surface, thus yielding RT FM.

Magnetism and Transport Properties of ZnO films doped with Co or Mn and Al.

G. Gehring, A. J. Behan, A. Mokhtari, H. J. Blythe, D. Score, J. R. Neal, M. Fox
Physics and Astronomy, University of Sheffield, Sheffield, United Kingdom

The subject of ZnO doped with magnetic ions continues to receive much attention [1-4]. It has been found that not all doped films exhibit ferromagnetism, and that the mobile carrier density, n_c , can be very different in those compounds that do [5, 6]. It has been found that the addition of Zn interstitials, which affects both the number of neutral and ionised donors, leads to an increase in the ferromagnetism [7]. In fact, most of the work on doped ZnO has concentrated on the insulating phase, to such an extent that some authors now refer to ZnO as a dilute magnetic insulator (DMI) [5]. However, we have recently reported the observation of ferromagnetism in Al-doped films where n_c is very high [6, 8], which highlights the importance of exploring the full range of carrier densities from the insulating to the metallic phases.

We discuss here how the electronic properties of these films, specifically carrier density and magneto-resistance are correlated with the magnetisation.

An Al ion doped into ZnO acts as a shallow donor so that it is expected to contribute one carrier per Al at room temperature. However the presence of the carriers due to Al provides screening for the other donor states in the sample so that they may also become ionised. Hence it is found that actually the carrier density rises by more than one carrier per Al ion [9, 10]. In Figure 1 we show the carrier density as a function of the percentage of Al for $\text{Zn}_{1-0.02-x}\text{Al}_x\text{Mn}_{0.02}\text{O}$ and Fig 2 shows an equivalent plot for $\text{Zn}_{1-0.05-x}\text{Al}_x\text{Co}_{0.05}\text{O}$, the solid line indicates the carrier concentration expected if each Al ion contributed one carrier. All of these films were grown by PLD on sapphire substrates held at 450C at an oxygen pressure of 0.05mTorr. In the case of the Co and Mn doped films we have added a dotted line to indicate the density of magnetic ions and have also indicated the magnitude of the magnetisation as measured from a SQUID loop at room temperature.

It is clear that in all cases there are more carriers than can be accounted for by the Al ions. This effect is more pronounced for the samples that also contain Mn and Co indicating that these ions are also contributing to the carrier density. However the films with the largest magnetisations are those with the carrier density less than or comparable to half that of the magnetic ions as has been noted before [6, 8].

The magneto-resistance, MR, of Co doped ZnO is shown in Figure 3. We note that comparable MR signals are seen for samples that are not ferromagnetic. These results are discussed and compared to earlier work [11] and also in terms of the importance of both the number of free carriers and types of defect responsible for the magnetism.

Ferromagnetism of manganese-doped indium tin oxide films deposited on flexible polymer substrates.

T. Nakamura, K. Tanabe, S. Isozaki, K. Tachibana

Department of Electronic Science and Engineering, Kyoto University, Kyoto, Japan

Diluted magnetic semiconductors (DMS) have attracted considerable attention because of their potential applications to spintronic devices. Low temperature deposition is required to grow magnetic films on polymer substrates for the development of flexible spintronic devices. There are several devices using transparent conducting films fabricated at low substrate temperatures in the market. Among the existing transparent conducting films, indium tin oxide (ITO) is widely used in flat panel displays, optoelectronics, solar cells, and so on. In this work, we fabricated Mn-doped ITO films on flexible polymer substrates, and investigated the magnetic, electrical, and optical properties of the films.

Mn-doped ITO films were grown on polyethylene naphthalate (PEN) substrates at room temperature using rf magnetron sputtering. For comparison, the films were deposited on glass substrates. The distance between the target and substrate was maintained at 50 mm. After the chamber was evacuated to a high vacuum of about 1×10^{-6} Torr, working gas of argon was introduced. Before the deposition, the target was pre-sputtered for 30 min to obtain a clean target surface. The process pressure was controlled at 7 mTorr during the sputter deposition. The rf power was 80 W.

Magnetic properties were characterized by a superconducting quantum interference device (SQUID) magnetometer. Magnetization versus applied magnetic field curves were measured at 77 and 300 K for the Mn-doped ITO film. The magnetic field was applied parallel to the film plane. A well-defined hysteresis loop with a coercive force of about 80 Oe was observed at 300 K, signifying room temperature ferromagnetism. The temperature dependence of the magnetization for the Mn-doped ITO film was measured from 5 to 400 K using SQUID. The magnetization data were taken in an applied field of 1000 Oe parallel to the film plane. The Curie temperature is estimated to be higher than 400 K.

Transport properties (resistivity, carrier density, and mobility) of the deposited films were measured by Hall effect measurements using van der Pauw geometry. The Mn-doped ITO films deposited at room temperature exhibited low electrical resistivity of the order of 10^{-3} Ω cm, although the resistivity of the films was increased by low temperature deposition.

Optical transmission spectra in the wavelength region of 300-800 nm were acquired using a UV-visible spectrophotometer. The transmittance exhibits interference in the visible range. The average transmittance of the Mn-doped ITO film ranges from 75 to 90%. The Mn-doped ITO film is optically highly transparent.

In summary, Mn-doped ITO films were deposited on flexible organic substrates as well as glass substrates by rf magnetron sputtering. The magnetization as a function of magnetic field exhibited hysteretic behavior at room temperature. According to the temperature dependence of the magnetization, the Curie temperature is higher than 400 K. The Mn-doped ITO film exhibited low electrical resistivity of the order of 10^{-3} Ω cm and high optical transmittance between 75 and 90% in the visible region. Mn-doped ITO films fabricated at low temperatures can be one of the most promising candidates of ferromagnetic transparent conductive materials for flexible spintronic devices.

Fabrication of shielded planar type single-pole head.

K. Ise, T. Kiya, K. Taguchi, K. Yamakawa
AIT, Akita Prefectural R&D Center, Akita, Japan

Introduction:

We have proposed a new single-pole head with planar structure [1] which is composed of a multi-charged-surface (MCS) main pole [2] to produce a strong head field and a wrap-around shield to realize a steep head field distribution for high density recording. This new head was fabricated using novel technique that is different from that for present recording heads. First recording test of the head was done. In this work, we report the detailed fabrication method and fundamental recording properties of the shielded planar head.

Head design and fabrication:

Fig.1 shows the schematic illustration of the proposed shielded planar head. The main pole consists of a truncated pyramid tip and a rectangular back pole. A shield yoke is equipped not only in down track direction but also in cross track direction.

In order to fabricate the head, following processes were used. A shape of the main pole tip was formed using a template of a quadrangular pyramid which was created by a chemical anisotropy etching of a Si (100) substrate. Next, magnetic material was embedded in the template. After formation of the main pole tip, a two-layered pancake-type coil was fabricated. After fabrication of a return yoke over the coil layer, the Si substrate was bonded to a dummy substrate by an anode bonding. Then, the Si substrate was removed by chemical etching to appear the pyramidal-shaped main pole tip. After that, the gap and the shield yoke layers were deposited on the etched surface. Finally, lapping process was performed to define the track width.

Fig.2 shows the plane view of the fabricated shielded planar head near the main pole. It was confirmed that the main pole and the wrap-around shield with a narrow gap were successfully formed. In this fabrication, Fe-Si-N film with Bs of 1.9 T was used for the main pole material. The nominal write track width was 1 μm . A number of the coil was six. DC resistance and inductance of the fabricated head were about 40 Ω and 1 nH, respectively.

Recording test:

In order to evaluate head performances, read-write tests were performed in sliding contact recording. A commercial TMR head and a Co-Cr system alloy medium with coercivity of 3.9 kOe were used for the evaluation of the fabricated head.

We successfully obtained read-back signals from the bits recorded by the fabricated head as shown in Fig.3. Although high recording performance was not yet obtained, it is suggested that the result has opened a path for new paradigm of recording head.

New Type Side Shield Head for Ultra High Density Recording.

Y. Kim, S. Kukhyun, K. Na

HDD Core Tech TF, SAIT(Samsung Advanced Institute of Technology), Yongin-Si, South Korea

I. INTRODUCTION

There is no revolutionary jump of areal density in magnetic recording especially in write head, we need to optimize writing head to increase track density[1][2]. By these reason we concentrate to increase track density by reducing leakage field to disturb the written data in side track. We propose new type side shield to satisfy these needs for write head, which we named shell shield.

This head can reduce side leakage without any degradation head field and field gradient at write gap.

II. ANALYSIS MODEL

A. Head Model

The head field and its gradient were calculated using the nonlinear finite element method (Jmag software)[3] with write head of 100 nm track width, 50 nm gap length, 200 nm yoke thickness, and 150 nm throat height. The number of elements is more than 38,000 and nodes are 67,000. The magnetic spacing was 20 nm. To find the optimization condition, shell thickness is changed from 50 to 170 nm and distance between pole tip and side shield is changed from 80 to 220 nm.

B. Track Width Simulation

To confirm the head performance, the write field was simulated with several coil currents 30, 50 and 70 mA and the media locations were 0, 50 and 250 nm from pole tip surface. The applied head field at each media position of recording disk was calculated to simulate minimum track width of each combination of head & media by using the calculation method explained in fig. 2 b).

C. Optimization

We used Minitab software to search optimized condition of shell shield and conventional wrap around shield head. We used central composite method in surface response method which is one typical method of DOE(design of experiment) [4]. We found three optimization points depends on the media nucleation field(Hn).

III. RESULTS AND DISCUSSION

Simulated head field distribution of conventional and shell side shield head were shown in Fig. 3 for comparison. In the figure, we can find out the head field is concentrated to the center of pole and the side leakage field is distributed to all area of shield.

To see the result we can imagine the shell side shield can concentrate field to the center of head pole and decrease side track erasure, so it would achieve high track density.

Fig. 4 shows the optimized results of conventional head and shell shield head. We can see the possible track width of conventional head is about 300 nm and shell shield head is about 250 nm. In addition to, the maximum field gradient of shell shield head is almost 120 Oe/nm, so the linear density of proposed head (about 110 Oe/nm) would be also higher than that of the conventional head.

IV. CONCLUSION

We suggest the shell side shield head for high density recording head and evaluate the performance by comparison between the optimized conditions of conventional wrap around side shield head and proposed shell side shield head.

Optimal Side Shield Write Head Design for Ultra High Recording Density.

Y. Kim, S. Kukhyun, K. Shin

HDD Core Tech TF, SAIT(Samsung Advanced Institute of Technology), Yongin-Si, South Korea

I. INTRODUCTION

There is no revolutionary jump of areal density in magnetic recording especially in write head, we need to optimize write head to increase track density. We concentrate to increase track density by reducing leakage field to disturb the written data in side track[1][2], by optimizing side shield shape.

II. ANALYSIS MODEL

A. Head Model

The head field and its gradient were calculated using the nonlinear finite element method (JMag software)[3]. The magnetic spacing was 20 nm. To find the optimization condition, the angle of side shield, which is shown in Fig. 1, is changed from 7 to 28 degree and distance between pole tip and side shield is changed from 80 nm to 220 nm.

B. Track Width Simulation

To confirm the head performance, the write field was simulated with several coil currents 30, 50 and 70 mA and the media locations were 0, 50 and 250 nm from pole tip surface. The applied head field at each media position of recording disk was calculated to simulate minimum track width of each combination of head & media by using the calculation method explained in fig. 2.

C. Optimization

We used Minitab software to search optimized condition of shell shield and conventional wrap around shield head. We used central composite method in surface response method which is one typical method of DOE(design of experiment) [4]. We found three optimization points depends on the media nucleation field(H_n).

III. RESULTS AND DISCUSSION

Simulated head field distribution of conventional wrap around side shield and separated side shield head were shown in Fig. 3 for comparison. In the figure, we can find out each head has different the maximum track width position, red arrow shows maximum track width position in Fig. 3, so the optimized condition is completely different.

Fig. 4 shows the optimization condition of wrap around head and separated side shield head. In the results, we can imagine the expected areal densities are almost same, track width is about 300 nm and field gradient is about 110 Oe/nm, but the optimized conditions are completely different. The condition in wrap around head is that angle is about 10 degree and distance is around 140 nm, and about 22 degree and around 150 nm in separated side shield head.

IV. CONCLUSION

We studied optimized conditions of side shield heads for high density recording and evaluate the performance by comparison between the optimized conditions of each heads, but two head types has almost same performance and in fabrication point of view, separated side shield is ease to manage because gap length is controlled easily by process time.

Magnetic 1/f noise in MgO tunneling magnetoresistive sensors.

N. Smith, D. Mauri, J. A. Katine, Y. Hong
Hitachi Global Storage Technologies, San Jose, CA

The appearance of 1/f noise in the resistance across tunneling barriers, and tunneling magnetoresistive devices in particular, and is generally attributed to electrical, rather than magnetic origins, e.g., electron trapping sites inside the tunnel barrier [1]. This talk reports on the clear observance of a predominant magnetic component of 1/f noise in CoFeB/MgO/CoFe/CoFeB tunneling magnetoresistive sensors fabricated into small (~ 100 nm) test structures representative of TMR read sensors. The devices have tunnel barriers with typical RA product of ~ 2 -3 ohm- μm^2 , and TMR ratios of ~ 80 -100%.

Fig. 1 shows measured R-H loops for an 80nm circular (E-beam defined) device subject to two-axis orthogonal fields: a stationary H_{long} of 800 Oe is aligned collinearly (parallel or antiparallel) to the exchange pinning direction of the IrMn/CoFe/Ru/CoFeB pinned-layer (PL)/reference-layer (RL) synthetic antiferromagnet (SAF). A transverse field H_{trans} is then continuously swept to rotate the CoFe/CoFeB free-layer (FL). Fig. 2 shows measured rms low-frequency noise vs H_{trans} (during which the bias voltage is fixed at 140 mV) at selected frequencies of 0.3 MHz and 3 MHz. (Noise at zero bias voltage has been subtracted out.) A notable minimum in the low-f noise occurs when RL and FL magnetizations are aligned collinearly, either parallel (P) or antiparallel (AP). The absolute noise level is virtually the same for either P or AP states, but rises particularly fast for initial deviation from the AP state. This pattern is observed for both the 0.3 MHz and 3 MHz noise, the latter being essentially just smaller in amplitude by about $\sqrt{10} \sim 3$, as would be expected for 1/f type noise. (The 1/f-like nature was also confirmed by spectral measurement over a frequency continuum.) Although the amplitude of the maximum noise level can vary from device to device, this basic pattern of field-dependent noise shown was observed in tens of devices. The overall noise amplitude scales fairly linearly with bias voltage ≤ 140 mV.

A field-independent minimum/collinear noise level was found to remain unchanged in "magnetically-poisoned" CoFeB/MgO/Ru/CoFe barriers which had the same RA but TMR $< 1\%$. It represents an electronic 1/f noise intrinsic to this tunnel barrier. The field (and thus magnetic orientation) dependence of the excess 1/f noise (i.e., that above the minimum/collinear level) conclusively demonstrates its magnetic origin, and strongly suggests it arises from magnetization fluctuations of the relative angle θ between RL and FL magnetizations which naturally produce TMR resistance fluctuations which scale as $d\cos\theta/d\theta = \sin\theta$ and hence vanish for collinearity. Although the FL sees an 800 Oe H_{long} field in either case, the noticeably larger levels of 1/f noise for the near-AP state, compared to the near-P state, suggest the origin of this noise is in RL fluctuations enhanced when H_{long} is antiparallel (hence destabilizing) with respect to the nominal RL magnetization orientation. This observation is consistent with alternative experimental conditions and device structures which will be described in the talk, including the lack of significant 1/f magnetic noise in the analogous tri-layer structure of CeFeB/MgO/CoFe without the IrMn pinning layer or the SAF PL/RL.

Proposal of new method to fabricate nano-contacts in CoFe-NOL.

Y. Shiokawa, Y. Saki, S. Kawasaki, M. Doi, M. Sahashi
Electronic Engineering, Tohoku Univ., Sendai, Japan

Domain wall MR with FeCo-AlO_x NOL (nano-oxide-layer) spacer is much attracting attention as a future reader element for magnetic head because of its low resistance and high MR ratio [1]. The formation mechanism of CoFe-AlO_x NOL has reported [2]. The ferromagnetic nano-contacts (NCs) were fabricated during *in-situ* annealing by the migration and cohesion of Al from CoFe-Al mixing layer in the vacuumed chamber with remained oxygen. Meanwhile, by *in-situ* annealing, Al diffused to the inside of CoFe layer at the same time (Fig.1). So, the concentration of Al on the surface of CoFe layer after annealing became poor due to these diffusion. Therefore, by the Natural Oxidation (NO), CoFe in NCs were also oxidized with patterned Al. As result, the current intensity of conductive channels was weak in the current image of conductive-AFM.

In this study, we propose a new method to fabricate the NCs which is formed by the diffused Al, which was the problem in the past study, with partial reduction of oxygen in CoFe-NOL.

The ion beam sputtering method was used for the sample preparation. We fabricated the two kinds of the SV film. One was seed-layer/IrMn 7/Co_{0.9}Fe_{0.1} 3 (pinned layer: PL)/Ru 0.85/Co_{0.9}Fe_{0.1} 2.7 (reference layer: RL)/Cu 2 or Al 1.5/*in-situ* annealing (200°C, 30min)/Co_{0.9}Fe_{0.1} 5 (free layer: FL)/Capping-layer (nm), the other was seed-layer/IrMn 7/Co_{0.9}Fe_{0.1} 3/Ru 0.85/Co_{0.9}Fe_{0.1} 2.7/NO (O2 pressure: 2.5×10⁻⁴ Torr, 39 min)/Co_{0.9}Fe_{0.1} 1/Cu 2 or Al 1.5/Co_{0.9}Fe_{0.1} 5/Capping-layer (nm). An interlayer coupling field between a RL and a FL (H_{in}), and exchange bias field (H_{ex}) were measured for SV film systems with vibrating-sample magnetometer (VSM).

First, in order to confirm the diffusion of Al, we compared the SV composed Al spacer and GMR-SV composed Cu spacer without CoFe-NOL. By the change the spacer from Cu to Al, the magnetization of RL decreased by 14% and H_{in} increased from 0 Oe to 139 Oe. In addition, with *in-situ* annealing to Al, not only the magnetization of RL decreased by 73% but also H_{ex} decreased from 1872 Oe to 1087 Oe against GMR-SV. We thought these phenomena were caused by the diffusion of Al to the inside of RL and Ru in synthetic antiferromagnetic structure.

Figure.2 (a) and (b) show the M-H curve of the GMR-SV composed Cu spacer and the SV composed Al spacer with CoFe-NOL, respectively. In Fig.2 (a), the magnetization process of FL shows the H_{in} is about 7 Oe and the magnetization of FL increased by 18% corresponds to 0.9nm of CoFe. In consideration of the thickness of 0.9nm, this CoFe is thought CoFe of upper layer of CoFe-NOL. Thus, this result suggests that CoFe-NOL cuts the coupling between under RL and upper RL because CoFe is oxidized equally (Fig.3 (a)). In Fig.2 (b), by the change the spacer from Cu to Al, we didn't observe the cut between under RL and upper RL by CoFe-NOL, while observed the H_{in} of 160 Oe and the decrease of the magnetization of RL against GMR-SV with CoFe-NOL. These phenomena indicate that the followings: the diffused Al atoms arrive to the surface of CoFe-NOL, these metallic Al atoms rob oxygen in CoFe-NOL, and it makes the ferromagnetic NCs of Co or Fe in the insulator of (Co,Fe,Al)O_x (Fig.3). That is to say, the tri-layer of CoFe-NOL/CoFe/Al fabricates the NCs. We suggested the new method to fabricate the NCs, which was formed by the diffused Al into upper CoFe layer and induced partial deoxidation of CoFe-NOL by the formation mechanism of AlO_x.

Effect of Spin Transfer Torque on 1/f Noise in TMR Heads.

J. Masuko, H. Akimoto, H. Kanai, Y. Uehara
Fujitsu Limited, Nagano, Japan

Introduction

It is suspected that magnetic noise is increased by narrowing the track width and by the spin transfer torque as a result of high current density in TMR heads. In particular, we are interested in the spin torque effect on magnetic noise in the frequency range below 1 [GHz] from a practical viewpoint. In the numerical [1] and experimental [2] studies of CPP-GMR, it is mentioned that 1/f noise is the result of chaotic magnetization precession induced by the spin transfer torque. And it is interesting to examine the magnetic normal modes [3] or the spatial distribution of resistance fluctuation in other words in this frequency range to understand the phenomena induced by the spin transfer torque.

Simulation Model

We investigated the spin torque effect on magnetic noise using macromagnetic simulation. The track width and the stripe height of the free layer are set to 69[nm] and 90[nm], respectively. Biasing field is applied to the free layer from PM. In addition, external field is applied perpendicular to the biasing field. A positive current is defined as the current from the reference layer to the free layer and a positive external field parallel to the magnetization of the reference layer. And the absolute value of external field is 300 [Oe].

Results and Discussion

Fig.1 is the current density dependency of the current – normalized magnetic noise spectrum and Fig.2 is the current density, direction of external field and spin polarization dependencies of integrated magnetic noise with the origin at zero sense current. 1/f noise appears only if the spin polarization P is not zero and the specific conditions between the polarity of current and field are satisfied.

Fig.3 is the spatial distributions of amplitude and phase of resistance fluctuation at 100 [MHz]; (i) $P=0$, current: positive, field: positive ((a), (e)), (ii) $P=0.48$, current: positive, field: positive ((b), (f)), (iii) $P=0$, current: positive, field: negative ((c), (g)) and (iv) $P=0.48$, current: positive, field: negative ((d), (h)). Comparing these conditions, 1/f noise only appears in (ii) and (ii) is different in the amplitude distribution and has a small spatial phase distribution. In addition, the maximum value of amplitude of (ii) is about two times larger than that of others. The magnetization of the free layer behaves as if it were at the resonant frequency without the external field as shown in Fig.3 (b) and (f). These results indicate that the spin torque effect has a superiority over the thermal fluctuation in a low frequency range and induces the coherent behavior of the magnetization.

Fig.4 is the frequency dependency of the spatial distributions of amplitude and phase in the same condition as (ii) of Fig.3. It is found that the spatial phase coherency is disordered at 1 [GHz] and the amplitude distribution comes to other conditions as shown in Fig.3 (a), (c) and (d). These results indicate that the thermal fluctuation has a superiority over the spin torque effect in a high frequency range and inhibits the coherent behavior of the magnetization.

The role of pre-oxidation on the interface structure of Co/MgO multilayers.

D. S. Eastwood¹, W. F. Egelhoff, Jr.², B. K. Tanner¹

1. Physics, Durham University, Durham, United Kingdom; 2. National Institute of Standards and Technology, Gaithersburg, MD

Pre-oxidation of the bottom electrode of a magnetic tunnel junction (MTJ) in a low pressure of oxygen prior to depositing the oxide barrier layer has been shown to result in a major reduction in the coupling field between electrodes for both alumina and MgO based MTJ structures [1,2]. The coupling field, defined as the shift from zero of the center of the easy axis hysteresis loop, has been attributed to Néel orange-peel coupling associated with free poles induced across the MTJ barrier as a result of conformal roughness. Néel's model [3] predicts a variation of the coupling field which increases with roughness amplitude but decreases as the in-plane length scale of the roughness increases. The overall trend of H_f with barrier thickness is in good agreement with the variation found in Co/MgO/Co/IrMn MTJs [2]. Thus the implication is that the pre-oxidation suppresses the roughness amplitude, resulting in the drop in coupling field.

We have used grazing incidence specular and diffuse x-ray scattering to determine the layer and interface parameters of MTJs and Co/MgO multilayers grown on a 200Å NiFeCuMo seed layer deposited on thermally oxidised Si wafers. The films were deposited at room temperature, in a deposition chamber with base pressure of 7x10⁻⁸ Pa by dc-magnetron sputtering. To pre-oxidize samples, 10⁻³ Pa (≈10⁻⁵ Torr) O₂ was admitted to the chamber and there was a 10 s delay prior to turning on the magnetron gun and depositing the MgO layer by reactive sputtering. For samples not pre-oxidized, Mg metal was deposited and subsequently oxidized by an oxygen plasma.

X-ray scattering in the standard reflectivity geometry was undertaken from Si/SiO₂/20nm NiFeCuMo [20nm] {Co [10nm] / MgO [2nm] }₅ / Co [2.5nm] / AlOx [1nm] multilayers at station I16 of the Diamond Synchrotron Light Source during its first period of user beam delivery. Data were fitted to a model structure using the Bede REFS code. Out-of-plane measurement of the diffuse scatter from the same samples was performed using the MAR two dimensional detector at the XMaS (BM28) beamline of the ESRF.

Unlike comparative data taken from annealed [4] or pre-oxidised AlOx based tunnel junction structures, no statistically significant change in either the overall interface width (from the specular scatter) or the topological roughness (from the diffuse scatter) was observed between the two types of specimen.

However, the diffuse scatter measured out of the plane of incidence was systematically different between samples.

Quantitative analysis of the intensity as a function of the wavevector component perpendicular to the plane of incidence revealed typical scaling law behaviour [5] at high wavevector. The correlation length, determined from the inflexion in the scattering distribution where fractal scaling behaviour ceases, was greater for pre-oxidised samples than for untreated samples. In other words, the pre-oxidation appears to result in suppression of the higher spatial frequency components of the roughness and a consequent reduction in coupling field. The results of the out-of-plane scatter suggest that the reduction in coupling in MgO based tunnel junction devices arises primarily from the change in the in-plane spatial frequency of the roughness, rather than a reduction in the out-of-plane roughness amplitude.

Hard bias effect on magnetic noise in different types of tunnel magnetoresistive heads.

G. Han, B. Zong, P. Luo, Z. Guo

Data Storage Institute, A*STAR, Singapore, Singapore

Thermally excited magnetization fluctuation noise, often called as mag-noise, has become a major concern due to continued decrease in the dimensions of the read sensors to accommodate increasing storage density. High-frequency mag-noise, in addition to being practical concern, can be used as a nondestructive diagnostic tool for read head design. A characteristic feature of the mag-noise is that there exists a ferromagnetic resonance (FMR) at a frequency of several GHz. As the mag-noise magnitude in recording band is proportional to the peak value of the resonance[1], FMR measurements can serve as an alternative method to characterize the noise characteristics of sensors. The mag-noise is not only determined by the volume of the free layer, but also the sensor structure, in particular, the hard bias strength in terms of effective stiffness field. Hard bias effect on the mag-noise has been theoretically examined in our previous work [2]. However, no work is reported on the experimental study of the hard bias effect so far. To investigate the bias effect without involving in the variations of sensor major parameters (size, materials, variation of sensor structure, etc), we study the bias effect through artificially changing the hard bias direction with respect to the magnetization of the reference layer (RL).

The mag-noise is measured by a spectrum analyzer. The measurements are performed on TMR heads in finished slider form. Contact is made with the bonding pads of the head by means of a 50 ohm micro-probe. A magnetic field is applied perpendicular to the head's air bearing surface by an electromagnet. A 2 Tesla of magnetic field was applied to set the hard bias at any angle θ with respect to the RL magnetization direction.

Transfer curve was measured before noise measurement to understand sensor performances. For MgO-TMR head, no hysteretic loop is observed at various bias angles, while TiO-TMR head shows hysteretic jumps at near zero fields for $\theta=0^\circ$. The transfer curve of AIO-TMR heads shows an open loop at high positive fields at small θ s. Examples of the noise spectra for these three types of TMR heads are shown in Fig.1(a,b,c). From these figures, one can see the different variations of the noise spectra for different TMR heads. However, this characteristic difference is not necessarily attributed to their different tunneling mechanisms, but rather the different structures and geometries. For MgO-TMR, one can see that for strong bias ($\theta=60^\circ - 90^\circ$), the resonance peak is broad with a low magnitude. For low bias, the resonance shifts to low frequency with larger magnitude and narrower width. If one considers the resonance as two-peak structure, the variation in the main peak can be understood by the stiffness mechanism from the thermally activated fluctuations of the free layer. For the satellite peak at higher frequency, strong bias tends to enhance its amplitude without changing its position. This peak is believed to be from the composite RL and pinned layer. On the other hand, the main peak follows the stiffness-determined characteristics, i.e., the peak increases in magnitude and shifts to lower frequency as the hard bias becomes weak due to the peak frequency (f_p) $\sim \sqrt{M_s H_{\text{stiff}}}$. For AIO-TMR heads, the resonance appears only at strong bias ($\theta=60^\circ - 90^\circ$) at zero external field. The absence of the resonance at weak bias is due to the sensor saturating at antiparallel state, which is confirmed by the transfer curve measurements. At the weak bias, the FMR peaks can be seen at positive fields and its magnitude varies consistently with the change of the sensor sensitivity. For TiO-TMR heads, the noise characteristics can be understood with the combination of its transfer curves (Fig.1(d)). The dynamic region of the transfer curves shifts to negative and positive fields for $\theta=0^\circ$ and 15° , respectively. As a result, the stiffness field decreases as θ decreases till $\theta=15^\circ$, resulting in increasing reso-

nance magnitude and lowering the resonance frequency. In comparison to $\theta=15^\circ$, the stiffness field for $\theta=0^\circ$ increases in its value, but along an opposite direction. For $\theta=90^\circ$, the situation seems different. First its transfer curve shifts up in comparison with $\theta=60^\circ$ or even 45° , suggesting weaker biasing. The weaker bias for $\theta=90^\circ$ is in agreement with noise characteristics shown in Fig.1(a). Careful examination shows that this is from the misalignment of the bonded head from the field setting direction.

Field (H) dependence of the mag-noise show that there is a valley (or dip) in f_p versus H curves for all measured heads. There is an offset in the dip position from the zero field. More detailed examination shows that the offset is determined by the hard bias direction and the internal field (e.g., interlayer coupling). More detailed discussion will be given in the presentation.

Laser Application Technology Center, Industrial Technology Research Institute, Tainan, Taiwan

In this study, the effect of annealing conditions on the magnetic characteristics of multilayered perpendicular magnetic tunnel junctions (pMTJ) of the structures SiNx/Pt/(Co/Pd)₁₀/MgO/(Co/Pt)₅/Pt with various MgO barrier thicknesses are explored. It is reported [1] that inserting a 0.4 nm Mg layer can reduce the RA value while maintaining high magnetoresistance in very thin MgO barrier regions. Consequently, we also fabricated pMTJ of the structures SiNx/Pt/(Co/Pd)₁₀/Mg/MgO/(Co/Pt)₅ as a comparison. The magnetic properties were measured using an alternating gradient magnetometer (AGM). Current-in-plane tunneling (CIPT) [2] was also conducted for the measurement of the magnetoresistance.

Figure 1 (a) shows the hysteresis loops of the free layers for (Co/Pd)/MgO/(Co/Pt) structures with various annealing temperatures from 25 to 250°C for one-half hour. Here the Co/Pd multilayer was used as the pinned layer and the Co/Pt multilayer acted as the free layer. Equivalent results for similar structures with insertion of Mg layer are shown in Fig. 1(b). From these figures we see that the coercivities increase as the annealing temperature increases for both pMTJ structures. This may arise from an improvement of the interface roughness during the annealing process. However, the squareness decreases with the increasing annealing temperature. Comparing Fig. 1(a) and Fig. 1(b), we see that insertion of an Mg layer makes the free layer coercivities even higher but adds long canted tails into the loops which, further deteriorate their squareness. Figure 2 displays the relationship between the MgO thickness and free layer coercivity under different annealing temperatures. It illustrates that the coercivities have a weak dependence on the MgO thickness, and annealing at 300°C causes an obvious increase in coercivities compared with other temperatures.

Figure 3 shows the result of magnetoresistance measurement for the sample with MgO layer thickness 1.5 nm annealed at room temperature.

Effects of Current-Confined-Path on the Spin-Torque Noise in CPP-GMR Heads with a Current-Screen Layer.

M. Shiimoto, H. Katada, K. Nakamoto, H. Hoshiya
Central research laboratory, Hitachi, Ltd., Odawara-shi, Kanagawa-ken, Japan

Introduction

Current-perpendicular-to-plane-giant-magneto-resistive (CPP-GMR) heads is one of the most promising candidate technologies to achieve high-areal-density recording. The CPP-GMR heads with a current-screen layer (nano-oxide layer having metallic nano-holes) has a high MR ratio because the sensing current is confined by the nano-holes [1]. Moreover, in the current-screen CPP-GMR heads, spin-torque noise [2] is not induced in well-biased heads [3], even though the sensing current is concentrated in metallic-conductive nano-holes. This suggests that the spin-torque noise behavior in screen CPP-GMR heads is different from that in all-metallic CPP-GMR heads. Furthermore, it was reported that critical current density is changed depending on the metallic-conductive area in tunneling magneto-resistive heads [4]. In this study, we investigated the effect of current-confined-path on spin-torque noise in CPP-GMR heads with a current-screen layer through the measurements and calculations.

Experiment and calculation

We measured broadband noise spectrum in two kinds of current-screen type CPP-GMR heads with resistance-area-product (RA) of $1.0 \mu\Omega\text{m}^2$ and $0.25 \mu\Omega\text{m}^2$, respectively. Note that the large RA indicates a small metallic-conductive area and vice versa. We prepared heads with the large asymmetry ($>20\%$) and heads with the small asymmetry in order to analyze the spin-torque noise easily. The peak asymmetry is a good indicator of the relative angle of magnetization between the free layer and the reference layer. The operating voltage was set to 120 mV. We also calculated the head noise using micromagnetic simulation in which the sensing current only flows through the conductive area in the current screen layer.

Results and Discussion

Figure 1(i) shows the measured noise spectrum in the heads with 0% of the peak asymmetry. The RA of Heads A and B were $1.0 \mu\Omega\text{m}^2$ and $0.25 \mu\Omega\text{m}^2$, respectively. The head noise below 1 GHz in Heads A and B agreed with the sum of Johnson noise and mag-noise. Figure 1(ii) shows the measured noise spectrum in the heads with RA of $1.0 \mu\Omega\text{m}^2$ (Head C) and $0.25 \mu\Omega\text{m}^2$ (Head D). The peak asymmetry of both heads was more than 20%. The noise levels in Heads C and D were much larger than that of the well-biased heads shown in the figure 1(i). These large noise levels in these heads indicate that the spin-torque noise is induced. Comparing the noise profiles of Head C and D, shape of noise profile is significantly different. In the case of Head C, pronounced $1/f^n$ noise was observed below 1 GHz. On the other hand, in the case of Head D, the noise level in most of the bandwidth was increased and the noise profile was becoming chaotic. To understand this difference in profiles, we analyzed the spin-torque noise using simulation. Figure 1(iii) shows calculated noise spectrum in Heads C and D. The calculated noise profiles of both heads qualitatively agree with the experimental results shown in Figure 1(ii). The difference in noise profiles in heads C and D can be understood by considering the magnetic coupling in the free layer. The magnetization in the conductive areas fluctuates largely than that in the non-conductive area. Therefore, magnetic coupling between the large fluctuated magnetization in the conductive area and the stable magnetization in the non-conductive area induced $1/f^n$ noise.

The distribution of nano-metallic holes is important to enhance the magnetic coupling of the magnetizations. Figure 2 shows calculation model of two kinds of screen layer for Heads E and F. The

calculation results for head noise in these heads are shown in table 1. The calculated noise in Head E was smaller than that in Head F, because the magnetizations in a nono-metallic hole for Head E have larger areas coupling with the stable magnetization than that for Head F. Therefore, controlling the distribution of metallic-nano-holes is important to suppress spin-torque noise in CPP-GMR heads with a current-screen layer.

Electrical 1/f noise in CCP-GMR with current-confined-pass nano-oxide layer.

M. Shimizu, M. Takagishi, M. Takashita, H. Iwasaki

Corporate Research & Development Center, Toshiba corporation, Kawasaki, Japan

Introduction

Large 1/f noise has been reported for TMR heads. It is assumed to be caused by charge trapping mechanism in the insulator barriers or near the FM-insulator interfaces [1]. On the other hand, single metal nano-hole also causes electrical 1/f noise, interpreted by defect motions [2]. CCP(current-confined-path)-CPP-GMR, which is one of promising candidates for future high-density recording heads, have Cu metal passes with a few nanometer in size, penetrated through an Al-O spacer layer [3]. Therefore, defects in or near the metal passes may cause 1/f noise, resulting in SNR degradation. However, there has been no report about 1/f noise for CCP-CPP-GMR. In this paper, we report 1/f noise characteristics for CCP-CPP-GMR with various RA (resistance area product) and discuss about 1/f noise level for small size element required for tera-bits high-density recording.

Experiments

Test chips were fabricated for CCP-CPP-GMR films with RA ranging from 0.25 to 1.4 $\Omega\mu\text{m}^2$ and MR ratios up to 7.7% [3]. A 600 Oe field was applied to maintain a parallel magnetization configuration of pinned and free layers, so that the noise was measured as electrical origin. A spectrum analyzer was used to measure the noise power density up to 10 MHz. The noise magnitudes up to 7 Hz were also acquired applying a Fourier transform (FFT) on voltage series by using a voltmeter.

Results and Discussion

Fig.1 shows the noise power spectra from 50 kHz to 10 MHz at room temperature for all-metal and CCP-CPP-GMR with an RA of 0.45 $\Omega\mu\text{m}^2$. Both spectra are composed of a broadband 1/f component at low frequencies. All-metal CPP-GMR shows low 1/f noise, suppressed below background at $f > 200\text{kHz}$, while CCP-CPP-GMR shows prominent 1/f noise even at $f = 3\text{ MHz}$. It is found that CCP-CPP-GMR shows larger 1/f noise than all-metal CPP-GMR.

Fig.2 shows normalized noise parameter, $\alpha = fS_V A / V^2$, where A is the sample size, as a function of RA ($A = 0.3 \times 0.3\ \Omega\mu\text{m}^2$). High RA films show large α . However, α decreases with decreasing RA. The same level 1/f noise as all-metal films was obtained at an RA of less than 0.2 $\Omega\mu\text{m}^2$. This dependency implies that the increase in metal path number suppresses 1/f noise because high RA films have less metal paths. We also confirmed that smaller element size up to $A = 0.14 \times 0.14\ \Omega\mu\text{m}^2$, resulting in less metal pass numbers and an enhancement of 1/f noise, shows constant α independent of size. We estimated 1/f noise for small size elements by using the noise level shown in Fig.1. It is found that the 1/f noise of films with $RA = 0.2\ \Omega\mu\text{m}^2$ is in the order of 1 nV/rt.Hz at 10 MHz even for $V = 120\text{mV}$ and $A = 0.02 \times 0.02\ \mu\text{m}^2$, corresponding to 1~2Tbit/inch². This estimation indicates that such 1/f noise is not a concern for CCP-CPP-GMR.

In conclusion, CCP-CPP-GMR has 1/f noise caused by current-confined-pass structure. This noise is suppressed by using lower RA films with many metal paths.

Dependence of Thermal Stability on Cap Layer and Top Lead for Current Screen CPP-GMR Sensor.

K. Hoshino, H. Hoshiya, Y. Sato

Storage Technology Research Center, Central Research Laboratory, Hitachi, Ltd., Odawara-shi, Japan

Introduction

Current-perpendicular-to-the-plane giant-magnetoresistance (CPP-GMR) film using a spin-valve (SV) structure is an attractive read sensor for high-density recording. However, it generally shows a small magnetoresistance (MR) ratio. To enhance the MR ratio, the concept of the confined current path was proposed [1] and some improvements in the MR ratio by inserting a current screen layer (nano-oxidized layer) into an SV were reported [2-4].

We also reported that a high MR ratio was obtained by inserting an oxidized CoFe layer into the SV structure as the current screen layer. It was found that the confined current path in the current screen layer reconstructed with increasing annealing temperature after deposition of CPP-GMR film [5]. Therefore, clarification of how to create the confined current path in the current screen layer was needed. In this study, to foster a better understanding of the formation of confined current path, we investigated the thermal stability of current screen CPP-GMR sensors with various cap layers and top leads after patterning CPP-GMR film.

Experiment

We fabricated three CPP-GMR sensors using various materials for the cap layers and top leads. CPP-GMR films had a synthetic-pinned bottom-type SV. An oxidized CoFe layer was used for the current screen layer, and it was inserted into the Cu intermediate layer. The thickness of the current screen layer before oxidation was around 1.5 nm. All films were annealed at 270°C for three hours after deposition, and we used a 100-nm thick Cu layer for the bottom lead. The size of the CPP-GMR sensors varied from $5.0 \times 5.0 \mu\text{m}^2$ to $0.3 \times 0.3 \mu\text{m}^2$. The MR curves were measured using the four-terminal method. The annealing temperature changed from 180 to 250°C over a three-hour period after patterning to evaluate thermal stability of a current screen CPP-GMR sensor.

Results and Discussion

Figure 1 shows the thermal stability of MR ratio for three types of CPP-GMR sensors with various cap layers and top leads. Type A had Cu (5 nm)/Ru (4 nm) cap layers and a Ta (2 nm)/Au (200 nm)/Ta (5 nm) top leads. The MR ratio drastically degraded above 200°C. The reduction can be explained by increasing of current path in the current screen layer because the resistance area product also decreased. Type B had Cu (2 nm)/Ta (7 nm)/Ru (2 nm) cap layers and a Ta/Au/Ta top leads. The MR ratio also degraded above 200°C. However, thermal stability improved by replacing the cap layers. For Type C, Ta (5 nm)/NiFe (15 nm) layers were inserted between the Cu/Ta/Ru cap layers and the Ta/Au/Ta top leads. The MR ratio was maintained up to 250°C.

Two possibilities were considered for the degradation of the MR ratio. The first possibility was due to the damage at the edge of the current screen layer. We observed that there was no dependence of the MR ratio on sensor size for types A and B. This indicated that damage at the edge of the current screen layer did not occur.

The second possibility was due to the structural change of the current screen layer. The reason for poor thermal stability may have been caused by stress induced from the cap layers and top leads. Thermal expansion coefficients of Cu and Au were larger than those of the Ru, Ta, and NiFe layers. For type A, thermal stress led to the structural change of the current screen layer. The current confined path enlarged, and the effect of the confined current path weakened. As a result, the MR

ratio degraded. On the other hand, as the materials with low thermal expansion coefficients were used for type C, they suppressed thermal stress, and thus thermal stability was maintained as shown in Fig. 1. Therefore, the materials of cap layers and top leads are important for good thermal stability in CPP-GMR sensor.

Conclusion

The thermal stability of the CPP-GMR sensors depended on the materials of the cap layers and top leads. The MR ratio was maintained until 250°C for the CPP-GMR sensor with the Cu/Ta/Ru cap layers and the Ta/NiFe layer-insertion between the cap layers and top leads. The maintained MR ratio might be due to the suppression of thermal stress into the current screen layer during annealing.

Stoichiometry and sintering temperature influence on magnetostrictive properties of cobalt ferrites.

L. Boutiuc¹, O. Caltun¹, I. Dumitru¹, M. Feder², N. Lupu³, H. Chiriac³

1. "Alexandru Ioan Cuza" University, Iasi, Romania; 2. National Institute of Material Physics, Bucharest, Romania; 3. National Institute of R&D for Technical Physics, Iasi, Romania

In the last time the magnetostrictive materials started to be intensively studied due to the growing number of possible applications. Among these materials the cobalt ferrites could be a promising materials because of the high values of magnetostriction coefficients [1].

In our study, two categories of samples, stoichiometric cobalt ferrite CoFe_2O_4 and cobalt ferrite with excess of iron $\text{Co}_{0.8}\text{Fe}_{2.2}\text{O}_4$, were prepared by conventional ceramic method. The samples were sintered for 5 hours in air at 1250°C, 1275°C, 1300°C and 1325°C followed by natural cooling. The structural characterization of the samples were performed by X ray diffraction analysis and scanning electron microscopy. The magnetic properties were measured using vibrating sample magnetometry and magnetostriction coefficients were measured using tensile strain gauge technique, at room temperature.

The X ray analysis shows that the studied samples are two-phase systems: spinel and hematite. The sample CoFe_2O_4 has a small concentration of hematite (97.80% spinel, 2.20% hematite) while $\text{Co}_{0.8}\text{Fe}_{2.2}\text{O}_4$ has higher concentration (75.60% spinel, 24.40% hematite). The lattice parameters of studied samples are not influenced by the sintering temperature and are: 8.3776 Å for CoFe_2O_4 and 8.3825 Å for $\text{Co}_{0.8}\text{Fe}_{2.2}\text{O}_4$.

The SEM micrographs of the samples, displays for the stoichiometric ferrites a microstructure with relatively uniform grains, with open porosity including big hematite particles. The iron rich cobalt ferrite display a microstructure with relatively fine grains and with a narrow dispersion of grains size but the big hematite grains are more frequent. For both categories of samples, the density increase with sintering temperature but the density of $\text{Co}_{0.8}\text{Fe}_{2.2}\text{O}_4$ sample are considerable lower than that of CoFe_2O_4 sample.

Magnetization and coercive fields of samples depend on sintering temperature. Iron-rich cobalt ferrite shows a higher specific magnetization comparatively with the stoichiometric cobalt ferrite justified by the iron cations excess. For $\text{Co}_{0.8}\text{Fe}_{2.2}\text{O}_4$, the increase of sintering temperature leads to a decrease of specific magnetization. The coercive fields of $\text{Co}_{0.8}\text{Fe}_{2.2}\text{O}_4$ samples are considerable higher than that of CoFe_2O_4 samples which can be explained by the higher content of hematite characterized by big grain size.

The magnetostriction coefficient was measured along and perpendicular to the applied magnetic field direction. For both categories of samples, the magnetostriction coefficients decrease when the sintering temperature increase.

The measured magnetostriction coefficients along the magnetic field direction, have negative values and depend on the sintering temperature. CoFe_2O_4 sample has a higher value of magnetostriction comparing with $\text{Co}_{0.8}\text{Fe}_{2.2}\text{O}_4$ sample. The maximum of the magnetostriction coefficient is -196 ppm for CoFe_2O_4 sintered at 1250°C and -132 ppm for $\text{Co}_{0.8}\text{Fe}_{2.2}\text{O}_4$ sintered at 1250°C.

On the perpendicular to the applied magnetic field direction the magnetostriction coefficients are positive and depend also on the sintering temperature. In this case, the maximum value of magnetostriction is 57 ppm for CoFe_2O_4 sintered at 1250°C and 47 ppm for CoFe_2O_4 sintered at 1250°C.

The study reveals that the sintering temperature and stoichiometry of the samples influence the magnetic properties and magnetostriction coefficients. The excess of iron ions and the increase of sintering temperature reduce the magnetostriction coefficients.

Spontaneous magnetostriction of $R_2Fe_{13.6}Si_{3.4}$ ($R = U, Lu$).

A. V. Andreev¹, S. Daniš²

1. Institute of Physics, Prague, Czech Republic; 2. Charles University, Prague, Czech Republic

R_2Fe_{17} intermetallic compounds (R is a rare-earth metal) undergo a large spontaneous magnetostriction in the magnetically ordered state. This originates mainly from the Fe sublattice [1,2]. In combination with relatively low Curie temperatures T_C , this leads to Invar behavior in a wide temperature range. U does not form “2-17” binary compounds with 3d metals but the hexagonal Th_2Ni_{17} -type crystal structure can be stabilized by a small amount of a third element, e.g. Si [3]. In the Ref. [4], the magnetization of $U_2Fe_{13.6}Si_{3.4}$ was studied on single crystals together with $Lu_2Fe_{13.6}Si_{3.4}$ where Lu is non-magnetic analogue of U. The U contribution to the total magnetic moment estimated from the difference between the magnetic moments of $U_2Fe_{13.6}Si_{3.4}$ and $Lu_2Fe_{13.6}Si_{3.4}$ is almost negligible. Nevertheless, U influences strongly the magnetic properties. Based on comparison of magnetic anisotropy of $U_2Fe_{13.6}Si_{3.4}$ and $Lu_2Fe_{13.6}Si_{3.4}$ [4], as well as on Mössbauer spectroscopy results [5], the magnetic state of uranium was deduced with the U magnetic moment μ_U up to $2.6 \mu_B$ ferromagnetically coupled with the Fe sublattice. In the present work, we studied the thermal-expansion anomalies accompanying the magnetic ordering in $U_2Fe_{13.6}Si_{3.4}$ and $Lu_2Fe_{13.6}Si_{3.4}$ in order to determine influence of the U sublattice on the spontaneous magnetostriction.

Single crystals of $U_2Fe_{13.6}Si_{3.4}$ and $Lu_2Fe_{13.6}Si_{3.4}$ were grown by the Czochralski method in a tri-arc furnace. A piece from each crystal was ground for X-ray powder-diffraction measurements, which were carried out on a Siemens D-500 diffractometer equipped with a helium-flow cryostat using filtered Co radiation. The diffraction patterns were taken in the temperature range 5-600 K.

The experimental temperature dependencies of the lattice parameters in the paramagnetic range were extrapolated to the magnetically ordered range using a value for the Debye temperature of 450 K, as determined from acoustic measurements on R_2Fe_{17} [2]. The relative differences between the experimental and the extrapolated values of the lattice parameters are the spontaneous linear magnetostrictive strains λ_a and λ_c . The spontaneous volume magnetostriction ω_s is equal to $2\lambda_a + \lambda_c$. The thermal expansion of $U_2Fe_{13.6}Si_{3.4}$ and $Lu_2Fe_{13.6}Si_{3.4}$ is qualitatively similar. In both compounds, it is isotropic, the c/a ratio is nearly constant at low and room temperature. The spontaneous magnetostriction is also rather isotropic, λ_c exceeds λ_a only by 15% (Lu) or 30% (U), in difference with binary R_2Fe_{17} where the uniaxial component λ_c is very large, exceeds λ_a by factor of 4 and leads to a pronounced Invar effect along the c-axis [1,2]. In $U_2Fe_{13.6}Si_{3.4}$ and $Lu_2Fe_{13.6}Si_{3.4}$, λ_c is not high enough to overcome the phonon thermal-expansion contribution and to provide Invar-like behavior. This is also result of the relatively high Curie temperature T_C (larger by ~150-200 K than in binary R_2Fe_{17}).

Since both compounds have the easy-plane magnetic anisotropy, they should undergo an orthorhombic magnetostrictive distortion at the magnetic ordering. However, no distortion was observed which means that the anisotropic magnetostriction responsible for the distortion is below the experimental sensitivity $2 \cdot 10^{-4}$, e.g. at least by one order of magnitude smaller than the exchange magnetostriction seen in the volume effect ~1%.

The observed similarity of spontaneous magnetostriction in $U_2Fe_{13.6}Si_{3.4}$ and $Lu_2Fe_{13.6}Si_{3.4}$ points to a dominant role of the Fe sublattice in formation of this property. Nevertheless, a certain quantitative difference allows us to distinguish the contributions originated from the Fe-Fe and U-Fe exchange interactions. The volume effect in the ground state of $U_2Fe_{13.6}Si_{3.4}$ is larger than in the Lu analogue, however, it becomes the same at elevated temperatures. In $Lu_2Fe_{13.6}Si_{3.4}$, it follows satis-

factorily the square of the magnetic moment in a wide temperature range whereas in $U_2Fe_{13.6}Si_{3.4}$ it decreases evidently faster. Both features can be attributed to the contribution to the total volume effect ω_s from the U-Fe exchange interaction ω_{U-Fe} which is expected to decrease faster with increasing temperature than the main contribution from the Fe-Fe exchange interaction ω_{Fe-Fe} . Direct subtraction of ω_{Fe-Fe} from ω_s gives the lowest limit of $\omega_{U-Fe} = 2 \cdot 10^{-3}$ in the ground state. However, this means $\omega_{U-Fe} = 0$ and, respectively, the non-magnetic state of U above 200 K whereas it is known from the measurements of magnetic anisotropy [4] and from the ^{57}Fe Mössbauer spectroscopy [5] that U is still magnetic at 300 K. The average Fe magnetic moment μ_{Fe} in the ground state of $Lu_2Fe_{13.6}Si_{3.4}$ and $U_2Fe_{13.6}Si_{3.4}$ is estimated to be $1.69 \mu_B$ and $1.33 \mu_B$, respectively [5]. Assuming w_{Fe-Fe} to be proportional to the square of the Fe magnetic moment, we can estimate ω_{Fe-Fe} in $U_2Fe_{13.6}Si_{3.4}$ as $6 \cdot 10^{-3}$. Therefore, $\omega_{U-Fe} = \omega_s - \omega_{Fe-Fe} = 5 \cdot 10^{-3}$ is surprisingly high, almost the same as ω_{Fe-Fe} .

Tuning the magneto-electric effect of multiferroic composites via crystallographic texture.

M. Vopsaroiu¹, M. Stewart¹, M. Cain¹, G. Srinivasan²

1. Functional Materials, National Physical Laboratory, Teddington, United Kingdom; 2. Physics Department, Oakland University, Rochester, MI

Multiferroics (MF) are an interesting class of materials, which can respond simultaneously to multiple stimuli (magnetic, electric, mechanical) by changing their physical properties. A very important feature of MF materials is the occurrence of the magneto-electric (ME) effect, which is defined as the coupling between the electric and magnetic fields. Normally this is defined by the linear ME coupling coefficient, α which can be induced either electrically ($\alpha_E = dM/dE$) or magnetically ($\alpha_H = dP/dH = \epsilon_0 \epsilon_r \times dE/dH$). The effective ME coupling coefficient is essential for the functionality of the devices / sensors based on MF and its value can be altered by a number of factors such as material properties, microstructure, measurement geometry, temperature or mechanical stress conditions. In this paper we examine how the ME coupling is correlated to the intrinsic crystallographic texture of the magnetic phase of NiFeO / PbZrTiO bi-layer laminated MF (acronym NFO/PZT). Three different laminated bi-layers with a disk shape of about 8 mm diameter have been fabricated (figure 1). The samples have identical PZT layers, while the polycrystalline NFO layers have been fabricated with different microstructures. The code names of the samples are: NFO_111, NFO_110 and NFO_100, where the numbers denote the dominant crystallographic plane of the NFO of each sample. The PZT and NFO layers are 500 nm thick. They are glued together without perfect overlapping to allow the application of measurement wires to the PZT electrodes (figure 1). We measured the magnetically induced ME effect, which simply involves the determination of the induced open circuit voltage on the PZT electrodes under applied magnetic fields. This requires a combination of two collinearly applied magnetic fields: a DC bias field and a small amplitude AC magnetic field. The measurement geometry was transverse, i.e. electric polarization transverse to the applied magnetic fields (figure 1). Figure 2 shows the induced voltage versus DC bias field measured at constant amplitude and frequency of the applied AC magnetic field. The graphs show a typical non-linear behaviour for the laminated multiferroics with a peak in the induced voltage at the optimum DC bias field. The data indicates a clear difference between the position of the maximum ME effect of each sample. In order to maximize the linear ME effect, the samples must be biased at their optimum DC bias field. This is a critical parameter for the operation of multiferroic sensors and devices, as the requirement of high DC bias fields can limit their applicability. Figure 2 indicates that the bias field value can be easily tuned via the crystallographic properties of the magnetic phase. The NFO_111/PZT has an optimum DC bias of 465 Oe. We have achieved a reduction by almost a factor 3 for the NFO_110/PZT sample, which has a maximum ME effect at 160 Oe DC bias. This is due to the variation in the magnetostriction properties of different crystallographic phases of NFO. Using the optimum DC bias conditions, the linear ME effect can be measured by varying the amplitude of the applied AC field. Figure 3 shows the induced open circuit voltage as a function of the amplitude of the AC field at constant optimum bias. From the slope of the linear curves the magneto-electric coefficient can be derived as: $\alpha = (1/t) \times (dV/dH)$, where t is the thickness of the PZT layer. The values obtained for α are in units of (mV/Oe cm): 116 for NFO_111, 62 for NFO_110 and 19 for NFO_100.

Multiferroic properties of spin-spray deposited Ni_{0.23}Co_{0.13}Fe_{2.64}O₄ ferrite film on PZT substrate.

M. Liu, O. Obi, J. Lou, S. Stoute, Y. Chen, V. G. Harris, N. X. Sun
Electrical and Computer engineering, Northeastern University, Boston, MA

Multiferroic materials have drawn an increasing amount of interests due to their capability of efficient energy transfer between electric energy and magnetic energy and their potential applications in many multifunctional devices¹. Such materials can display the magnetoelectric (ME) effect, a dielectric polarization variation as a response to an applied magnetic field, or an induced magnetization by an external electric field. Several synthesis methods have been developed for multiferroic composite materials, such as, pulsed laser deposition, physical vapor deposition, and sol-gel process.

Spin-spray process, which was invented in 1983, is developed to plate crystalline spinel ferrite film directly from aqueous solution². Compared to conventional ferrite film preparation methods such as sputtering, MBE, PLD, etc., which require high temperatures (>600°C), spin-spray technique allows formation of crystalline ferrite film at low temperature of 60-100°C due to oxidation reaction and hydrolytic dissociation.

In this work, the synthesis of multiferroic materials prepared by spin-spraying Ni_{0.23}Co_{0.13}Fe_{2.64}O₄ (NCFO) ferrite on PZT substrate was reported. As shown in figure 1, uniform single phase ferrite NCFO film was coated on PZT substrate with excellent adhesion. Our adhesion tests results showed that these spin spray deposited ferrite films show strong adhesion which is crucial for achieving strong magnetoelectric coupling. The structure characterization were performed by XRD and AFM (Figure 2) which showed well defined single NCFO ferrite phase as well as PZT ferroelectric phase patterns without preferred orientation. The NCFO ferrite grain sizes are in the range of 150~350nm. Magnetic properties multiferroic materials were characterized by VSM as shown in Figure 3, which displayed a well defined full film hysteresis loop behaviors with a saturation magnetization of ~5000 G, an in-plane coercivity of 190Oe and out-of-plane coercivity of 260Oe. Magnetoelectric coupling was demonstrated by observing the shifts of the M-H curve by applying electric field on PZT substrate. As shown in Fig. 3(b), an applied E-field of 1 MV/m across the PZT substrate lead to an upward shift of the M-H loop at low applied magnetic fields.

Stress and magneto-elastic properties control of amorphous Fe80B20 thin films during triode sputtering deposition.

I. Fernández-Martínez, J. L. Costa-Krämer, F. Briones

Inst. Microelectronica Madrid, CNM-CSIC, Tres Cantos, Spain

In-situ stress measurements during sputtering of amorphous Fe80B20 films are used to control their stress and magneto-elastic properties. Substrate curvature induced by the deposited film is measured optically during growth and quantitatively related to deposition induced accumulated stress. The resulting magnetic properties are correlated with the measured stress for a wide range of sputtering pressures ($2\text{--}25 \times 10^{-3}$ mbar). A significant tensile stress develops at the film-substrate interface during the early growth stages (initial 2-3 nm). At a critical thickness a transition is observed from tensile to compressive stress that is associated with amorphous islands coalescence. An increasing compressive stress follows which is related to the local distortion induced by ion peening effect. Monte Carlo simulations of the sputtering process describe quantitatively the experimental results as a function of Ar pressure and target bias voltage. A fine control of stresses, together with tunable anisotropy, high magnetostriction, excellent adhesion, and stability makes these films ideal for magnetostrictive-based NEMS actuators [1].

The substrate curvature evolution during deposition of Fe80B20 films under a range of Ar sputtering gas pressures for a constant target potential of -2 kV, is shown on Fig 1. Three regimes are clearly distinguished: I, II & III. The first one, I, a nearly instantaneous rise of an apparently compressive stress when target potential is switched on, is reversible and disappears when target potential is switched off. In the case of amorphous metallic films, surface diffusion is limited and no large adatom population is expected. The difference between the effective kinetic surface temperature and the bulk would give rise to a substrate bending equivalent to a surface stress of compressive character and sign. The amplitude of this effect, proportional to the instantaneous deposited power on the substrate, depends indeed strongly on the target bias potential, deposition rate and Ar gas pressure, but disappearing reversibly when growth is interrupted, it does not contribute to the total accumulated stress.

The stress accumulated during the initial few nanometers growth (regime II) is tensile, corresponding to the interface stress increase that accompanies the nucleation of islands strongly interacting with the glass substrate surface. This interface stress seems to be the dominant source of the large component of tensile stress measured, as it depends on the interaction between the growing film and the substrate. Confirming the above arguments, it has also been found experimentally that the stress sign and magnitude in regime II depends strongly on the type of substrate, changing as well if a buffer layer is present.

A critical thickness can be defined between this initial tensile (II) and the following compressive regime (III). This would be the thickness value at which the film becomes continuous and coalescence or building of a columnar structure takes over.

All the amorphous Fe20B20 films grown on the glass cantilevers exhibit a uniaxial anisotropy. The films were grown under a small external applied magnetic field that is used to confine the plasma and at 45 degrees incidence with respect to the cathode plane. For lower Ar pressures the induced magnetic uniaxial anisotropy points in the direction of the plasma confinement field. This uniaxial anisotropy results from local atomic-pair ordering in the amorphous matrix [2]. For Ar pressures above 8×10^{-3} mbar the stress induced anisotropy overcomes the effect of the field induced anisotropy. The total anisotropy direction starts deviating from the plasma confining field direction and turns perpendicular at about 14×10^{-3} mbar as shown in Fig. 2 at -2 kV target potential.

Poisson ratio of amorphous nanoporous alumina as determined from thermal expansion of Ni nanowires at low temperatures.

C. A. Ramos¹, E. Vassallo Brigneti¹, S. García², M. Vázquez²

We measured the thermal expansion (TE) of Ni nanowires (NW) embedded in amorphous nanoporous alumina (NPA). We observe an anomalous NW TE characterized by a TE coefficient $\alpha = -1.8 \text{ } 10^{-5}/\text{K}$ as the sample (NW + NPA + Al) is cooled down. From this anomalous NW TE we conclude the NPA is characterized by a Poisson coefficient $\nu = 0.42$ indicating a significant departure from polycrystalline alumina (PCA). This result is consistent with the observed changes in the uniaxial anisotropy (UA): from easy axis at room temperature (T) towards easy plane at low T.

Recently there has been a growing interest in the study of magnetic NW grown on artificial templates [1]. While polycarbonate templates have been widely used to grow nanowires, amorphous NPA templates have the advantage of having a regular array with a very uniform alignment of the porous and a quite uniform pore-size distribution [2].

Our samples were grown by a two-step controlled anodization process using sulfuric (S1) and oxalic (S2) acid which yields a pore diameter typically of 20 (S1) and 35nm (S2) with interpore separation of 65nm (S1) and 105nm (S2). These templates were used to electro-deposit Ni nanowires (NW) in the NPA holes and thus create an ordered array of NW which can be used to study the magnetic anisotropy as a function of the topology [3, 4]

Previous studies on magnetic NW as a function of T [5-7] have shown an anomalous change of the magnetic anisotropy from easy axis at room T to a significantly different anisotropy at low T. These effects have been associated with magnetoelastic effects, though not always have they been measured by x-rays.

Also, recently there have been reports on the hardness of the NPA differing from that of polycrystalline alumina (PCA) [7] thus pointing to the fact that annealing is required for hardening these templates.

In this work we present thermal expansion measurements on S1 and S2 samples. The X-ray pattern shows the NW grow textured with the (110) plane along the wire direction. Thermal expansion measurements were performed using a Philips PW1700 apparatus with a low-temperature set up going down to 100K. The (311) reflection of Al was used as an internal reference for characterizing the room T scan which showed the Ni NW present an undistorted lattice parameter at this T.

When cooling down the Al peak follow very closely the expected thermal contraction of a bulk specimen [8]. The NW (220) peaks, however, expand as the sample is cooled. As the NW fill 10% of the NPA film [3] we may expect the NW to serve as a nanometric strain sensor, thus revealing the anomalous thermal expansion of the amorphous NPA as the sample is cooled down. As the NW can be considered a “perturbation” to the NPA we can derive some conclusion from the observed thermal expansion. If a uniform thin film is subject to strains in the plane the thermal expansion along the perpendicular direction is given by [9]

$$e_{zz} = -\nu (e_{xx} + e_{yy}) / (1 - \nu) \quad (1)$$

and $e_{xx} = e_{yy}$. This in-plane strain should be originated in the differential thermal expansion between the Al substrate (1 mm) and the NPA (2-3 micons). The average thermal expansion coefficient of Al between 300K and 100K is about $18 \text{ } 10^{-6}/\text{K}$ and that of PCA is tabulated as $6 \text{ } 10^{-6}/\text{K}$

at room T. This leads to $e_{xx} = 2.4 \text{ } 10^{-3}$ for the 300K-100K difference. The average e_{zz} measured with in the NW is $3.6 \text{ } 10^{-3}$ ($3.4 \text{ } 10^{-3}$ for S1 and $3.8 \text{ } 10^{-3}$ for S2) thus leading to an estimate of $\nu(\text{NPA}) = 0.42$. A lower limit would be given by a zero thermal expansion of the NPA, thus leading to a larger strain and to $\nu(\text{NPA}) = 0.33$. On the other extreme we may argue that the Ni NW only represents a lower limit to the e_{zz} of the NPA, however, this would lead to an even larger value of $\nu(\text{NPA})$, which should be limited by $\nu = 0.5$. This shows the NPA differs significantly from the $\nu = 0.231$ value of the PCA, and points to the fact that untreated NPA is more easily deformable than PCA.

Two contributions to the stresses acting on the NW are present: the one observed by measuring e_{zz} , leading to $\sigma_{zz} = E e_{zz} = (200\text{GPa}) 3.6 \text{ } 10^{-3} = 0.72 \text{ GPa}$ and the in-plane one coming from the thermal expansion difference between the NPA and the Ni. As the NPA should “follow” the Al as long as is easily deformable we can estimate the in-plane strain on the Ni is directly caused by the difference between Al and Ni. This leads to $\sigma_{xx} = E e_{xx} = E (\alpha(\text{Al}) - \alpha(\text{Ni})) \Delta T = E (-1.8 \text{ } 10^{-5} + 1.08 \text{ } 10^{-6}) 200 = 0.288\text{GPa}$ and similarly for σ_{yy} . The three stresses contribute in the same direction to the magnetoelastic energy through the relation:

$$K = \lambda_{110} \sigma_{110} \quad (2)$$

where K is the magnetoelastic energy, σ is obtained from the addition of the three independent contributions and taking $\lambda_{110} = -30 \text{ } 10^{-6} \text{ [5]}$ we obtain a UA contribution given by $\Delta H_a = 1600\text{Oe}$, very similar to the observed value [10].

Customizing the magnetic properties of magnetostrictive amorphous $(\text{Fe}_{80}\text{Co}_{20})_{80}\text{B}_{20}$ multilayers with orthogonal anisotropies by using different buffer layers to control the induced-deposition stress.

M. González-Guerrero¹, J. Prieto², P. Sánchez¹, C. Aroca¹

1. Física Aplicada, ETSI Telecomunicación UPM, Madrid, Spain; 2. ISOM, Universidad Politécnica de Madrid, Madrid, Spain

The modulation of magnetic anisotropy in the thickness, by means of the deposition of multilayers with orthogonal anisotropies, has been previously proved to reduce the coercivity of magnetostrictive amorphous $(\text{Fe}_{80}\text{Co}_{20})_{80}\text{B}_{20}$ thin films, allowing a strict control of the magnetic anisotropy, the total magnetostriction not being affected [1]. The mechanical energy accumulated in every layer was thought to be the origin of that striking behavior. Here, we experimentally confirm that initial assumption, showing how buffer layers with different thermo-mechanical properties govern the total magneto-elastic energy of FeCoB multilayers, and provide the needed key to customize their magnetic properties.

FeCoB films, composed of five bilayers 26-9 nm thick with orthogonal anisotropies, were deposited on SiO_2 substrates buffered with different materials: Al, Cr, Cu and Mo. All the buffer layers are deposited with 50 W power and 5 mTorr Ar pressure, with a thickness around 100 μm . In Fig. 1(a) a schematic picture of the samples is shown.

The hysteresis loops of the samples show just one anisotropy axis, as in those shown in Fig 1(b), belonging to the sample with Mo buffer (this buffer layer was deposited with the sample continuously rotating during deposition).

Figure 2 shows the coercive (along the hard axis) and the anisotropy field of all the studied samples. Though all their hysteresis loops have the same shape, the magnetic anisotropy and the coercive field are quite different depending on the buffer material and the way it is deposited.

X ray diffractograms not shown in this digest suggest that the differences between depositing the buffer rotating or not rotating the sample lie in the promotion of nanocrystalline texture, that is transferred to a certain extent, to the FeCoB multilayers[2].

The behavior of the coercive field of the samples with different buffer layers points toward the influence of the thermal and mechanical properties of the buffer in the behavior of the magnetic layer, as expected, due to the well known influence of the substrate properties on the deposition conditions[3] and to the essential effect of the stress on the properties of FeCoB layers[4]. Buffer materials that bring together a high Young modulus, Y, high thermal conductivity, σ_t , and low coefficient of thermal expansion, CTE, do not allow the dissipation of the stress induced during deposition, producing a single domain-like behavior, with coercive field values higher along the easy axis and lower along the hard one, as well as smaller anisotropies.

In table I, the thermo-mechanical parameters of the buffer materials, and the coercive and anisotropy field values of the samples are displayed, showing the mentioned correlations.

Material	Y (GPa)	σ_t (W/K \times m)	CTE $\times 10^6$ (K $^{-1}$)	Y $\times\sigma_t$ /CTE (GPa \times K/m)	H _C HARD (Oe)	H _C EASY (Oe)	H _K (Oe)
Al	70	235	23.1	712	4.6	2.5	33

Low Temperature Magnetoelastic Effects In Template Grown Ferromagnetic Nanowires.

J. De La Torre Medina, M. Darques, L. Piraux

Université Catholique de Louvain, Louvain-la-Neuve, Belgium

Arrays of electrodeposited Ni, permalloy Py (Ni80Fe20) and Co nanowires (NW) into polycarbonate (PC) membranes are studied by ferromagnetic resonance (FMR). Magnetoelastic (ME) effects are quantified by measuring transmission spectra by applying a DC field in the direction of the wires. In Ni NW, ME effects are evidenced at low temperature and are attributed to the thermal expansion coefficients mismatch between the NW and the PC membrane[1,2]. Figure 1, shows transmission spectra recorded at 33 GHz and at temperatures from 4.3 K to 300 K for Ni and Py NW arrays with pores diameter $d=50$ nm and membrane porosity $P=2\%$. For the Ni sample, the resonance field shifts by a large value, indicating the presence of a strong ME effect as T decreases from 300 K down to 4.3 K. However, the resonance field shift δH_r measured in the Ni sample is not only related to ME effects because the magnetocrystalline (MC) anisotropy is no longer negligible at low T [3]. This is, since electrodeposited Ni NW arrays are textured in the [110] direction (parallel to the wires)[2], variations of the MC anisotropy have to be considered together with ME effects at low T . Conversely, no ME effects are observed in Py NW into in the same membranes. The small δH_r for the Py sample is related to variations of the saturation magnetization M_s with T . In the case of Co NW, the total anisotropy at 300 K results from the competition between magnetostatic (MS) and MC contributions. Control of the structure of Co by means of the electrolyte pH leads to three different regimes. At $pH \sim 2$, the wires are polycrystalline, whereas at higher pH values the anisotropy is affected by the MC anisotropy which depends on the orientation of the hcp c -axis with respect to the wires[4]. At $pH \sim 4$ the c -axis is perpendicular to the wires and the MC contribution reduces the MS anisotropy and at $pH \sim 6$ the c -axis is parallel to the wires and the MC anisotropy adds to the MS one. At low temperature, ME effects appear in a similar way as in the case of Ni NW. Besides this, the non negligible hcp Co magnetostriction λ depends on the relative orientation between the magnetization M , the stress σ and the hcp c -axis[5]. In our NW λ is expected to be positive or negative if the c -axis is parallel or perpendicular to the wires. Further, the MC anisotropy of Co increases by a significant amount as the temperature is lowered[6], and a coupled MC-ME effect must be considered. In the FMR measurements, the DC field is parallel to σ and the c -axis can be perpendicular or parallel to the wires. In this configuration, from ref[5] we may expect that λ is negative or positive if the c -axis is perpendicular or parallel to wires. In addition, Co NW having like-fcc grains ($pH \sim 2$) are expected to present both small variations of the MC anisotropy and negligible ME effects at low temperature because of the small polycrystalline grains and the MC constant at 300 K is of one order of magnitude smaller than for hcp Co. Figure 2 shows transmission spectra measured at 38 GHz and at 200 K (empty symbols) and at 300 K (filled symbols) for three samples, where the first one has like-fcc grains ($pH \sim 2$), and the second ($pH \sim 4$) and third ($pH \sim 6$) ones have hcp grains. It is observed that the spectra of the second and third samples, shift toward higher and lower fields respectively (represented by the arrow in fig. 2). The difference in amplitude and direction of δH_r shows the existence of two different mechanisms on the competition of the anisotropies involved at low temperature. Moreover, the spectra for the $pH \sim 2$ sample shifts by a very small amount, which is of the order of the variation of the M_s with T . Finally, a more detailed analysis is in current progress in order to decouple the different anisotropy contributions at low T .

Magnetostriction of Fe-Ti alloys.

C. Bormio-Nunes¹, A. B. Belarmino¹, C. T. Santos¹, V. C. Ugeda¹, L. Ghivelder², C. A. Baldan¹
 1. Escola de Engenharia de Materiais, Universidade de Sao Paulo, Lorena, Brazil; 2. Instituto de Fisica, UFRJ, Rio de Janeiro, Brazil

Hall [1] showed that small additions of transition metals (V, Cr, Mo) increase the λ_{100} magnetostriction of pure iron. Besides, very high magnetostriction values were found in FeGa alloys recently [2], about 90 ppm in polycrystalline materials [3] and $\lambda_{100} = 400$ ppm in single crystals [2]. Similar behavior is expected by adding Ti to Fe, because Ti has an atomic radius larger than Ga and could cause a significant dilatation on the Fe A2 structure. The A2 structure is the one that gives the highest magnetostriction (Fe-Ga) and is also present in the FeTi alloys (Ti~10at.% at 1290°C). Below 1290 °C the α and the C14 phase coexist.

The $\text{Fe}_{100-x}\text{Ti}_x$ alloys ($x = 10, 15, 20$) were produced by arc melting. Samples were submitted to heat treatments in the $1000 \leq T \leq 1250$ °C interval (5 h).

The microstructure characterization was done by scanning electron microscopy/backscattered electrons (SEM/BSE), energy dispersive spectroscopy (EDS) and X-ray powder diffraction. Magnetostriction measurements were made with a miniature capacitance dilatometer [4] and were carried out at temperatures close to 238 K for fields up to 1.5 T. The dc magnetization was measured using a PPMS-QD model 6000 for temperatures of 4.2, 77 and 300 K.

Tab.1 shows the samples characteristics. Tab.2 shows samples A-C saturation polarization (J_s) results. Sample A has the maximum J_s and sample B presents a higher J_s than sample C since A and B samples are richer in Fe. Sample C has higher Fe content in the α -phase than sample B, even though has the lowest J_s value. The C14 phase do not contribute to J_s because C14 is ferromagnetic only below 180 K [5] and the decrease of J_s due C14 is clearer at 300 K (B and C samples). In Fig. 1, the microstructures of the samples show that C14 is present in samples B and C, but sample A is a single α phase sample. The matrix of samples B and C are C14 and α phases, respectively. Peaks of C14 phase are present in powder diffraction patterns of samples B and C (not shown). Fig. 2 shows longitudinal (λ_{long}) and transversal (λ_{trans}) magnetostriction at 238 K, plus $\omega = \lambda_{\text{long}} + 2\lambda_{\text{trans}}$ (volume magnetostriction) and $\lambda_s = \lambda_{\text{long}} - \lambda_{\text{trans}}$ (saturation magnetostriction). The highest ω value was obtained for sample B decreasing for samples C and A respectively. This behavior is due to that the matrix in sample B is the C14 phase while in sample C is the α -phase.

Concluding, $\text{Fe}_{100-x}\text{Ti}_x$ Fe rich alloys contract in the presence of field and as the Ti content increases the contraction decreases (in modulus) due the presence of C14 phase that do not contribute to the magnetostriction. The maximum λ_s value was -12 ppm (sample A), and this is very small compared to 90 ppm of Fe-Ga. Although Ti atom is larger than Ga, it causes a negative magnetostriction, the opposite effect of the Ga addition. Therefore, the lattice dilatation is not the source of the high magnetostriction in Fe-Ga alloys.

Picosecond magnetization dynamics of single-crystal Fe_3O_4 thin films.

C. Bunce¹, J. Wu¹, R. Chantrell¹, Y. Lu², Y. Xu²

The time-resolved magnetization dynamics of epitaxial Fe_3O_4 ultra-thin films grown on a GaAs(100) substrate were investigated using a field pumped TRMOKE (time-resolved magneto-optical Kerr effect) experiment. The dynamic response of the magnetisation in the film to excitation by a 100 mT field pulse with a 90-10% rise time of 350 ps was recorded and compared to a single spin Landau-Lifshitz-Gilbert (LLG) simulation of the system. The comparison allowed the LLG damping factor and anisotropy constants of the system to be determined.

The 6 nm Fe_3O_4 thin film studied was created by oxidising an Fe film already deposited onto the GaAs substrate, the epitaxy of the film was checked using RHEED and the chemical composition was confirmed with XPS and XMCD as described by Lu et al [1]. The film has also been studied by Zhai et al [2] using FMR to determine its anisotropy which is a mix of a cubic anisotropy, an in-plane uniaxial term and an out-of-plane term where the relative contributions are functions of thickness.

The TRMOKE is based around a $\frac{1}{2}$ turn 600 μm diameter micro-coil which generates an out-of-plane pulse field at the sample when a 7 kV electronic pulse generator discharges into it. An in-plane bias field larger than the coercivity is applied so the sample is initially in a single domain state as a result of which the pulsed field should induce a largely coherent damped precessional motion of the magnetisation vector. A 400 nm pulsed laser probe focussed onto the centre of the coil, measured the change in the out-of-plane component of the magnetisation vector. A stroboscopic arrangement between the pulsed laser and the electronic pulse generator allows time resolved measurements to be made with 25 ps resolution.

The equipment measures the variation of the out-of-plane component of magnetisation in the time domain as shown in figure 1. The LLB simulations take the constants which characterise the anisotropy system, the M_s and the damping factor as input parameters. The anisotropy system M_s can be determined for the sample by fitting the measurements in the frequency domain. The process is similar in principle to determining the parameters from FMR measurements, in this case the precessional frequency is determined from the measurements using an FFT and is fitted by FFT's of the LLG simulations. Figure 2 shows the frequency domain fitting for sample which determined the best fit anisotropy as a cubic term of -8×10^4 , an in-plane uni-axial term of less than 1×10^4 and an out-of-plane uni-axial term of -1.6×10^6 ergs/cc. The cubic and out-of-plane terms compare well with those determined by Zhai et al [2] but the in-plane anisotropy appears to be absent from these measurements, this is assumed to be due to inter-sample variation.

Once the anisotropy parameters are known the measurements can be fitted more easily in the time-domain to find the best fit damping factor for each applied field. A selection of typical fits is shown in figure 1.

The damping factor does not show a significant systematic variation with applied field strength for either of two orthogonal in-plane directions. The value of the damping factor obtained from numerical LLG simulations is about 0.1, which is one order of magnitude higher than metallic thin films such as Fe, Co, Ni. While the mechanism of the large damping in Fe_3O_4 needs further investigation, our results suggest that Fe_3O_4 could operate at a significant higher working frequency than its metallic counterparts.

Deconvolution of the ferromagnetic resonance absorption through the Verwey transition of magnetite.

A ferromagnetic resonance (FMR) study was carried out on sintered polycrystalline samples of magnetite (Fe₃O₄), at a constant frequency of 9.4 GHz (X-Band) and dc magnetic fields (H_{dc}) in the 0–8000 G range. The temperature measurements were recorded in the 77–300 K range and was controlled by flowing cold N₂ gas through a double walled quartz tube, placed at the center of the microwave cavity. An evolution of FMR lineshape was observed as a function of temperature, and which is related with the passage through the Verwey point (T_v~120 K) [1]. Deconvolution calculations were carried out on FMR spectra [2], and with it was possible to separate two contributions which can be associated with tetrahedral A and octahedral B sites of the crystal structure.

These contributions have different lineshapes: the one is a single broad symmetric Lorentzian line, in the entire temperature range, due to A-sublattice site, see Fig. 1; and the other one is of Dysonian-type (T>120 K), that is associated with B-sublattice site, as shown in Fig. 1. The Dysonian lineshape shows an asymmetric signal due to a conducting mechanism and it is described as a combination of absorption and dispersion components [3,4]. Above of 120 K, the Dysonian lineshape changed to Lorentzian lineshape in the B-sublattice site, due to a discontinuous drop in electrical conductivity upon cooling below T_v [1].

Additionally, the parameters FMR obtained of deconvolution fitting can be associated with change of the magnetic anisotropy, as a consequence of the charge localization below the Verwey transition; i.e. temperature dependence of the resonant field (H_{res}) and the peak-to-peak linewidth (DHLFA), can be related with an anisotropy decrease in the neighborhood of the Verwey transition, due to a charge rearrangement. These results suggest that the magnetization dynamics is influenced by the electronic nature of the metal-insulator transition mechanism and the structural transition at Verwey transition. Additionally, below the transition temperature, the anisotropy increases due to an additional contribution to magnetostriction that appears as a consequence of a distorted cubic phase [5].

Dynamic Magnetic Properties of NiFe₂O₄ Nanoparticles Embedded in SiO₂ Matrix.

S. Mitra¹, K. Mandal¹, E. Choi²

1. Materials Science, S. N. Bose National Centre for Basic Sciences, Kolkata, India; 2. National High Magnetic Field Laboratory, Tallahassee, FL

In recent years, ferrite nanoparticles have firmly been established as an important class of soft magnetic materials owing to its attractive magnetic properties at high frequencies, resistivity that is in the insulating range, and the high corrosion resistance [1]. Dynamic magnetic behaviors of sol-gel synthesized NiFe₂O₄-SiO₂ nanocomposite [2] system including temperature dependent relaxation phenomenon were examined and the results are reported in this article.

In X-ray diffraction (XRD) pattern (Fig.1) the peaks correspond to only the spinel phase of NiFe₂O₄ nanoparticles. The average crystallite size was determined from the peaks using Scherrer equation and it was found to be ~3.5 nm (sample SA), 5.6 nm (sample SB), 6.8 nm (sample SC) and 19 nm (sample SD). Particle sizes of the samples determined from transmission electron microscope (Fig.2) corresponds well with the particle sizes determined from XRD. The temperature dependence of the ac susceptibility measured in the frequency range of 10 Hz to 100 kHz shows a maximum in χ' which is interpreted as the blocking temperature T_B at that frequency (shown for representative samples SA in Fig.3). The position of the peak shifts towards higher temperatures as frequency increases. In absence of a magnetic field, at finite temperature, the ferromagnetic moments in a single domain particles fluctuate between their two energetically degenerate ground states on a time scale given by $\tau = \tau_0 \exp(KV/k_B T)$, where τ is the relaxation time and τ_0 is the inverse of attempt frequency estimated to be within 10^{-10} - 10^{-12} s for non-interacting single domain particles. At T_B , $\tau = \tau_{ex}$, the measurement time or the experimental time window of the instrument. For $T > T_B$, The particles rapidly achieve thermal equilibrium during the measurement time as $\tau < \tau_{ex}$ and the system shows superparamagnetism. On the other hand, at $T < T_B$, the particles are said to be blocked, i.e. their magnetic moments remain at a fixed direction during a single measurement as $\tau > \tau_{ex}$. Hence at $\tau = \tau_{ex}$, the ac susceptibility vs temperature data shows a peak. From Arrhenius law we get, $\ln \tau = \ln \tau_0 + KV/k_B T$. It indicates linear dependence of $\ln \tau_{ex}$ on $1/T_B$ which was observed experimentally also (top right insets of Fig.3).

For magnetic relaxation study, samples are field cooled in presence of a field of 7T at different temperatures from 5K to 50K. After the removal of the field, magnetization evolves with time towards a demagnetized state. The M versus $\ln(t)$ curves (Fig.4) for representative samples SA measured at different temperatures shows a deviation from the linear behavior at the initial stage of measurement time. Hence a scaling hypothesis has been employed to analyse the experimental data.

Analyzing the permeability and permittivity dispersion spectra of $(\text{Ni}_{0.4}\text{Zn}_{0.59}\text{Co}_{0.01})\text{Fe}_{1.98}\text{O}_4$ spinel ferrites with Fe deficiency.

M. Han, L. Deng

State Key Laboratory of Electronic Thin Films and Integrated Devices, University of Electronic Science and Technology of China, Chengdu, China

Spinel ferrites (MeFe_2O_4 , Me = Ni, Co, Zn, Cu, Mg etc) are one of frequently used magnetic materials for radio frequency (RF) applications due to their high electrical resistivity, high permeability values and chemical stability, such as RF inductors[1], RF electromagnetic wave absorbers[2], RF noise suppressors[3], etc. For high frequency applications, the permeability dispersion behaviors are widely believed governed by the Snoek's law [4]. In order to further increase the resistivity of spinel ferrite, ferrites with Fe deficiency in compositions are often prepared so as to inhibit the electrons hopping between Fe^{2+} and Fe^{3+} in the octahedral sites of unit cells. In this paper, we have prepared the $(\text{Ni}_{0.4}\text{Zn}_{0.59}\text{Co}_{0.01})\text{Fe}_{1.98}\text{O}_4$ ferrites with Fe deficiency using a double sintering route. The starting oxides were ball milled for 1.5 h, then the milled powders were sintered at 980°C for 2 h. The pre-sintered powder was then ball milled again for 3 h. The final sintering was carried out at 1230°C for 2 h. The permeability and permittivity dispersion spectra were taken on HP4291B Impedance Analyzer within the frequency of 1MHz – 1 GHz. XRD investigation shows the final sintered sample having a typical spinel-like cubic structure.

It is widely accepted that there are two magnetizing mechanisms contributing to the permeability dispersion behaviors: domain wall movement (DW) and spin rotation [5]. Unfortunately, these two contributions are often mixed together in an obtained dispersion spectrum, which make analyzing their respective dispersion behaviors difficult. In this paper, we report an approach to separate the dispersion spectra into the DW components and spin rotation components. We find that good fittings with a nonlinear least square method can be obtained if we suppose the DW components with a resonance-type dispersion and the spin rotation components with a relaxation-type dispersion. In this way, the permeability dispersion behavior can be expressed as [6]:

$$\mu_r' = 1 + [\omega_d^2 \chi_{d0} (\omega_d^2 - \omega^2)] / [(\omega_d^2 - \omega^2)^2 + \omega^2 \beta^2] + \chi_{s0} \omega_s^2 [(\omega_s^2 - \omega^2) + \omega^2 \alpha^2] / \{[\omega_s^2 - \omega^2 (1 + \alpha^2)]^2 + 4\omega^2 \omega_s^2 \alpha^2\} \quad (1)$$

$$\mu_r'' = \omega_d^2 \chi_{d0} \omega \beta / [(\omega_d^2 - \omega^2)^2 + \omega^2 \beta^2] + \chi_{s0} \omega_s \omega \alpha [(\omega_s^2 - \omega^2) + \omega^2 (1 + \alpha^2)] / \{[\omega_s^2 - \omega^2 (1 + \alpha^2)]^2 + 4\omega^2 \omega_s^2 \alpha^2\} \quad (2)$$

where ω , χ_0 , α , β denote the angular frequency, static permeability, damping constant of spin rotation, damping constant of domain wall movement respectively. The subscript d and s denote the domain wall component and spin rotation component. The fitting results are shown in Fig. 1(a) and (b). As shown, the spin rotation makes major contributions to the permeability dispersion, and the spin rotation resonance occurs at higher frequency. The fitting results for ω_d , ω_s , χ_{d0} , χ_{s0} , α and β are 6.6×10^7 Hz, 7.7×10^{11} Hz, 108, 304, 4476 and 6.1×10^7 . The permittivity dispersion behavior is shown in Fig. 1(c). Rather than using the Debye's dielectric dispersion law with a single relaxation time, here we adopt the Cole-Cole dielectric dispersion law [7], which assumes that there should be a distribution of relaxation time for polarization processes due to the inhomogeneous microstructures of materials. According to Cole-Cole law, the real part of permittivity can be expressed as: $\epsilon' = \epsilon_{\infty} + (\epsilon_{rs} - \epsilon_{\infty}) \times [1 + (\omega\tau)^{1-\gamma} \sin(\pi\gamma/2)] / [1 + 2(\omega\tau)^{1-\gamma} \sin(\pi\gamma/2) + (\omega\tau)^{2(1-\gamma)}]$, where ϵ_{rs} , ϵ_{∞} , τ , γ ($0 \leq \gamma \leq 1$) are the static permittivity, permittivity when frequency is infinity, the relaxation time, and the distribution of relaxation time, the corresponding fitting results are 24.8, 15.5, 4.99×10^{-8} s, 0.253 respectively. The RF electromagnetic wave absorbing performance generally evaluated by the reflection loss (RL) in dB can be calculated based on the equation [8]:

$Z_{in} = Z_0 (\mu_r / \epsilon_r)^{1/2} \tanh \{j(2\pi ft/c)(\mu_r \epsilon_r)^{1/2}\}$ and $RL = 20 \log |(Z_{in} - Z_0) / (Z_{in} + Z_0)|$. Supposing that single layer of our prepared NiZnCo ferrites are attached on a metal plate, the thickness of ferrites is 4.3 mm. The electromagnetic wave absorption performance has been evaluated and is shown in Fig. 1(d). Clearly, it has a good EM wave absorption ($RL < -20$ dB) within the frequency band of 164 MHz – 390 MHz.

Introduction

Hexagonal strontium ferrite ($\text{SrFe}_{12}\text{O}_{19}$; SrM) has a magnetoplumbite structure with easy magnetocrystalline anisotropy along the c-axis of the hexagonal unit cell [1]. The large anisotropy field in these ferrites acts as a built-in magnetic field and permits the application of ferrimagnetic resonance (FMR) in millimeter wave devices [2]. Thus, microwave devices such as resonance isolators, circulators, tunable filters and oscillators can be operated in the millimeter-wave frequency range with moderate external magnetic bias fields. Substitution for Fe^{3+} and Ba^{2+} is an effective method for tailoring the magnetic properties of barium ferrite [3]. Although hexagonal ferrites have been extensively investigated in the past decades, the search for new cationic substitutions, especially the rare earth elements, has been a field of intense research and less reported to date. Rare-earth elements are very unique because of their characteristic structure of electronic shells; physical, mechanical and magnetic properties could be improved by doping these elements in the hexagonal crystal lattice of hexaferrites. In this work it was found that Sm-doped SrM single crystal possess 25 kOe of uniaxial anisotropy.

Experimental

Single crystals of samarium doped SrM (Sm-SrM), are grown in platinum crucible using a high temperature furnace. The primary mixture of $\text{SrCO}_3:\text{Fe}_2\text{O}_3:\text{Na}_2\text{CO}_3$ with small additions of Sm_2O_3 is used to grow single crystals. The reagents were blended and thoroughly ground together in a pestle for 1 hour. The finely blended powder is filled in a platinum crucible with approximately three-fourths of the volume. The platinum crucible is then placed in a top-lift enclosed furnace and fired at the temperature of 1450 °C for 12 hours to homogenize the melt. After completely homogenizing the melt for 12 hours, it is slowly cooled at the rate of 2.5 °C/hr to 1000 °C, and then cooled more rapidly in the furnace to room temperature. The, thus obtained, crystals were slowly separated by leaching in hot dilute nitric acid from the platinum crucibles.

Results and Discussion

The obtained crystals exhibited the typical hexagonal ferrite growth habit with a plate like geometry and are 4 to 6 mm in diameter and 2 to 3 mm in thickness, respectively. The hysteresis loop measured in the out-of-plane and in-plane directions of the Sm-SrM single crystal has a saturation magnetization of 69.8 emu/g and the uniaxial anisotropy of 25 kOe as shown in Fig. 1, respectively. It was observed that the magnetization is reduced to 69.8 emu/g from its bulk value of 74.3 emu/g but the anisotropy value is increased to 25 kOe from 18.7 kOe, respectively. The x-ray diffraction pattern confirmed that the structure is an extended single crystalline array of SrM with good c-axis crystallographic orientation. We also obtained the permeability spectra from the LLG equation assuming the damping constant (α) of 0.01 for single crystal BaM. The μ' in the out-of-plane direction was found to be 1.6 at 5 GHz and resonance frequency at 9.5 GHz respectively. Similarly, we obtained the μ' for the in-plane direction to be 1.1 at 60 GHz and thereafter the resonance occurs at 72 GHz as shown in Fig 2. To confirm the theoretical data with the experimental work we made circular disk samples by grinding the Sm-SrM single crystal coarse powder and

measured the permeability spectra by the standard co-axial cable method and the data obtained is in good agreement with calculated μ' value. The detail microwave properties will be presented.

Conclusions

Samarium doped M-type strontium ferrite single crystals have been successfully grown from melts using a flux system of $\text{SrCO}_3\text{-Na}_2\text{CO}_3$. The large anisotropy, 25 kOe, of the Sm-SrM hexaferrites leads to high FMR frequency operation at relatively low external field compared with the traditional isotropic ferrites. The saturation magnetization and anisotropy field are greatly affected by the doping concentration of the element. Permeability measurements performed on a circular disk sample is in good agreement with the calculated value.

Relaxation Effect of $\text{NiCr}_{1.8}\text{In}_{0.1}\text{Fe}_{0.1}\text{O}_4$ with Magnetic Anisotropy.

S. Park, D. Choi, C. Kim

Department of Physics, Kookmin University, Seoul, South Korea

Introduction : Many researchers have conducted researches on the chromite materials of spinel structure because of multiferroic effects.[1-3] The $\text{NiCr}_{1.9}\text{Fe}_{0.1}\text{O}_4$ is a ferrimagnet cubic normal spinel at room temperature, in which Ni^{2+} ions occupy the tetrahedral-sites and Cr^{3+} and Fe^{3+} ions occupy the octahedral-sites.[2] Also in the $\text{NiCr}_{1.9}\text{Fe}_{0.1}\text{O}_4$ is a cubic to tetragonal ($c/a < 1$) transition for the Fe concentration $x = 0.1$ around 230 K.[4]

In this paper, we have studied the impact on magnetic properties of the $\text{NiCr}_{1.9}\text{Fe}_{0.1}\text{O}_4$ as a function of the nonmagnetic Indium(In) ion doping by using an x-ray diffraction and magnetization curve measurements and Mössbauer spectroscopy.

Experiments : Polycrystalline samples of the $\text{NiCr}_{1.9-x}\text{In}_x\text{Fe}_{0.1}\text{O}_4$ ($x=0.0, 0.1$) were prepared by annealing 24 hour in atmosphere at 1200 °C with a solid state reaction. The x-ray diffraction patterns of the samples at room temperature were obtained with $\text{Cu-K}\alpha$ radiation by an x-ray diffractometer (X'PERT). The temperature dependent moment curve was measured by a vibrating sample magnetometer(VSM). The hyperfine magnetic relaxation effects on magnetic anisotropy of samples were evaluated to analysis with temperature dependence of Mössbauer spectra. Mössbauer spectra were measured that a Mössbauer spectrometer of electromechanical type was used in the constant-acceleration mode with a ^{57}Co single-line source in a rhodium(Rh) matrix.

Results : The crystalline structure of $\text{NiCr}_{1.8}\text{In}_{0.1}\text{Fe}_{0.1}\text{O}_4$ sample at room temperature was determined to be a cubic spinel of $Fd\bar{3}m$ with a lattice constant $a_0 = 8.342 \text{ \AA}$ at 295 K by Rietveld refinement, while the Bragg R_B and R_F factors were 3.17 and 2.47 % (Figure 1). Figure 2 shows the temperature dependence of the zero field cooled(ZFC) and field cooled(FC) magnetization curves for the $\text{NiCr}_{1.9-x}\text{In}_x\text{Fe}_{0.1}\text{O}_4$ ($x=0.0, 0.1$) under external field of 100 Oe. The magnetic Néel temperature(T_N) is determined by comparing the $d\sigma/dT$ curve of the ZFC measurements with the Mössbauer spectra analysis. As the $\text{NiCr}_{1.8}\text{In}_{0.1}\text{Fe}_{0.1}\text{O}_4$, the T_N is determined to be 130 K. Figure 3 shows Mössbauer spectra of $\text{NiCr}_{1.8}\text{In}_{0.1}\text{Fe}_{0.1}\text{O}_4$ at various temperature ranges. The Mössbauer spectra show two magnetic phases with the two different magnetic spin direction sites of the Cr^{3+} ion state.[1,5] Mössbauer absorption lines are sharp below 77 K and become broader with increasing temperature. The asymmetric intensities are different from those of the powder pattern 3:2:1. In order to explain the Mössbauer line broadening and 1,6 and 3,4 line-width difference due to the magnetic anisotropic relaxation effect, we use the Blume-Tjon[6] expression. It is noted that the relaxation effect increases rapidly as the temperature approaches the Néel temperature, 130 K.

Temperature dependence of magnetic losses in soft ferrites.

F. Fiorillo, C. Beatrice, L. Zhemchuzhna

Istituto Nazionale di Ricerca Metrologica INRIM, Torino, Italy

The magnetic properties of soft ferrites can be tailored to good extent by finely acting on their composition, so that anisotropy compensation may lead to the softest behavior upon the temperature range useful for specific applications [1]. Recognizing the effect of the magnetic anisotropy on the domain wall energy (i.e. coercivity) can provide partial explanation for the behavior of the quasi-static losses and their dependence on temperature. However, the contribution of the dynamic losses, predominant above a few hundred kHz, is poorly understood in the literature [2]. In this work we present significant results on the temperature dependence of loss and permeability in soft ferrites upon a wide range of frequencies (DC – 10 MHz). The frequency-temperature loss behavior of the material is explained and assessed through an approach founded on the statistical theory of magnetic losses [3], here applied to a physical system where eddy currents are not relevant. Fig. 1 shows representative energy loss vs. frequency behaviors at different temperatures in commercial Mn-Zn ferrite ring samples, designed to have good properties around 100 °C. Magnetic softening with increasing temperature applies at low and medium frequencies, while minor changes are observed beyond a few hundred kHz. We address these and other results by considering the separate contributions of domain wall (d.w.) displacements and moment rotations and clarifying the role of eddy currents. It is observed in all the investigated types of ferrites that strong decrease of ring thickness (e.g. from about 5 mm to 1 mm) does not lead to appreciable loss variation between DC and 10 MHz. Energy dissipation by the macroscopic eddy current paths can therefore be neglected. This result is substantiated by specific modelling of the electrical conduction versus frequency [4] and supplemented by the finding that the micro eddy currents circulating within the individual semiconducting ferrite grains are equally ineffective. The loss at any frequency, written as the sum of d.w. and rotational contributions $W = W_{dw} + W_{rot}$, can therefore be ascribed to spin damping mechanisms, usually accounted for through introduction of the phenomenological damping constant α_{LL} [5]. The d.w. term is $W_{dw} = W_h + W_{exc}$, the sum of hysteresis (DC) W_h and dynamic W_{exc} contributions. W_h is obtained by experiment, while W_{exc} can be formulated in terms of α_{LL} and the experimental parameter $k_{irr} = J_{irr}/J_p$, the fractional irreversible contribution to the peak polarization J_p . With known hysteresis loss value W_h , $W_{dw}(f)$ is calculated by reasonable guess of the α_{LL} value. The rotational term W_{rot} , largely prevailing in the MHz range, is associated with resonant absorption of energy. It is calculated by postulating a distribution function for the strength of the local effective anisotropy field H_k , the combination of the magnetocrystalline anisotropy fields and the internal demagnetizing fields. With small amplitude oscillations, the real χ'_{rot} and imaginary χ''_{rot} rotational susceptibility components are found as solutions of the Landau-Lifshitz-Gilbert equation for the damped precession of the magnetic moments. $W_{rot}(J_p, f)$ is calculated by taking the previous α_{LL} value and a Γ distribution for H_k , the average value $\langle H_k \rangle$ being consistent with the upper part of the magnetization curve, and no additional arbitrary parameters. It is concluded, from theory and experiment (see Figs. 1 and 2), that the temperature induced variations of the magnetocrystalline anisotropy energy are chiefly reflected in the d.w. loss contribution W_{dw} , that is, in the low-medium frequency range properties. The rotational term W_{rot} is little affected by the value of $\langle H_k \rangle$ and so is, consequently, the loss at high frequencies.

Introduction

The most advanced digital electronic devices are equipped with multilayered printed wiring boards (PWBs), which are commonly composed of an inner ground and a power source layer and outer signal wiring layers. Recently, electromagnetic noise radiation from such PWBs has become a serious problem. Most of the noise radiation is attributed to high frequency currents up to several GHz excited in the inner ground and/or power source layer. In order to suppress such high frequency noise currents, however, it is not effective to mount the existing noise suppression parts such as impedance components or composite-type noise suppression sheets [1] on the outer signal wiring layers. We previously revealed that the Ni-Zn ferrite film kept high imaginary permeability even in the GHz range. The ferrite film of 3 μm thickness that was plated directly on a micro-strip line exhibited transmission attenuation power ratio ($P_{\text{loss}}/P_{\text{in}}$) exceeding 0.5 in the range of 2-8 GHz [2]. This means that the ferrite film sufficiently attenuated the GHz noise current. In the present study, we measured electromagnetic noise radiation from four-layered PWBs that incorporated ferrite films of 3 μm thickness plated directly on the inner ground or power source layers.

Experiments

Ferrite films $\text{Ni}_{0.2}\text{Zn}_{0.3}\text{Fe}_2\text{O}_4$ were deposited using spin-spray ferrite plating [2] directly on both sides of double-sided PWBs made of epoxy resin. Then the ferrite-plated PWBs were incorporated as the inner ground or the power layer into the following two different types of four-layered PWBs (a) and (b). PWB (a), which was most commonly used structure, was composed of the outer signal layers and an inner ground and a power layer as illustrated in Fig.1. PWB (a) was composed of the outer signal layers, which contained the power supply lines as well, and two inner ground layers. On those PWBs, the following elements were mounted: a PLD (Programmable Logic Device) with a clock frequency of 75 MHz, four driver ICs (Integrated Circuits), resistors and capacitors. Electromagnetic noise radiation of 1-8 GHz were measured in an anechoic chamber for PWBs (a), (b) and those without ferrite films (PWBs (a') and (b')) when they were operated on the same condition.

Results and discussion

As shown in Fig.2, emission of radiated noise from the ferrite film-embedded PWB (a) was suppressed by 2 to 5 dB than that without the ferrite film (PWB(a')). This tendency became more prominent with increasing frequency. The similar noise suppression effect was also observed for the ferrite film-embedded PWB (b) by up to 4 dB. This suggests we can suppress noise radiation also in the case that the ground or the power plane are not placed symmetrically in the inner layers, meaning that there is a lot of flexibility in circuit designing of a power source layout. The noise suppression effect by the ferrite film observed for both PWBs (a) and (b) corresponded to the frequency dependence of $P_{\text{loss}}/P_{\text{in}}$ due to magnetic loss characteristics in the film [2]. This confirmed that suppression of emission noise radiated from the four-layered PWB was attributed to the attenuation of GHz noise current in the ground and/or the power layer.

Conclusion

We successfully suppressed the electromagnetic noise in the GHz range radiated from multilayered PWBs by plating the ferrite films of 3 μm thickness directly on the inner ground and/or the power layer.

Spin Device Technology Center, Shinshu University, Nagano, Japan

Introduction

For local temperature sensing, the temperature telemeters by means of lumped elements using the conventional temperature sensitive ferrite were already reported [1]. However, it was difficult to integrate and miniaturize these lumped element temperature sensors, because of too low natural resonance frequency and resistivity of many conventional ferrites containing Fe^{2+} ion. This study describes a novel chip temperature sensing device using transmission-line technique with Mn substituted Li-Zn-Cu ferrite. The authors recently clarified remarkable temperature sensitivity of polycrystalline Mn substituted Li-Zn-Cu ferrites [2]. It was also found that such spinel ferrites have both large Snoek's product and high resistivity in previous study [3]. The transmission-line device using such ferrite substrate can be miniaturized by an increase of the operating frequency, and an integration of the lumped elements is attained simultaneously. Namely, our novel transmission-line device operates as an integrated LC resonance type temperature sensing device because such device has both temperature dependent distributed inductance and capacitance due to the ferrite substrate.

Device fabrication and experiments

Fig. 1 shows a schematic view of the fabricated chip temperature sensing device. Such device was attained by an introduction of spiral strip-line structure with Mn substituted Li-Zn-Cu ferrite substrate. 500 μm thick ferrite substrates were prepared by LTCC process. Spiral signal line and ground plane were formed by thin film process. An open-ended spiral line has total length of 130 mm, 3 μm thick, line/space of 50/50 μm , and spiral turns of 5. Its temperature dependence ($T = -27$ - 100°C) of frequency characteristics ($f = 10$ - 100 MHz) of input impedance was measured by using an impedance analyzer and a temperature controlled bath.

Results and discussion

Fig. 2 shows the frequency characteristics of input impedance of chip temperature sensing device in each ambient temperature. Frequency dependent input impedances exhibited double peaks in the range from 10 and 100 MHz. Since the chip device is an open-ended stub, it was considered that the minimal peaks around 30 - 40 MHz mean quarter wavelength $\lambda/4$ resonance and the maximal peaks around 40 - 65 MHz mean half wavelength $\lambda/2$ resonance, respectively. Both peaks decreased with an increase of temperature. A main cause is that complex permeability of ferrite substrate was increased by increasing temperature [2]. In order to consider a possibility of amplitude modulation type temperature sensing, the temperature dependence of input impedance in fixed excitation frequency was evaluated. Fig. 3 shows temperature dependent input impedance at 30.7, 41.5, and 65.4 MHz, respectively. With the temperature rise, the input impedance in fixed frequencies increased or decreased extremely like the PTC or the NTC thermistor because these dependencies were enhanced by $\lambda/4$ resonance or $\lambda/2$ resonance. For instance, input impedance at 41.5 MHz increased by 10.8 times in the range from -27 to 100°C . These results suggest a realization of the integrated chip temperature sensing device using temperature sensitive ferrite for high sensitive local temperature sensing.

Introduction

Soft magnetic ferrites with a spinel structure have been extensively used in many surface mounting electronic devices because they show high permeability in radio frequency range, high electrical resistivity, good mechanical hardness and excellent chemical stability. Moreover, the production cost of these ferrites is very cheap compared with that of other magnetic materials. Unfortunately, these ferrites with a spinel structure cannot be used in devices operating in hyper frequency range (300-1000 MHz) [1,2], which is due to Snoek's limit. As such, Co2Z-type hexaferrites have been attracted much attention for microwave devices, especially a miniaturized antenna for digital broadcasting services such as digital video broadcasting-handheld (DVB-H) assigned from 170 MHz to 800 MHz.

In this experiment, the effects of the substitution of divalent ions (Zn at Co or Fe site and Fe at Co site) on the initial permeability of Co2Z-type ferrite were investigated. In addition, we analyzed the feasibility of miniaturized antennae using various Co2Z-type hexaferrites as a substrate.

Experimental Procedures

Co2Z-type hexaferrite with the nominal molecule composition of Ba3Co2Fe24O41 was fabricated by a solid state reaction method. BaCO3, Co3O4, α -Fe2O3 and ZnO powders, which were weighed according to the composition, were used as raw materials. These powders with de-ionized water were milled for 24 hr using zirconia balls. The ball-milled powder mixtures were dried at 100°C and then calcination was performed at 1200~1300°C in O2 atmosphere. The calcined powders were re-ground (2nd ball milling) for 30 hr. Before finishing the 2nd ball milling, polyvinyl alcohol (PVA) was added as a binder. These powders were granulated through a 0.12 mm sieve and then were pressed by 3 t/cm2 to form sheets, pellets (10mm) and toroidal shape samples (outer diameter:8mm, inner diameter:3mm). Finally, these samples were sintered in O2 atmosphere at 1200~1300°C

The crystal structure and phase identification of hexaferrites were analyzed by X-ray diffractometer (XRD, Rigaku D/MAX-2500) with Cu-K α radiation. Morphologies and microstructures of the hexaferrites were observed by a scanning electron microscope (SEM, Jeol, 6330F). The density was measured by an Archimede's method. The magnetic properties were measured by a vibration sample magnetometer (Toei VSM-5) and an impedance network analyzer (HP 4291A). For the estimation of antenna characteristics, HFSS simulator (Ansoft, v. 9.2) has been used.

Results and Discussions

A tapered slot antenna with a size of 30 mm \times 10 mm \times 2.4 mm was fabricated as depicted in Fig. 1(a). Various synthesized Co2Z-type ferrites were used as the substrate of the antenna. The measured voltage standing wave ratio (VSWR) of the antenna with a Ba3Co2Fe24O41 ferrite ($\mu=6$) substrate is presented in Fig. 1 (b). As shown in the figure, the band gap (VSWR<3) of this antenna is ~ 500 MHz but the maximum gain is obtained at 1.16 GHz. According to the specification of a Nokia 7700 sized terminal, it was reported that the realized gain of a DVB-H antenna was -10 to -7 dBi in the frequency range of 470 - 702 MHz [3]. Thus this peak position is too high to apply to a broadband antenna such as DVB-H antenna.

In order to overcome the above problem, increasing permeability is known to be an effective method [4]. As shown in Fig. 2, the substitution of divalent ion (Zn, Fe) in Co2Z-type ferrite effec-

tively increases the initial permeability. In particular, the initial permeability reaches 20 in Ba3Co2Fe23.7Zn0.3O41 ferrite. In a tapered slot antenna using this modified sheet, HFSS simulation results show that the peak position appears at 500 MHz with a bandwidth of 300 MHz. This indicates that modified Co2Z type ferrite can apply to a miniaturized broadband antenna.

Enhancement of magnetostriction in internally-biased Terfenol-D 2-2 composites.

L. Garcia-Gancedo¹, S. C. Busbridge², T. W. Button¹

1. IRC in Materials Processing, School of Engineering, University of Birmingham, Birmingham, United Kingdom; 2. School of Environment and Technology, University of Brighton, Brighton, United Kingdom

Introduction:

Terfenol-D has excellent room temperature magnetomechanical properties, but its frequency range of applications is limited to a few kHz by eddy current effects [1]. Self-biased Terfenol-D 2-2 composites with laminations perpendicular to the [112] crystallographic direction and internal magnetic field along [112] improve the magnetomechanical performance of Terfenol-D by reducing the eddy current losses at high frequencies (via electrically insulated metallic layers) [2]. However the inclusion of non Terfenol-D layers within the composite is detrimental for its overall magnetostriction [3]. In this paper we investigate the effects on magnetostriction of the incorporation of different permanent magnetic materials layers within the composites.

Experimental results:

Seven composites formed by Terfenol-D, insulating material and permanent magnetic material were produced with different layer thicknesses of materials by alternatively bonding the layers of Terfenol-D and permanent magnet with the insulating material. Neodymium-Iron-Boron has been chosen as permanent magnetic layer due to its higher energy product, remanent magnetisation and coercive fields than all the other permanent magnets discovered so far. The internal magnetic field provided by the magnet layers ranges from 17 kA/m to 53 kA/m for the composites with lower and higher content of NdFeB respectively. Magnetostriction at the edges of the composites was measured using typical strain gauges techniques and was found to be between 600 and 800 ppm. The strain at the central region of the composites was measured using interference microscopy and was found to be up to 8% lower than at the edges.

Theoretical analysis:

Finite Element Analysis (FEA) of the magnetostriction of such composites has been carried out using the commercial package ABAQUS. Cubic elements of side length 40 μm were used for calculations, although it was found that the element size has little influence on the results as long as there are a sensible number of divisions. Comparison between experimental and theoretical results at the edge of three composites is shown in Figure 1, where it can be seen that the agreement between experiments and theory is better than 95%. The FEA has shown that the magnetostriction within the Terfenol-D layers effectively increased between 75 and 200 ppm (for the composites with lowest and highest internal fields, respectively) with respect to the bulk material, although the high elastic modulus of the Nd₂Fe₁₄B and its nearly zero magnetostriction is detrimental for the overall strain of the composite. Therefore Alnico or Samarium-Cobalt could be better choices as permanent magnetic layers due to their elastic moduli are lower than that of Nd₂Fe₁₄B.

FEA and optimisation of strain has been carried out using different permanent magnetic materials. Table 1 shows the main magnetic and mechanical properties of the permanent magnetic materials used for the simulation. The internal field provided by the Alnico and Samarium-Cobalt is slightly lower than that provided by Nd₂Fe₁₄B, due to their poorer magnetic properties. A comparison of the strain at the edge of a composite with Terfenol-D, permanent magnetic layer and insulating layer thicknesses of 280 μm , 200 μm and 40 μm , respectively is shown in Figure 2. It can be seen that choosing Alnico as the permanent magnetic material layer produce the highest strains due its good

magnetic properties and low elastic modulus and therefore improved magnetomechanical performance is also expected.

Magnetoelastic properties of Tb-Dy-Ho-Fe-Co alloys.

I. Tereshina¹, G. Burkhanov¹, O. Chistyakov¹, S. Nikitin², G. Politova²

1. Baikov Institute of Metallurgy and Material Science RAS, Moscow, Russian Federation; 2. Faculty of Physics, M.V. Lomonosov Moscow State University, Moscow, Russian Federation

The rare earth – iron intermetallics RFe_2 ($MgCu_2$ -type Laves phase structure) are widely known as the most important class of magnetostrictive materials which show great potential for application in actuators and transducers [1, 2]. In order to obtain benefits from the technical employment of magnetostrictive alloys, it is important to provide high values of magnetostriction λ at room temperature under an action of relatively small magnetic fields (in other words, alloys should have high values of magnetostrictive susceptibility $\Delta\lambda/\Delta H$).

The purpose of the present work was synthesis of novel magnetostrictive materials $Tb_xDy_yHo_zFe_2$ ($x + y + z = 1$) and $Tb_{0.23}Dy_{0.27}Ho_{0.5}Fe_{2-x}Co_x$ ($x = 0 - 2$) in high-pure state which possess high values of both: saturation magnetostriction and magnetostrictive susceptibility within the given interval of magnetic fields and temperatures. The complex investigation of the crystal structure, magnetic and magnetoelastic properties, determination of the main regularities of formation of high magnetostrictive characteristics depending on the composition, and also determination of the optimal compositions of the compounds were done.

First, regimes of purification of rare-earth (RE) metals using vacuum sublimation (for Dy and Ho) and distillation (for Tb) have been worked out; certification of the purified metals was performed using laser mass spectrometry. The synthesis of five samples of quasi-ternary $Tb_xDy_yHo_zFe_2$ system was performed using obtained high-purity rare-earth metals by arc melting in a helium atmosphere using a water-cooled copper bottom and non-consumable tungsten electrode. Prepared compounds were certified using metallographic and X-ray fluorescence analysis and X-ray diffraction. A combined analysis of magnetic properties by means of traditional magnetometric methods as well as ^{57}Fe Mössbauer spectroscopy was also performed. Magnetostriction was measured in magnetic fields up to 10 kOe and in 80 – 400 K temperature range by means of the strain-gauge method. Strain gauges were glued on their surface of the disk-shaped ($d = 6$ mm, $h = 2$ mm) samples. Magnetostriction measurements were performed in magnetic field applied along the axis of the gauge (longitudinal magnetostriction $\lambda_{||}$).

Table 1 shows values of the saturation magnetostriction and magnetostrictive susceptibility of $Tb_xDy_yHo_zFe_2$ system at room temperature.

Detailed analysis of our results and available literature data [3, 4] showed that there are two pronounced maxima on the concentration dependencies of both saturation magnetostriction and magnetostrictive susceptibility in the range of concentrations of holmium: $z = 0.25 - 0.3$ and $z = 0.5 - 0.6$, respectively. Thus, the contribution to the magnetocrystalline anisotropy (MCA) energy from the rare-earth sublattice was minimized due to combination of rare-earth elements with different signs of MCA constants. A substitution of cobalt atoms for iron led to a decrease of the contribution to MCA from the 3d transition metal sublattice due to the fact that Fe and Co single-ion constants have different signs. Eleven samples of $Tb_{0.23}Dy_{0.27}Ho_{0.5}Fe_{2-x}Co_x$ ($x = 0; 0.1; 0.2; 0.4; 0.6; 0.8; 1; 1.2; 1.4; 1.6; 2$.) system were prepared and certified as showed before.

It was established that the unit cell volume and the value of longitudinal magnetostriction in $Tb_{0.23}Dy_{0.27}Ho_{0.5}Fe_{2-x}Co_x$ decrease monotonously with Co content increase. Concentration dependencies of Curie and spin-reorientation transition temperatures, saturation magnetization and the mean value of hyperfine field of Fe atoms demonstrate a non-monotonous behavior. It was found that $Tb_{0.23}Dy_{0.27}Ho_{0.5}Fe_{2-x}Co_x$ compounds with $x = 1.3$ have the maximum value of magnetostric-

tive susceptibility at room temperature, where the magnetic anisotropy is compensated in the rare-earth as well as in the 3d transition metals sublattice. Our investigations demonstrate the positive role of substitutions of Co for Fe in the improvement of magnetostriction properties in $RR'R''(Fe,Co)_2$

Modeling of bimorph type cantilever for actuators.

G. Yun^{1,2}, B. Narsu¹

1. department of physics, inner mongolia university, Hohhot, China; 2. department of physics, inner mongolia normal university, Hohhot, China

A cantilever system fabricated by combining giant magnetostrictive films (GMFs) and nonmagnetic substrate (NMS) produces a class of multi-functional microelectromechanical system (MEMS) devices [1]. A series of works had devoted to model the behaviors of such a GMF-NMS system as sensors and actuators in the last decades [1-3]. But most of works have encountered some difficulties to predict and optimize the cantilever actuator [4, 5]. Recently, Honda et al. [6] prepared a versatile structure of Polyimide cantilever which TbFe film and SmFe film are coated on both surfaces of the substrate. This TbFe/Polyimide/SmFe can be applied as micromotors and micropumps. However, such development on the device fabrication requires the theoretical modeling to achieve more realistic and optimal configuration in the application.

The purpose of this work is to present a valid and efficient theory for the trilayer cantilever that consists of GMF1/NMS/GMF2, where GMF 1 and 2, respectively, with positive and negative magnetostriction constants. Especially, the difficult problems of cantilever modeling, mechanical features and optimal conditions of the trilayer cantilever for actuator application are mainly considered and resolved.

The results indicate, when the thickness of the GMF1 is kept constant, thicker substrate and GMF2 will result in larger force exerted outside (Figure 1a), namely the ability of taking load is swelled. At the same time, the free end exerted force will increase with the increasing stiffness of GMF2. And the exerted force of the trilayer cantilevers of GMF1/NMS/GMF2 is always greater than the bilayer ones of GMF1/GMF2 or GMF/NMS. But for the case where the total thickness of the trilayer cantilever is kept constant, the free end exerted force will experience a maximum as a function of the GMF2-to-GMF1 thickness ratio (Figure 1b). Furthermore, the maximum value of force exerted will reduce with the increasing substrate thickness and GMF2-to-GMF1 stiffness ratio, while the optimal thickness ratio corresponding to the maximum value of the exerted force is an increasing function of the stiffness ratio (Figure 2b and Figure 3).

Generally, in the case of fixed substrate thickness, in order to obtain larger exerted force of the trilayer cantilever, the substrate should be made of harder materials, and the films be thicker and softer. And while for the case of the total thickness is kept constant, however, the substrate should be made of thinner and softer materials, and the films be harder and the GMF-to-GMF thickness ratio should be designed at the optimal thickness ratio for the maximum exerted force.

Introduction

It has been recognized that substituting about 20 at.% of non-magnetic Ga for Fe in bcc solid solution results in a ten-fold increase of the magnetostrictive constant to 270 ppm in directionally solidified polycrystalline samples [1], and to 350 ppm in quenched single crystal [2]. The alloys of Fe and Ga may be useful in magnetostrictive actuators and sensors due to their large saturation magnetostriction at low saturation fields, high mechanical strength and good ductility [1, 3]. Eddy current losses are problematic at frequencies above 1 kHz. A solution to this problem is to embed the magnetic particles in a non-conducting binder to create a composite. Epoxy-bonded Fe-Ga composites possess additional benefits of reduced eddy-current losses and low material cost. In this work, we report the microstructure and magnetic characteristics of epoxy-bonded Fe-Ga particulate composite with different grain size.

Experiment, results and discussion

Fe₈₀Ga₂₀ alloy ingots each with a mass of ~15 g were prepared by arc-melting high purity elements. The bulk samples were initially crushed. Composite particles were obtained by blade-milling in an argon atmosphere and sieving to powders with three different size ranges: 20-50, 50-100 and 100-200 µm. The powders were then mixed with an epoxy binder and compressed under a pressure of 120 MPa along the shortest dimension to obtain rectangular samples of dimensions 7-10 mm x 10 mm x 40 mm. Compaction was carried out without an applied magnetic field. Volume fractions of Fe-Ga powder used was nominally 0.80.

Fe-Ga alloys exhibit a strong correlation between the structure and magnetoelastic properties and it is commonly believed that the formation of an ordered D0₃ phase, as the amount of Ga atoms approaches 25 at.%, has a detrimental effect on magnetostriction. X-ray diffraction does not show superlattice peaks, but only peaks originating from the disordered bcc structure. The absence of long range order in investigated samples is confirmed by Mössbauer studies.

The magnetic hysteresis loops for the bulk alloy, powders with different grains size and composites (Fig. 1) show little coercivity (H_c) and remanence, reflecting low anisotropy at room temperature. The tendency of the saturation magnetization to decrease with decreasing particle size (from $M_s = 172$ emu/g for the largest grain size to $M_s = 159$ emu/g for the smallest ones) may be caused by the increasing surface area to volume ratio because the saturation magnetization at the surface is expected to be lower than that of the bulk alloy. M_s for the composites is less than for powders because the volume fraction of Fe-Ga is only 80 %. H_c shows the opposite behaviour with decreasing grain size and varies from 35.4 G for the largest grain size to 69.7 G for the grain size range from 20 to 50 µm. For bulk alloy H_c is an order of magnitude lower with a value of 3.4 G.

The highest saturation magnetostriction $\lambda_s = 360$ ppm is obtained for composites whose grain size varies from 50 to 100 µm. The maximum value of λ_s for composites with the largest grains is slightly smaller (330 ppm). However, these samples show magnetostriction hysteresis, which is not observed in composites with the smallest grains ($\lambda_s = 100$ ppm) and for bulk alloy ($\lambda_s = 70$ ppm). We believe that the magnetostriction hysteresis may be associated with mechanical connection between the matrix and the Fe-Ga particles. In order to explain this effect we have observed the magnetostriction as a function of time from 80 s to 3000 s (Fig. 2). Longer measurement times should

allow stresses in the epoxy-matrix to relax stresses so that changes occurring in the particles can be observed.

This work had been supported by the European Union (Interreg IIIa grant number 349).

Magnetostriction (MS) is defined as a deformation of a crystallographic mesh in magnetic materials when they acquire magnetization. The first magnetostrictive materials used as sensors or actuators were compounds with nickel, iron, and permalloy technologically applied on telephone receivers [1], hydrophones, and scanning sonars [2]. These materials exhibit bulk saturation strains up to 100 ppm.

Currently Terfenol-D is the material usually used for technological applications with many scholar papers and commercial patents. Examples of successful sensor designs include hearing aids, load cells, accelerometers, proximity sensors, torque sensors, magnetometers and many more [3-5].

More recently, the discovery on the $\text{R}_5(\text{Si,Ge})_4$ system of a colossal MS [6] and other large magnetic effects, intensified the research on these family of compounds. This colossal MS (and other effects) is related with the martensitic-like transition which exhibits a colossal magnetic field-induced volume strain. Additionally, such strain can be induced thermally namely in the $\text{Gd}_5\text{Si}_2\text{Ge}_2$ and $\text{Tb}_5\text{Si}_2\text{Ge}_2$ compounds with an induced strain as high as ~ 10000 ppm along the crystallographic a axis of a single crystal [7,8]. These properties make them ideal candidates for replacement of materials currently used in actuators like Terfenol-D where linear strain is limited to ~ 2000 ppm and volume strain is close to zero.

Another type of MS was found in Gd_5Ge_4 compound which presents large MS at low temperatures when an external magnetic field or external pressure is applied, changing the system from AFM (antiferromagnetic) to FM (ferromagnetic), with a simultaneous change of structure from O(II)- Gd_5Ge_4 type to the O(I)- Gd_5Si_4 type. In the present work, we show that Ho_5Ge_4 compounds exhibit a similar behaviour as Gd_5Ge_4 , at low temperatures. MS(H) and M(H) simultaneous measurements under dc magnetic field using the extensometers method (strain gauge technique) in a SQUID magnetometer ($H_{\text{max}}=5\text{T}$) were performed and extended to magnetic fields up to 27T (pulsed field).

The MS results are shown in Figs 1 a) and b), for the pulsed magnetic fields and DC magnetic field, respectively. For temperatures below $T_{\text{SR}} \sim 18\text{K}$, the MS behaviour shows a critical increase at $H_c \sim 2\text{T}$ reaching strain saturation around $\text{MS}=1700$ ppm (at $H=5\text{T}$). The nature of this magnetostriction is related with a metamagnetic transition from a low magnetization state to a high magnetization state, also confirmed by our magnetization measurements.

Microscopically, this large spontaneous MS is probably related with the interatomic distance changes due to the formed covalent bond dimers between Ge-Ge atoms (like in the Gd_5Ge_4), which increases the electronic charge corresponding to a direct change of the exchange interactions (RKKY), leading to the magnetic transition.

For temperatures above T_{SR} and below $T_{\text{N}} \sim 25\text{K}$, the MS presents a smoother MS curve (without criticality) with a linear H dependence for high magnetic field and with higher MS values, developing a strong forced MS.

Above T_{N} , the MS behaviour starts to decrease, being negligible for $T=40\text{K}$ until $H=5\text{T}$.

In the perpendicular configuration (applied magnetic field perpendicular to the longitudinal strain gauge filament) measurements (not shown) present a drastic decrease of MS saturation revealing large anisotropy effects in this compound. The volume change found was of $\Delta V/V \sim 600$ ppm and $\lambda_{\text{f}}=800$ ppm for shape MS.

The simultaneous measurements of M(H) and MS(H) allow to infer about the correlation between both quantities. Our analysis of MS(H) and M(H) reveal quadratic dependence ($\text{MS(H)} \sim \text{CM}^2$) in the PM regime.

We will also discuss the absence of magnetic hysteresis in both measurements, which is an important aspect for technological applications.

Voltage controlled magnetic properties of polycrystalline Terfenol-D film on PMN-PT single crystal substrate.

J. Kim, V. Ravindranath, S. Shin
Physics, KAIST, Daejeon, South Korea

To achieve ultra-high density integration in a magnetic random access memory (MRAM), suitable data recording and retrieval methods have to be determined. There were some studies for overcoming limitation of the conventional method of data recording using a magnetic field obtained from a current carrying conductor. Electric-write and magnetic-read memory device using magnetoelectric coupling between magnetic and electric properties have been proposed.[1] The a method of controlling the direction of magnetization easy axis using voltage has been reported in the Pd/Co1-xPdx/PZT/Pt/MgO heterostructures.[2] In the present work, we report a considerable change of magnetic anisotropy in Terfenol-D film on PMN-PT single crystal substrates for the study of voltage-control of magnetization easy axis.

Terfenol-D film was deposited on commercially available 300-um PMN-PT single crystal substrate with d33 value of 1500 pm/V by DC magnetron sputtering method. 10-nm thick polycrystalline terfenol-D film was grown at a sputtering power of 50 W, 5 mTorr Ar pressure at 300°C substrate temperature. After deposition, the film was annealed in a magnetic field applied in a direction perpendicular to the film plane for 20 min and cooled to room temperature. A Pt capping layer with a thickness of 3 nm was then deposited on Terfenol-D to prevent oxidation. Polar magneto-optical Kerr effect measurements were carried out with a 45° incident laser beam by using a photoelastic-modulator method. A voltage was applied using function generator and voltage amplifier across the PMN-PT substrate by Au electrode attached to the backside of substrate and the Pt capping layer. The Kerr ellipticity hysteresis loops of Terfenol-D film have been investigated in the presence of stress produced by the inverse piezoelectric effect of the PMN-PT substrate.

Fig. 1 presents the Kerr ellipticity hysteresis loops of the Terfenol-D/PMN-PT film. Each loop was measured at a given dc voltage shown in the inset of fig. 1. Fig. 2 shows variation of squareness and coercivity as function of applied voltage can be obtained from fig. 1. A change in coercivity from 240 Oe to 420 Oe and change in squareness from 0.45 to 0.9 have been observed. Both plotted graphs in fig. 2 show a similar butterfly loop. Considering the fact that the strain hysteresis curve of PMN-PT substrate shows well-known butterfly shape, the change of magnetic anisotropy of Terfenol-D film must be due to stress from PMN-PT substrate. The electric field induced stress changes in magnetoelastic energies given by . when voltage is increased from 0 V, PMN-PT substrate produce tensile stress. As a result, perpendicular magnetic anisotropy (PMA) of Terfenol-D film is decreased. On the other hand, when voltage is increased above electric coercivity field of PMN-PT (~90 V), PMA of Terfenol-D film is increased. It is clear that this large magnetoelectric effect in this system comes from the interplay between magnetostrictive property in Terfenol-D film and piezoelectric property of PMN-PT substrate.

I. INTRODUCTION

The rare-earth iron giant magnetostrictive material can be used to convert magnetic energy into mechanical energy and vice versa [1]. If an external force is applied onto magnetostrictive material, the magnetic status of the material will vary. This phenomenon is known as the inverse magnetostrictive effect or the Villari effect. This coupling between the magnetic and mechanical status of the material provides a capability of transduction, which can be utilized in a variety of ways [1-2]. According to the inverse magnetostrictive effect, a novel acceleration sensor can be developed using the giant magnetostrictive material. Compared with the other types of acceleration sensors, the giant magnetostrictive acceleration sensor has obvious advantages, such as high antiinterference resistance, withstanding heavy load, long service life, ability for working on adverse circumstances, and so on, which make them have more and more applications in the vibration detection field of aerospace industry, vehicle, chemical industry, civil engineering, and mechanical industry, etc [3]. In order to design and optimize giant magnetostrictive acceleration sensors effectively, it is necessary to found an accurate model, including the nonlinearities and the magneto-mechanical coupling. However, a little work on modeling of giant magnetostrictive acceleration sensor can be found. In this paper, a magneto-mechanical strong coupled model for input-output characteristics of magnetostrictive acceleration sensor has been founded.

II. A MAGNETO-MECHANICAL STRONGLY COUPLED MODEL FOR THE GIANT MAGNETOSTRICTIVE ACCELERATION SENSOR

Fig.1 shows a giant magnetostrictive acceleration sensor. When a force brought by acceleration exerts on the magnetostrictive rod, magnetic field in it will change. Magnetic flux density in the gap changes with the applied acceleration. Using a Gaussmeter, the magnetic flux density in the gap can be measured, then we can know the applied acceleration on the magnetostrictive sensor.

According the finite element method, it is necessary to give a functional of the sensor and then minimize it. The total energy of the sensor system includes elastic energy, work of external forces, magnetic field energy, potential energy of magnetic field boundary, mutual magnetoelastic energy and magnetocrystalline anisotropy energy. As for the Dirichlet condition, potential energy of magnetic field boundary is zero. If the giant magnetostrictive material is considered isotropic, the anisotropy energy is negligible.

The mechanical field boundary should be the contour of the magnetostrictive sensor. In computing, neglecting the distortions of the rest parts of the sensor, the domain enclosed by the surface of the magnetostrictive rod can be considered as the computed domain of the mechanical problem. In computation of the magnetic field, the magnetic vector potential is introduced.

Minimizing the functional of the sensor for each and every unconstrained vertex potential, we can obtain the magnetic vector potential and displacement vector. And then we can know the relation between magnetic flux density in the gap and applied acceleration on the sensor.

III. COMPUTED AND EXPERIMENTAL RESULTS

According to the magneto-mechanical strong coupled model for giant magnetostrictive sensors, the relation between magnetic flux density in the gap and applied acceleration on the sensor is calculated. In order to validate the presented model, it is necessary to measure the input-output relation of the sensor. The calculated and measured results are shown in Fig. 2. From Fig. 2, it can be seen

that the calculated results is in agreement with experimental ones. Therefore the presented model in this paper is valid.

1. Physics, Universidade de Aveiro, Aveiro, Portugal; 2. Chemistry, Universidade de Trás-os-Montes e Alto Douro, Vila Real, Portugal

Ni₂MnGa Heusler alloy is studied for its particular magnetic properties and applications. We can cite the memory shape properties, a first order structural transition from martensitic to austenitic phase [1] and its magnetocaloric effect (MCE) [2]. Besides its magnetic entropy change (ΔS) due to the magnetic transition from ferromagnetic to paramagnetic state at the Curie Temperature T_c , its structural transition is also accompanied by an entropy change [3]. Taking into account this alloy's composition sensitivity, both transitions have been coupled into a single one, resulting in a giant magnetocaloric effect (GMCE) [4].

The MCE has both applied and academic interest. From the applied point of view, the magnetic refrigeration is highlighted; several study groups have joined efforts to discover a good material to be used in thermo-magnetic devices usable at room temperature, and the compound Ni₂MnGa and its substitutes are promising. These materials have revealed interesting properties, good thermal conductivity, GMCE, low cost and more. Also, the ΔS , which is one of the physical quantities used to characterize the magnetocaloric potential, is a powerful tool to understand the physical mechanisms that rule the behavior of the material [4].

The studied Ni₂MnGa alloy has a critical temperature $T_c \sim 375$ K [5], and undergoes a structural transition between tetragonal martensitic and cubic austenitic phase at a temperature $T_m \sim 200$ K. It has a saturation magnetization of 4,17 μ_B below T_m and 3,90 μ_B above [5]. The structural transition has a ΔS of 5 J/kg.K [5], the magnetic transition has -1.29 J/kg.K [7], and finally, the coupled transitions have 20 J/kg.K [6].

Thus, our objective is to study the high magnetic anisotropy of the two phases of this alloy through measurements of the magnetization and ΔS . These results are interesting for researchers dealing with memory shape alloys, no matter the application they are looking for.

Our initial results revealed a distinct magnetic behavior above and below T_m , revealed by the change of shape of the magnetization curves (figure 1). The visible crossing of the isothermal magnetization curves, around 1.5 T, reveals different magnetic anisotropies between the martensitic and austenitic phases. Above T_m the magnetization reveals a softer ferromagnetic behavior, while below T_m a decreasing of the magnetization is observed, indicating either an increase of the magnetic anisotropy or a change in the easy-direction of the magnetization.

From these magnetization isotherms we obtain, using the Maxwell Relations [7], the ΔS for several values of magnetic field, around the structural transition. The maximum value of ΔS increases up to 1.5 T, where the magnetization curves cross. This result is expected because the ΔS is a function of the area between magnetic isotherms. Further increase of the magnetic field change leads to a decrease of the maximum ΔS and only at ~ 8 T both areas (above and below the crossing of magnetization curves), are balanced, and, consequently, the ΔS is zero (see figure 2). We can clearly see the increase in the maximum peak value, reaching its maximum around 1.5 T, steadily decreasing from this value on. From this result we can conclude that the use of this alloy for magnetic cooling purposes around the structural transition is limited to the use of fields below 1.5 T, having its maximum entropy variation value of about 3.8 J/Kg.K; fields above this value will in fact reduce its magnetocaloric power.

Finally, we will also discuss the influence of the substitution of Gallium by Bismuth in the Ni₂MnGa alloy, and analyse its influence on the magnetic anisotropy and magnetocaloric properties.

NiMnGa alloys have attracted a great deal of interest for huge magnetic-field-induced strains and giant magnetocaloric effects [1]. Both effects are linked to the occurrence of a martensitic transformation between a cubic and a lower-symmetry phase in the ferromagnetic state. The interplay between structural and magnetic degrees of freedom is further enhanced when structural and Curie transition coincide: i.e. first order transition from lower-symmetry ferromagnet to cubic paramagnet. Such a condition has been obtained in bulk systems by means of suitable composition changes and exploited to improve the magnetocaloric and magnetomechanical performances [2,3]. Up to now a lot of work aimed at understanding the fundamental properties and at tailoring the giant effects has been done mainly on bulk material. The research on NiMnGa thin film represents a new field of interest thanks to important possible applications in the field of sensors, actuators, and refrigeration materials [4]. In this case the properties can be tailored by means of composition and growth parameters changes, substrate choice and orientation, growth and annealing temperatures, thickness, and nano- and micro-scale structure. Aim of the present paper is to study the effects of growth parameters on the main properties of NiMnGa thin films of different thickness in order to tailor magnetic and structural transitions and to make them coincide.

NiMnGa thin films of thickness ranging from 20 to 100 nm were deposited by r.f. sputtering on oxidized Si and MgO(100) substrates. The Ni₂Mn_{1.2}Ga_{0.8} target was obtained by induction melting; its composition and homogeneity were confirmed by means of Energy Dispersive X-ray (EDX) analysis. Film growth was performed at a substrate temperature of about 400° C and Ar pressure $p=1.4 \times 10^{-2}$ mbar, with different target voltage V from 700 to 1200 V, giving rise to growth rates ranging from 2.45 nm/min for V=700 V to 7.5 nm/min for V= 1200 V. Structural and morphological characterization were performed by means of X-Ray Diffraction, Scanning Electron and Atomic Force Microscopy. The magnetic properties were studied by Alternating Gradient Force Magnetometry. Thermomagnetic analysis (magnetic susceptibility vs. temperature) and resistivity measurements as a function of temperature were also performed in order to study magnetic and structural transitions.

The films were found to be polycrystalline with a granular morphology with mean grain size dependent on thickness and growth parameters. Magnetization measurements confirm the ferromagnetic state of samples with saturation magnetization values at RT ranging from 350 to 400 emu/cm³, as expected for Mn-rich NiMnGa alloys. Selected results on transition temperatures are reported in Table I. It was found that Curie temperature (T_c) decreases by decreasing thickness and by increasing target voltage, independently of substrate.

An increase of Ni to Mn ratio by increasing target voltage has been evidenced by EDX analyses. The decrease of T_c by increasing Ni/Mn ratio is in qualitative agreement with the results reported on bulk Mn-rich systems [3]. A simultaneous increase of martensitic temperature has also been found. As an example in samples of thickness t=75 nm the martensite to austenite transformation (TAM) increases of 44°C by increasing target voltage from 900 to 1200V. Taking advantage of these results, the coincidence of magnetic and structural transition has been induced by modifying target voltage. In Figure 1 resistivity measurements versus temperature are reported for films of

thickness t=75 nm grown at V=900 V and V=1200 V respectively. In the first curve (a) the martensitic transformation (step with thermal hysteresis) and Curie transition (kink) are well separated while in the second one (b) they merge (TMA =83.7 °C) and show a thermal hysteresis of 15 °C. A suitable way to decrease both transition temperature and thermal hysteresis is to increase the sample thickness (see curve c for 100 nm thick sample).

Ni₂MnGa Heusler alloy and its off-stoichiometric derivatives exhibit a martensitic transformation resulting in a thermoelastic martensite with strong magnetocrystalline anisotropy. However, the relationship between the martensitic and magnetic structures on the micro(nano)scale is still a rather unexplored research area.

Thin films of Ni-Mn-Ga alloys are recently in the focus of interest. The thickness dependencies of the structural and magnetic properties of the martensitic Ni-Mn-Ga/substrate film composites have been studied [3-5]. These films are textured and exhibit plate-like twinning morphology with twin boundaries predominantly oriented parallel to the film plane, giving place to out-of-plane magnetization.

In this work, the influence of thickness and substrate nature on the occurrence of the perpendicular magnetic anisotropy and stripe domain pattern is analyzed.

The 10M-martensitic thin films with thicknesses of 0.1, 0.6 and 1 μm were fabricated at T=50 C by r.f. magnetron sputtering of a Ni_{49.5}Mn₂₈Ga_{22.5} (at.%) target on MgO(100). The texture characterization was made using X-ray beam-line at ANKA synchrotron source (FZK, Karlsruhe). In-plane and out-of-plane magnetization loops M(H) were studied by a SQUID magnetometer. In-plane minor M(H) loops were measured as a function of rotation angle by magneto-optical Kerr effect (MOKE). Magnetic force microscopy, MFM, and atomic force microscopy, AFM, measurements were performed with a Digital Instrument 3100 AFM probe microscope.

The X-rays measurements show drastic change from well-pronounced (220)-fiber texture of 1 and 0.6 μm films to a strong in-plane texture component for 0.1 μm film. The in-plane and out-of-plane M(H) hysteresis loops show coercivity values close to 105 Oe and 65-80 Oe, respectively. The initial out-of-plane magnetic susceptibility increases several times with decreasing film thickness while the anisotropy field is approximately constant, roughly corresponding to the value of (1-2)×10⁶ erg/cm³ typical for the bulk. MOKE results show an interesting behavior not observed before for similar films: for 0.1 μm film, the in-plane magnetic susceptibility shows a dependence on the measuring direction not observed in the other samples.

The MFM image for 1 μm film (Fig.1) reveals a magnetic contrast produced by magnetic stripe domains forming a maze pattern (a similar result is also found for 0.6 μm film). The MFM observations for the 0.1 mm film show a patch-like pattern rather than stripes on the same length-scale. The magnetic domains in Fig.1 represent bright and dark regions associated with the magnetization being parallel or antiparallel to the out-of-plane direction. Neighboring domains are assumed to be separated by Bloch-like 180° domain walls. The averaged width of the magnetic domains, as measured from the MFM images, is shown in Fig.2 versus the square root of the film thickness. For comparison sake, this dependence is also shown for similar Ni-Mn-Ga alloys deposited on other substrates [3-5]. In the simplest case of stripe domains for thick enough ferromagnetic films, the classical theory yields an equilibrium domain width $\delta = (d \times \delta_{dw})^{1/2}$ [6], where d is the film thickness and $\delta_{dw} = a(E \times A)^{1/2}$ is the domain wall width. Here a is the interatomic distance, E is the exchange energy density, and A is an anisotropy constant. The varying slopes of the lines in Fig.2 are related to δ_{dw} which appears to be dependent on the substrate nature.

Crystallographic twins or possible associated 90° magnetic domains are not revealed in normal-to-plane observations in this work because of the aforementioned twin boundaries orientation. The strong in-plane texture component, observed in the 0.1 μm film on MgO(100) can cause the only exception from this regularity. The work is now under way to clarify this point.

Substrate dependent structure and magnetic properties in HoMnO₃ films.

T. Han¹, J. Lin²

1. Department of Applied Physics, National University of Kaohsiung, Kaohsiung, Taiwan; 2. Center for Condensed Matter Sciences, National Taiwan University, Taipei, Taiwan

In the recent years, multiferroics open new avenues for the development of novel devices based on new functionalities such as control of the magnetic properties by means of electrical fields and vice versa [1]. HoMnO₃ (HMO) is a multiferroic material with both ferroelectric and antiferromagnetic orderings. Large magnetodielectric effects were observed in polycrystalline HMO samples with orthorhombic (OT) structure [2]; however, experimental data on the single crystals or the films are very rare. In this work, we make efforts to synthesize and characterize HMO in the form of epitaxial films.

Single-phased hexagonal (HX) HMO target was first prepared with solid state reaction method. Then, HMO films were grown on (111)-yttrium stabilized zirconia (YSZ), LaAlO₃ (110) and SrTiO₃ (100) substrates at 850 °C by the method of pulsed laser deposition (PLD) with a 248 nm KrF excimer laser. The oxygen pressure during the growth is 50 mtorr, and the pulse frequency is 5 Hz. After deposition, the films were in-situ annealed in an oxygen pressure of 100 mtorr for 10 min at the same temperature. The structural characteristics of the grown HMO films were examined by x-ray diffraction (XRD). The magnetic properties of the samples were measured by a superconducting quantum interference device magnetometer.

The XRD patterns of the HMO films deposited on (111)-YSZ substrate, strong (0001) peaks of HMO, and (111) peak of YSZ are identified, suggesting that the crystal structure of this HMO film is hexagonally grown with c-axis perpendicular to the surface of substrate. The crystal structures of HMO films are found to be either OT or HX. Various peaks for the HMO films on STO (100) representing different crystal orientations are observed. However, only strong (020) peak of HMO and (110) of LAO are observed in HMO/LAO film. These results indicate that the stability of film's structure is strongly dependent on the types of substrate. For HMO films, the (111)-YSZ produces a better HX structure and (110)-LAO yields a good OT structure.

Figure 1 and figure 2 display the magnetization (M) vs. temperature (T) for HMO/YSZ and HMO/LAO films with field parallel (in-plane) and perpendicular (out-of-plane) to the film surface, respectively. Solid symbols are the data with the zero field-cooled (ZFC) mode, while the open ones are for the field-cooled (FC) mode. In Fig. 1, both the in-plane and the out-of-plane M(T) curves of HMO/YSZ films display similar behavior with two transitions at ~ 80 K and 45 K, which correspond to the two different magnetic orderings of Mn³⁺ spins. The HMO/LAO film, on the other hand, shows an interesting anisotropy of M(T) as seen in Fig. 2. For in-plane measurement, ZFC-M(T) displays two cusps at ~ 42 K and 7 K, which correspond to the antiferromagnetic orders of Mn³⁺ and Ho³⁺-ions, respectively. FC-M(T) shows a sudden rise at 45 K and it keeps increasing at 7 K, indicating the ordering temperature of Ho³⁺-ion is effectively suppressed under an applied field of 500 Oe parallel to ab-plane. For out-of-plane measurement, the ZFC- and FC-M(T) curves form a split-to-close loop for 10 K < T < 45 K, which is absent in the data of in-plane measurement. In conjunction with the neutron diffraction data of HMO [3], it is suggested that the observed close-loop in the out-of-plane M(T) data reveals the incommensurate to commensurate transition of Mn³⁺-structure.

In summary, the crystalline orientation of HMO films is strongly dependent on the substrate. It is found that the pure HX- and OT- HMO films can be grown on the YSZ(111) and LAO(110) substrates, respectively. Based on the results of M(T), it is observed that the magnetic behavior of the

HX-HMO film is very different from that of the OT-HMO film. We expect that this systematic study will serve as a guidance to make high quality HMO films with different structures. And, these films can be eventually utilized for the applications of multiferroic devices.

Hexagonal RMnO₃ (R = rare earth element or Y) compounds present opportunities for the industrious applications due to their unique nature of multiferroism [1]. Namely, the ferromagnetism, ferroelectricity and ferroelasticity occur simultaneously in same material [2]. The characteristics of multiferroism includes a spontaneous magnetization which can be switched by an applied electric field, a spontaneous electrical polarization which can be reoriented by an applied magnetic field, and a strong coupling exists between these two properties. Most of hexagonal RMnO₃ exhibit ferroelectric transitions at high temperatures ($T_C \sim 600 - 1000$ K) and antiferromagnetic transitions at low temperatures ($T_N \sim 70 - 130$ K). Additional phase transitions at temperature below 10 K are observed in some hexagonal RMnO₃ with high magnetic moment of R^{3+} , which is related to the R-R exchange correlations [3]. In this work, we prepare a series of LuFe_xMn_{1-x}O₃ ($x = 0 \sim 0.5$) samples by solid-state reaction method to study the effect of Fe-doping on their magnetic properties.

The polycrystalline samples of LuFe_xMn_{1-x}O₃ ($x = 0 \sim 0.5$) are prepared by the solid-state reaction method. Stoichiometric mixtures of high-purity (> 99.9 %) Lu₂O₃, Mn₂O₃, and Fe₂O₃ powders were ground and calcinated in air at 1100 °C for 13 hours. To ensure better homogeneity the mixed powders were ground again, compacted into small pellets and reheated in air at 1100 °C for 12 hours. The crystalline structure of the samples was examined by x-ray diffraction (XRD) measurement. The magnetic properties of the samples were measured by a physical property measurement system (PPMS).

Figure 1 shows the powder XRD patterns of the LuFe_xMn_{1-x}O₃ ($x = 0 \sim 0.2$) samples. All the observed peaks can be indexed on the basis of a hexagonal unit cell of space group P6₃cm. However, as Mn ions are partially substituted by Fe ions, the structure starts to change with increasing the Fe concentration x . Based on the x-ray analysis, the structures of these compounds change from the hexagonal (space group: P6₃cm) to the orthorhombic perovskite (space group: Pbnm). In the Fe-doped LuMnO₃ samples, the lattice parameter a is slightly decreased but c is increased. The fact that a and c lattice parameters change systematically with increasing x indicates that the Fe-ions do replace the Mn ions.

The temperature-dependent magnetizations $M(T)$ are measured in a magnetic field of $H = 500$ Oe under conditions of zero field-cooled (ZFC) and field-cooled (FC). The ZFC magnetization $M_{ZFC}(T)$ and FC magnetization $M_{FC}(T)$ of the LuFe_xMn_{1-x}O₃ ($x = 0 \sim 0.2$) samples are displayed in Fig. 2, showing that the antiferromagnetic transition temperature (T_N) shifts from 85 to 130 K with increasing the Fe-content. It is also found that the values of effective magnetic momentum increase as the iron content increases. According to the result of M - H curves at 10 K, the magnetic moment increases continuously from 0.009 to 0.017 $\mu_B/f.u.$ with increasing the Fe-content from 0 to 0.2. In case of a strong coupling between magnetic moment and electric polarization, the Fe-doped sample may have a stronger polarization/ferroelectric effect than that of pure LuMnO₃ sample. However, further investigation on the properties of dielectric constant and polarization is essential for understanding the origin of the effect of Fe-doping on their magnetization.

In summary, a series of LuFe_xMn_{1-x}O₃ ($x = 0 \sim 0.5$) samples are synthesized and studied by the magnetization measurements. The XRD analysis shows that the structure of LuMnO₃ change with increasing the Fe-content from the hexagonal to the orthorhombic perovskite. The magnetic char-

acterization indicates that with an increase in the Fe-content, the antiferromagnetic transition temperature shift from 85 to 150 K. At the same time, the value of effective magnetic momentum increases from 0.009 to 0.017 $\mu_B/f.u.$ as the Fe-content increases. In case of a strong coupling between magnetic moment and electric polarization, Fe-doped sample may have a higher polarization/ferroelectric effect than that of pure LuMnO₃ sample, which should be a great advantage for its future applications.

Magnetic hysteresis in ErFeO₃ near the 4.1 K ordering transition.

L. T. Tsymbal¹, Y. B. Bazaliy^{2,3}, G. N. Kakazei^{3,4}, F. J. Palomares⁴, P. E. Wigen⁵

1. O. Galkin Donetsk Physics and Technology Institute, Donetsk, Ukraine; 2. University of South Carolina, Columbia, SC; 3. Institute of Magnetism, National Academy of Science, Kyiv, Ukraine; 4. Instituto de Ciencia de Materiales de Madrid, Madrid, Spain; 5. Ohio State University, Columbus, OH

The orthoferrite ErFeO₃ exhibits a number of interesting magnetic transitions [1]. Magnetism of the compound is due to both iron atoms and erbium atoms. The high temperature magnetic properties are characterized by the ordering of iron sublattice. At $T_N = 636$ K it orders into a non-collinear antiferromagnetic structure with the antiferromagnetic moment \mathbf{G} along the crystallographic a -axis and a small ferromagnetic moment \mathbf{M} along the c -axis. As the temperature is decreased, the spin-reorientation transition is reached where both vectors rotate by 90 degrees. The rotation transition happens continuously in the interval between $T_1 = 88$ K and $T_2 = 97$ K [1].

The spin-reorientation transition is already marked by the appreciable interaction between the iron and erbium magnetic subsystems. It was argued, that the very existence of this transition can be ascribed to Fe-Er interaction [2]. Recently some of us has shown that regardless of the transition mechanism the temperature dependence of rotation angle can be explained only if the magnetic moment of erbium is taken into account [3,4]. The magnetic moment of erbium becomes even larger as the temperature is further lowered. Eventually a compensation point $T_c = 46$ K is reached, where the iron and erbium magnetic moments are equal in magnitude and point in the opposite directions [5,6].

Finally, at very low temperature there is a transition with erbium ions playing the key role. At $T_{12} = 4.1$ K magnetic moments of erbium order into an antiferromagnetic structure [7] and vector \mathbf{G} starts to rotate in the (b,c) plane [8-10]. The erbium ordering transition is characterized by the unusual anomalies [12-15].

In this work, we performed precise measurements of the magnetic hysteresis loops at a series of temperatures above T_{12} using the SQUID-magnetometer Quantum Design MPMS-5S and the Vibrating sample magnetometer OXFORD MagLab VSM. Single-crystal samples of ErFeO₃ were used in all measurements. Magnetic field was applied along the a -axis, i.e., along the direction of spontaneous ferromagnetic moment $\mathbf{M} \parallel a$. Representative results are shown in the Fig. 1. At relatively high temperatures square loops are found. As the temperature is lowered from about 30K towards T_{12} the coercive field decreases, and eventually the "double-triangle" loops emerge (see $T = 9$ K and $T = 5$ K loops in Fig. 1). We interpret the change of the loop shape as evidence of the emergence of a ferromagnetic domain structure at low magnetic fields. Hysteresis loops measured at constant temperatures explain the results found in temperatures sweeps at constant applied $\mathbf{H} \parallel a$ (Fig. 2, left panel) in the situation when H is smaller than the loop width. Spontaneous magnetization obtained from hysteresis loops [3] is shown in Fig. 2, right panel.

In conclusion, we found that magnetic hysteresis loops in ErFeO₃ exhibit complicated shapes near the erbium ordering transition at $T_{12} = 4.1$ K. This work calls for theoretical understanding of the loop shapes (double-triangle loops) and especially of the relationship between the loop shapes and the proximity to the phase transition.

Mössbauer studies of ^{57}Fe -doped in LiCoPO_4 at low temperatures.

S. Moon, C. Kim

Department of Physics, Kookmin University, Seoul, South Korea

Introduction

Since the magnetoelectric (ME) effect was observed in Lithium-orthophosphates, LiMPO_4 (M=Transition metal) have been extensively investigated for information storage and electronic, magnetic and optical switches [1-3]. Also, the high lithium-ionic conductivity has been studied already as a high potential cathode material by using in secondary Li-ion rechargeable battery [4]. Recently, the observation of ferrotoroidic (FTO) domains in LiCoPO_4 was reported by Bas. Van Aken et al [5]. They claimed that the ferrotoroidic system has asymmetric structure by migration of Co^{2+} ions in antiferromagnetic (AFM) structure with rotation of the spins. The studies of neutron scattering demonstrated the magnetic properties of LiCoPO_4 which was related between 2D and 3D magnetic systems [2, 5]. These structures exhibit a strong linear magnetoelectric (ME) effect. AFM ordering reduces the symmetry from mmm to mmm', and weak ferromagnetism along y axis reduces the symmetry from mmm' to 2'mm', therefore, finally, it has two AFM and two FTO domains in LiCoPO_4 [5].

From these complex magnetic structures, LiCoPO_4 show the various anomaly effects. Therefore, it is essential to determine the unusual magnetic properties of LiCoPO_4 in low temperatures for properly understand the mechanism. We present crystallographic and magnetic properties of $\text{LiCo}_{0.99}\text{Fe}_{0.01}\text{PO}_4$ (LCFPO) using the Mössbauer spectroscopy and the x-ray diffraction (XRD) Experiments

The polycrystalline sample of (LCFPO) was made by using a direct reaction. Lithium carbonate, ammonium dihydrogen phosphate, cobalt oxide, and iron metal (^{57}Fe) were mixed in stoichiometric ratios and sealed in evacuated quartz tubes. The temperature was slowly raised up to 700 °C over a period of 1 day. The crystal structure of the sample was examined by using an X-ray diffractometer with Cu- $K\alpha$ radiation ($\lambda=1.5406 \text{ \AA}$) and was analyzed by using a Rietveld refinement. The Mössbauer spectra were recorded using a conventional spectrometer of the electromechanically type with a ^{57}Co source in a rhodium matrix.

Results and discussion

X-ray diffraction pattern for LCFPO showed a pure olivine single phase. The crystals structure was determined to be an orthorhombic with space group $Pnma$. The determined lattice constants a_0 , b_0 , and c_0 are 10.241 Å, 5.924 Å, and 4.698 Å, respectively.

The Mössbauer spectra of LCFPO at various temperatures ranging from 4.2 to 300 K are shown in Fig. 1. We have analyzed the Mössbauer spectra by using the full Hamiltonian. The Mössbauer spectrum shows a large asymmetric and distorted line broadening at 4.2 K. The magnetic hyperfine field (H_{hf}) and the quadrupole splitting (ΔE_Q) at 4.2 K were fitted and yielded the following results: $H_{\text{hf}} = 127 \text{ kOe}$, $\theta = 16^\circ$, $\phi = 0^\circ$, $\eta = 0.95$, $\Delta E_Q = (1/2)e^2qQ[1+(1/3)\eta^2]^{1/2} = 0.36 \text{ mm/s}$, and $R = 3.0$. Here, η is the asymmetric parameter, and R is the ratio of the electric quadrupole interaction to the magnetic dipole interaction. It is noticeable that the magnitude of R is greater than 1 below T_N . This result indicates that the electric quadrupole interaction is larger than the magnetic dipole interaction in the below T_N region. Generally, the H_{hf} has a maximum value at 0 K and decreases with increasing temperature. In Fig. 2, we observe that the H_{hf} has a maximum at 9 K. The unusual reduction of H_{hf} below 9 K can be explained in terms of the temperature dependence of the cancellation effect between the orbital current field term and the Fermi contact term in H_{hf} . The magnitude quadrupole shift at below T_N was caused by large crystal field due to the asymmetric struc-

ture through the rotation of the spins. From the analysis of Mössbauer spectra, we suggest that the asymmetric structure of LiCoPO_4 is closely related to the elevation of ME effect.

Effects of gallium distribution on terbium bismuth gallium iron garnet.

I. Park, C. Kim

Physics, Kookmin University, Seoul, South Korea

Introduction

Heavy rare earth (RE) iron garnet has canted magnetic structure which is described as a “double umbrella structure” at low temperature. The heavy RE ion spins form a double cone around the [111] axis, and these spin affect to the iron set of 16a site [1]. These materials related to the negative magnetization have been reported that the net magnetization has negative value at low temperature under field cooled condition for $\text{Tb}_2\text{Bi}_1\text{Fe}_5\text{O}_{12}$ [2], and $\text{Ho}(\text{Fe}_{0.6}\text{Mn}_{0.4})_{12}$ systems [3]. Terbium bismuth gallium iron garnet (TbBiGaG) is the candidate material for Faraday rotator for wide band and temperature-stabilized optical isolators [4]. It is well known that heavy RE iron garnet shows compensation phenomenon. Compensation phenomenon attracted attention for new concepts of integrated optical isolators based on nonreciprocal optical mode interference [5]. In RE iron garnet system, both octahedral (16a) and tetrahedral (24d) sites are occupied by Fe^{3+} ions. When the gallium ion is substituted in garnet system, the cation distribution of gallium and iron ions between 16a and 24d sites depends on the temperature. The heat treatment is able to change the sign of the faraday effect by moving some of the Ga ions from 24d to 16a site [5-6].

In this work, we report on the structural and magnetic properties of $\text{Tb}_2\text{Bi}_1\text{Ga}_1\text{Fe}_4\text{O}_{12}$ powders, which prepared by sol-gel and vacuum annealing process. The distribution of gallium and iron in $\text{Tb}_2\text{Bi}_1\text{Ga}_1\text{Fe}_4\text{O}_{12}$ is explained by the analysis of the local structure of iron sublattices using Mössbauer spectroscopy.

Experiments

$\text{Tb}_2\text{Bi}_1\text{Ga}_1\text{Fe}_4\text{O}_{12}$ compounds were prepared by a sol-gel method. Terbium, bismuth, gallium, and iron nitrate were dissolved in 2-methoxyethanol (2-MOE) and acetic acid. The solution was refluxed at 80 °C for 24 h and dried at 120 °C for 48 h in oven. The obtained powder was sealed in evacuated quartz tubes. The annealing temperature was room temperature initially and was slowly raised to 1000 °C over a period of seven days.

The crystal structure of the sample was examined using an x-ray diffractometer with $\text{Cu-K}\alpha$ radiation and analyzed by Rietveld refinement. Mössbauer spectra were recorded using a constant acceleration Mössbauer spectrometer with a ^{57}Co source in Rh matrix.

Results and discussion

The x-ray diffraction pattern of the compounds shows a single phase crystal structure of space group ($Ia3d$) { $\text{Tb}(24c)$; $\text{Bi}(24c)$; $\text{Fe}(16a)$; $\text{Ga}(16a)$; $\text{Fe}(24d)$; $\text{O}(96h)$ (u, v, w)} with its lattice constant $a_0 = 12.465$ Å. The refined X-ray diffraction pattern of sample is shown in Fig. 1. In order to study the change of the detailed local structure, we have obtained Mössbauer spectrum. Mössbauer spectrum of $\text{Tb}_2\text{Bi}_1\text{Ga}_1\text{Fe}_4\text{O}_{12}$ at room temperature is shown in Fig. 2. The Mössbauer spectrum for the sample was composed of two six-line hyperfine patterns 24d (inner sextet) and 16a (outer sextet). The spectrum of $\text{Tb}_2\text{Bi}_1\text{Ga}_1\text{Fe}_4\text{O}_{12}$ at room temperature consists of 2 sets of 6 Lorentzians, which is the pattern of single-phase garnet. From the analyzed results of Mössbauer spectrum at room temperature, the absorption area ratios of Fe ions on 24d and 16a sites are 74.7 % and 25.3 % (approximately 3:1), respectively. In case of our previous results for $\text{Tb}_2\text{Bi}_1\text{Fe}_5\text{O}_{12}$, the absorption area ratios of Fe ions on 24d and 16a sites are 60.8 % and 39.2 % (approximately 3:2), respectively. This proportion is the conventional absorption area ratios of Fe ions of garnet. It can be analogized the Ga ion distribution by this result. It is noticeable that all of the nonmagnetic Ga atoms occupy the 16a site by vacuum annealing process. This is also in accord with the x-ray dif-

fraction refinement results. We suggest that the control of site preference of Ga cation from 24d site to 16a site was accomplished by high temperature vacuum annealing process.

Ferrite has attracted much interest due to its broad magnetic properties and promising applications in microelectronic and microwave devices as well as sensitive sensors[1]. A lot of research has been focused on the magnetic properties of polycrystalline and single crystalline bulk materials or thin films. However, it is recognized that residual strain has played an important role in controlling the coercivity and other magnetic properties[2-3]. Therefore, synthesizing single crystalline ferrite thin films and establishing a comprehensive understanding on the strain effect become critical issues. In this paper, we fabricate a pure magnetite and a series of $\text{Fe}_{3-x}\text{Mg}_x\text{O}_4$ films on $\text{MgO}(001)$ and $\text{SrTiO}_3(001)$, respectively. The thickness of $\text{Fe}_{3-x}\text{Mg}_x\text{O}_4$ thin films are around 1000 Å. MgO is utilized for the growth due to small lattice mismatch ($\sim -0.3\%$) and epitaxial films are expected. On the other hand, $\text{SrTiO}_3(\text{STO})$ substrate is intended to include in this study because of its relatively large lattice mismatch ($\sim 7.58\%$) and dissimilar oxygen sublattice to ferrites so a relaxed thin film may be obtained for comparison. X-ray diffraction (XRD) measured along z direction reveals that these films are indeed epitaxial and strained for films grown on MgO but it shows two-phases of crystalline orientation and thus relaxed for films grown on STO. Figure 1 shows the XRD results from the films grown on $\text{MgO}(001)$. The major peaks at 94° are diffracted from MgO substrate and minor peaks (with mark) are from pure and mixed ferrite films with different Fe/Mg ratio, which indicate high crystalline quality of these ferrite films. However, the diffraction results from the films grown on STO show extra (111) series peaks indicating polycrystalline structure of these films. Relative to lattice matched substrate such as $\text{MgO}(001)$, these films show extra (111) series peaks indicating the relaxed feature of these films. Magnetic hysteresis curves are measured for all films with the external field parallel to the plane. The saturation magnetization (M_s) for films grown on MgO reduces from 500 emu/cm^3 roughly linearly from $x = 0$ to $x = 1.5$. However, M_s remains $\sim 400 \text{ emu/cm}^3$ in the range of $x = 0.3$ and 0.9 for the films grown on STO. The difference of M_s may be attributed by cation distribution. For the low M_s state found in film grown on MgO (strained case), Mg mostly replaced Fe from B site. However, for the high M_s state found in films grown on STO (relaxed case), Mg replaced both A and B sites. The mechanism for the high M_s may be related to the thin film layer-by-layer growth characteristic[4].

Resistance as a function of temperature (80 – 300 K) for all films is also carried out. Basically, the resistivity of the samples presents a typical Arrhenius temperature dependence with $\rho = \rho_0 \exp(E_p/k_B T)$ as shown in Fig. 2. The gap energies, which are estimated from the slopes of the straight lines gradually increase from 63 to 69 meV for the films with $x = 0.3$ to $x = 1.2$. However, the gap energy abruptly increases to 110 meV and tends to diverge as $x > 1.5$, which may indicate a possible metal (semiconductor)-insulator transition. Both the magnetization saturation and the electrical transition at $x = 1.5$ are related to the cation distribution in different crystalline sites. The cation distribution and the strain effect in these ferrite films will be discussed.

The use of magnetostrictive smart materials for development of sensors and actuators in a wide range of engineering applications has attracted remarkable research interest. This includes the need to develop low cost materials with improved mechanical, thermal and chemical properties of which ceramic oxides are good candidates. Among the ceramic oxides, Cobalt ferrite (Co-ferrite) and Co-ferrite based materials have been investigated as alternatives to the rare earth based magnetostrictive materials for sensor and actuator development [1,2].

Since magnetostrictive properties depend on the position and concentration of Co^{2+} ions, it follows that changes in the site occupancy will affect the magnetic and magnetostrictive properties of Co-ferrite. Studies have shown that magnetic and magnetostrictive properties can be optimized by both chemical substitutions [3,4,5] and heat treatment [6,7].

Most studies on the improvement of magnetostrictive properties of Co-ferrite have concentrated on samples prepared at a particular temperature in air. Since site occupancy of ions is crucial to improvement of magnetostrictive properties and can depend on sintering conditions, there is then a need for a systematic approach to understanding magnetostrictive behaviour as a result of heat treatment and sintering environment. This is particularly important due to the varying levels of magnetostriction obtained for Co-ferrite in different studies. Values ranging from 138ppm [8] to 225ppm [9] have been reported.

In this work, we present the results of a study on the effect of vacuum sintering, different sintering temperatures and holding times on the magnetic and magnetostrictive properties of Co-ferrite. Since oxygen partial pressure influences the compositional variation of Co-ferrite [6], the choice of vacuum condition is necessary to compare results with air sintered samples previously reported [8,9].

Co-ferrite powder was ball milled, pressed into buttons and sintered in vacuum at 10^{-5} Torr. Nine samples were studied, consisting of three samples sintered at each of three temperatures 800°C, 1000°C and 1200°C, and for different holding times of 6, 12 and 24 hrs. All samples were heated at a rate of 250°C/hr and cooled at the same rate in vacuum. The structures and microstructure of the sintered samples were characterized by x-ray diffractometry and scanning electron microscopy. Magnetic properties were studied with a superconducting quantum interference device (SQUID) up to a maximum applied field of 4000 kA/m. Room temperature magnetostriction was measured using strain gauges attached to the samples.

Coercive field (H_c) was found to decrease with sintering temperature and holding time as shown in Fig.1.

Using the Law of Approach to Saturation, we determined the variation of the first cubic anisotropy coefficient (K_1) with sintering temperature. The results show that K_1 is higher for smaller holding times at lower sintering temperatures. This indicates that vacuum sintering of Co-ferrite requires higher sintering temperature for lower anisotropy.

We observed that the highest magnetostriction (λ) was obtained for samples sintered at 800°C in vacuum. The results also show that the effect of change in sintering temperature is more pronounced than change in holding time. This is shown in Figs.2a and 2b for samples sintered for 24 hours at different temperatures, and for samples sintered at 800°C for different times.

From these results, it can be seen that λ is improved at lower vacuum sintering temperatures than at higher ones. This is likely due to the introduction of a detrimental second phase at higher temperatures as indicated by preliminary x-ray diffraction results. Additional results are needed for confirmation. Though higher λ is obtained for samples sintered in air [9], the value of λ obtained for vacuum sintering is comparable to other literature values obtained for air sintering [8]. Finally, comparing coercive fields for vacuum and air sintering, vacuum sintering seems to result in lower coercive field at lower temperature than air sintering [8].

The spinel powders with chemical compositions CoFe_2O_4 and $\text{CoMn}_{0.2}\text{Fe}_{1.8}\text{O}_4$ were synthesized by solid state ceramic and coprecipitation and oxidation wet methods [1]. In the solid state ceramic method, the homogenized raw materials ($\alpha\text{-Fe}_2\text{O}_3$, Co_3O_4 and MnCO_3) were calcined at 900°C (CoFe_2O_4) or 950°C ($\text{CoMn}_{0.2}\text{Fe}_{1.8}\text{O}_4$) for 5 hours, in air. The so calcined material was wet milled in ball mills for 16 hours. To obtain ferrites powders by the wet methods (coprecipitation and oxidation) the raw materials ($\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$, $\text{CoSO}_4 \cdot 7\text{H}_2\text{O}$, $\text{MnSO}_4 \cdot \text{H}_2\text{O}$ reagent grade) were dissolved in suitable proportions in water. The hydroxides were coprecipitated by adding a solution of 2N NaOH. The precipitates were then gradually oxidized by bubbling air at 80°C and $\text{pH} > 11$, for 8 hours. These powders were washed, filtered and dried at 80°C. The fine-divided ferrite powders were pressed into disk and toroidal shapes. The green density of all specimens was $> 55\%$ of the theoretical one ($\text{dRX} = 5.30 \text{ g/cm}^3$). Successive sets of specimens were sintered in a box furnace in air, for 5 hours at temperatures in the range 1050–1300°C.

The microstructure analysis on fractured surface of sintered samples was performed using surface electron microscope (SEM) and the magnetic properties were measured by means of a vibration sample magnetometer (VSM). The magnetostrictive properties were measured by strain gauge methods both in parallel and perpendicular to the applied magnetic field direction. Refinement the X-ray diffraction data show that the samples are mainly composed of spinel phase. Samples obtained by wet method are mono-phase system, while the other samples studied are two-phase system, as commonly obtained when solid state ceramic technique is used to get spinel ferrites [1]. The hematite content of the stoichiometric cobalt ferrite sample sintered by conventional ceramic method is bigger (13,10%) than the hematite content of the manganese substituted cobalt ferrite sample sintered by the conventional ceramic methods. Lattice parameters of studied samples are near to theoretical value for CoFe_2O_4 of 8.38 \AA [2]. The data obtained from MS lead to the conclusion that iron is present in the Fe^{3+} oxidation state, according to the isomer shift value. The SEM analysis confirmed the XRD data. In the micrographs of the sintered stoichiometric cobalt ferrite samples obtained by conventional ceramic method was observed large hematite particles having an average grain size of 13 microns distributed as islands between the spinel phase particles. The cobalt ferrite particles have, after the sintering process, a sub micron average grains size. In the micrographs of the manganese substituted cobalt ferrite, obtained by conventional ceramic method, the grain size distribution is more uniform and the hematite islands are rarely observed. In this case the average grain size is of few microns. The magnetostrictive properties shown in Figs. 1 depends on the microstructure of the samples. The samples sintered from conventional ceramic powders in the same condition as the sintered samples started from coprecipitated powders have very small specific magnetization values. The coercive field values for the samples sintered by the conventional ceramic method are bigger than the values of the coprecipitated samples. The specific magnetization threefold increased from 55 emu/g to 179 emu/g for the stoichiometric ferrite samples obtained from conventional and coprecipitated powders respectively. In the manganese substituted cobalt ferrite case the specific magnetization increased only twice, from 77 emu/g to 168 emu/g. The

most important purpose of the manganese substitution of the iron cations is the decrease of the Curie temperature [3]. As results of the iron cations substitution the values of the maximum of the magnetostrictive coefficient decreased. For the samples obtained from conventional powders the decrease is more evident as in the case of the samples started from coprecipitated powders. Although of this decrease of the maximum value of the magnetostrictive coefficients, the ferrites sintered from coprecipitated powders are very good candidates for magnetostrictive sensors application due to the high specific magnetization and low coercive field values. The best candidates for magnetostrictive sensors are the manganese substituted cobalt ferrite samples also characterized by lower values of the Curie temperature.

Nonequilibrium cation influence on the Néel temperature in ZnFe₂O₄.

I. Al-Omari¹, H. M. Widadallah¹, F. R. Sives², S. J. Stewart^{1,2}

The equilibrium cation distribution in ZnFe₂O₄ can be altered by employing nonequilibrium methods of synthesis and/or by reducing the ZnFe₂O₄ characteristic length down to nanometric ranges. As a consequence, the nonequilibrium distribution brings about changes in its long-range magnetic ordering that goes from antiferro, cluster-glass to ferrimagnetic state as the inversion, i.e. the fraction of tetrahedral A sites occupied by iron, increases [1,2]. The study of the magnetism of disordered ZnFe₂O₄ has been predominantly focused on its low temperature behavior and, to our knowledge, only one work has reported on its magnetization above ambient conditions [3]. A ferrimagnetic ordering has been reported to occur in disordered nanosized zinc ferrites below $T_N \approx 460$ -490 K. However, no studies have been performed in this system to determine how the ordering temperature T_N depends on the inversion or particle sizes.

To this aim we present here results on the temperature dependence (above 295 K) of the magnetization of ZnFe₂O₄ nanoferrites having different degree of inversion (c from 0.05-0.5) and sizes (6-50 nm) (Fig. 1). The maximum temperature achieved (610 K) was selected as a compromise between avoiding to surpass the stability region of the disordered state and being able to include a temperature region where the net magnetization were negligible. The sample shows a net magnetization in the 400 to 510 K range that mainly depends on the degree of inversion. Further, the reciprocal magnetization deviates from different temperature values of the linear behavior showed at high temperatures (inset Fig 1.). Our results show that, contrary to similar nanoferrite systems [4], a simple scaling law cannot be applied to explain the T_N dependence with the grain sizes. This can be interpreted due to the lack of correlation between size and inversion that occurs in ZnFe₂O₄ [5] and the strong T_N dependence on the JAB interaction strength [6]. These results will also be compared with theoretical predictions about T_N found by assuming a random distribution of superexchange interactions.

Synthesis and magnetic properties of surface coated magnetite superparamagnetic nanoparticles.

K. Kim¹, M. Kim², Y. Choa², Y. Cha¹, T. Hwang¹, D. Kim¹

1. Dept. of Physics, Yeungnam University, Gyeongsan, South Korea; 2. Dept. of Chemical Engineering, Hanyang University, Ansan, South Korea

Superparamagnetic (SPM) iron oxide nanoparticles and their surface modification have been widely used experimentally numerous biomedical applications such as magnetic resonance imaging contrast enhancement, cell separation, tissue repair, detoxification, drug delivery and hyperthermia, etc. [1]. Therefore, we investigated the synthesis and magnetic properties of the magnetite nanoparticles and the surface coated nanoparticles, respectively. The magnetite nanoparticles were synthesized by the coprecipitation method. $\text{FeCl}_2 \cdot 4\text{H}_2\text{O}$ and $\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$ ($\text{Fe}^{3+} : \text{Fe}^{2+} = 1 : 2$) were dissolved in deionized water under nitrogen with vigorous stirring at 80°C and then the magnetite nanoparticles were obtained by adding NH_4OH was added to the solution. A 3-thiopheneacetic acid (3TA) surface modification can introduce a dense and thin outer carboxylic acid group shell through a polymerization reaction. Therefore, the magnetite nanoparticles were encapsulated with 3TA. The 3TA was diluted to 2 mM by acetonitrile. A 1 g amount of magnetite nanoparticles was added into the 10 ml of 3TA solution with stirring for 30 min. And KMnO_4 solution (2 mM) was dropped into it with stirring at 80°C for 30 min. The solution was washed with ethanol for five times by magnetic separation.

Figure 1 (a) and (b) show the SEM images for morphology and the size distribution of the Fe_3O_4 nanoparticles and the surface modified with 3TA polymerization. The Fe_3O_4 and the 3TA coated Fe_3O_4 nanoparticles were spherically dispersed well. Figure 1 (c), (d) and (e) show the TEM, HRTEM images and the diffraction pattern of the magnetite nanoparticles. The average particle sizes are ~ 12 nm with fcc crystalline structure. In order to characterize the magnetic behaviors, the magnetic nanoparticles were measured by PPMS (Physical Property Measurement System) with the temperature range of 5 K to 300 K. The temperature dependence of the zero-field-cooled (ZFC) and field-cooled (FC) magnetizations of nanoparticles are shown in Fig. 2. The maximum in the ZFC curve defines the blocking temperature (T_B), where the thermal energy becomes comparable to the anisotropy energy barrier. T_B of uncoated and 3TA coated Fe_3O_4 exhibit ~ 245 K and ~ 220 K, respectively, which means the average particle size of 3TA coated Fe_3O_4 nanoparticles is a little bit smaller than those of uncoated Fe_3O_4 [2]. The calculated average nanoparticle size of uncoated and 3TA coated Fe_3O_4 are obtained 10 nm and 8.9 nm, respectively, which can be predicted by Langevin function and ZFC curves [3]. As it is well known, above T_B , SPM particles become thermally unstable and the magnetizations exponentially decrease. Figure 3 (a) and (b) show the magnetization curves with the function of temperature for uncoated and 3TA coated Fe_3O_4 nanoparticles, respectively. The magnetization curves for uncoated and coated Fe_3O_4 show the typical SPM behavior above T_B . The values of magnetization (at 3 Tesla) of 3TA coated Fe_3O_4 nanoparticles are smaller than those of uncoated Fe_3O_4 as shown in Fig. 3 (c). It implies that Fe_3O_4 with coated 3TA are a little bit smaller than those of uncoated Fe_3O_4 , which the reason would be resulted from the dead layer due to the interaction between core and shell interface. This result is consistent with that of ZFC magnetization results shown in Fig. 2 (a) and Stoner-Wohlfarth theory [4], which predicts an increase of the anisotropy energy barrier and, consequently, an increase of the T_B as the volume of the nanoparticles increase. Figure 3 (d) shows the coercivities which are decreased to nearly zero above T_B . Below the T_B , the coercivity as a function of temperature follows well the linear relation

[3]. As results, 3TA coated Fe_3O_4 nanoparticles were magnetically stable and dispersed well for biomedical applications.

The series RFe_6Ge_6 (R=rare earth) is a part of the family of AB_6X_6 compounds where A=Li, Mg, Sc, Nb, Y, Zr, Hf, B=Fe, Co, Ni, Mn, and X=Ge, Si [1]. The crystal structures are based on the SnCo-type (B35) hexagonal structure, which can be visualized as a sublattice of Co_6 hexagons (Kagomé planes) in a hexagonal sublattice of Sn atoms. The AB_6X_6 structures come out of the insertion of A atoms on the Sn-Sn axes (c-axis of B35). In the HfFe_6Ge_6 -type, the substitution is complete on alternating FeGe units, with $a=a_h$, $c=2c_h$ (h standing for the CoSn(B35) unit cell), with a single Fe crystallographic site.

The RFe_6X_6 (X=Ge,Sn) compounds (R=Y, Gd-Lu) show unusual magnetic properties. In contrast to most rare-earth intermetallics, the Fe and the R sublattices are magnetically independent. While the Fe sublattice orders antiferromagnetically at about 485 K for the X=Ge and about 555 K for X=Sn, the R sublattice orders at much lower temperatures, from 3 K for ErFe_6Ge_6 and 45 K for GdFe_6Sn_6 [1]. The magnetic structure of the Fe sublattice consists of ferromagnetic hexagons with the magnetic moments along the c_h axis, which are antiferromagnetically coupled along this axis. The absence of coupling between both sublattices is due to a net cancellation of the R-Fe exchange at the rare-earth sites [3]. In some cases (R=Ti, Zr, Nb, Yb, Ho), the magnetic structure shows some magnetic moments deviated from the c_h axis at low temperature, as in the parent compounds FeGe. It has been claimed [4], that in compounds where there is no magnetic order of the R sublattice (the 3d, 4d, 5d metals and Yb), the values of the hyperfine field values classify in valence values of the R atoms, which has been attributed to hybridization of the Fe d states with the d valence states of the R metal. In fact, also the compounds where the R sublattice orders magnetically (Gd-Er) fall into the same valence dependence [2]. In the present work, we have followed the magnetic behaviour of the dilutions $\text{Hf}_{1-x}\text{R}_x\text{Fe}_6\text{Ge}_6$ (R=Gd and Dy), where we have mixed trivalent and tetravalent atoms and the full rare-earth counterpart orders magnetically at low temperature.

Magnetization, ac magnetic susceptibility and ^{57}Fe Mössbauer spectroscopy experiments from 4.2 K to room temperature have been performed on $\text{Hf}_{1-x}\text{Gd}_x\text{Fe}_6\text{Ge}_6$ ($x=0, 0.4$ and 1) and $\text{Hf}_{1-x}\text{Dy}_x\text{Fe}_6\text{Ge}_6$ ($x=0, 0.5$ and 0.7). While the Gd sublattice of GdFe_6Ge_6 ($x=1$) orders magnetically at 29.3 K [2], a dilution of $x=0.4$ shows the same magnetic order at 10.5 K (Fig. 1). The Mössbauer spectra are shown in Fig. 2. The spectra of HfFe_6Ge_6 displays a sextet with asymmetric peaks below 50 K, which can be analysed as a fraction γ of Fe magnetic moments deviated from the c_h axis, as described in Ref. [5]. In contrast, GdFe_6Ge_6 shows a single sextet of symmetric peaks of small linewidths. The intermediate composition ($x=0.4$) also shows a sextet of symmetric peaks, but with linewidths of ≈ 0.4 mm/s at all temperatures. Similar spectra have been found in $\text{Hf}_{1-x}\text{Dy}_x\text{Fe}_6\text{Ge}_6$. The broadening of the diluted compounds can be produced by a disordered environment of the Fe sites as Gd/Dy substitute for Hf, which would mask a slight deviation of the magnetic moments, if there is any. The substitution of Hf by Dy or Gd decreases the hyperfine field values, B_{hf} , an effect which is slightly more pronounced in the case of Dy. The observed behaviour of B_{hf} in the $\text{Hf}_{1-x}\text{R}_x\text{Fe}_6\text{Ge}_6$, R = Gd and Dy, series can be explained with a combination of two effects. On one hand, since Hf is tetravalent whereas Gd and Dy are trivalent, the progressive substitution of Hf by Gd or Dy leads to a depletion of the d valence band of the R sublattice. Consequently, the Fe magnetic moment and the hyperfine magnetic field decrease when x increases. On the other hand, due to the lanthanide contraction, the 5d(Dy) states are more localized than the 5d(Gd) states. As a result, the hybridiza-

tion with the 3d Fe states is weaker in the Dy case, and the decrease of B_{hf} upon the Dy substitution is more pronounced.

Mössbauer study of iron sulfide nano-compound.

S. Hyun, I. Shim, C. Kim

Physics, Kookmin University, SEOUL, South Korea

Introduction

The Fe–S system has been studied to investigate a complex phase diagram by many researchers [1]. The iron (II) sulfide (FeS) has been much interested for the phase stability and physical properties under high pressure and temperature [2,3]. Stoichiometric iron (II) monosulfide (FeS), troilite has a hexagonal close packed structure with antiferromagnetic ordering at room temperature. It undergoes α transition into the ideal (NiAs) hexagonal structure which includes the pyrrhotites (Fe_{1-x}S) between 120 ~ 140 °C [1,4]. Besides, pyrrhotites (Fe_{1-x}S) show ferrimagnetic behavior due to unbalanced ferromagnetic coupling. In this paper, we report the ferrimagnetic behavior of nanocompound iron(II) monosulfide (FeS) at room temperature.

Experiments

The iron sulfide, FeS, was fabricated using a polyol method. The sulfur solution was the first prepared with sulfur powder and oleylamine. Iron(III) acetylacetonate was mixed in oleylamine for 30 min. under vacuum, then heated up to 80 °C to clearly dissolve it and maintained for 30 min. under Ar atmosphere. It reheated up to 340 °C and injected rapidly the sulfur solution under Ar atmosphere. Then, it cooled down to room temperature.

The phase purity and crystallinity of synthesized sample were characterized by X-ray diffraction (XRD) measurements using $\text{CuK}\alpha$ radiation ($\lambda = 1.5406 \text{ \AA}$). Mössbauer spectrometer of the electromechanical type with a 50 mCi ^{57}Co source in Rh matrix was used in the constant-acceleration mode. The Mössbauer parameters were obtained by a least-squares fitting program assuming Lorentzian line shapes. The magnetizations were measured by using a vibrating sample magnetometer (VSM).

Results and discussion

XRD was used to confirm the crystal structure and crystallographic parameters of FeS nanocompound, as shown in Fig. 1. An analysis of XRD patterns by Rietveld refinement method using FULLPROF program shows that the sample has a troilite hexagonal structure (space group $P-62C$) with a lattice constant $a_0 = 5.985 \pm 0.001$, $b_0 = 5.985 \pm 0.001$ and $c_0 = 11.658 \pm 0.001 \text{ \AA}$.

The hysteresis loop measured using VSM with maximum applied field 1 T at room temperature shows the ferrimagnetic behavior as shown in Fig. 2. The saturation magnetization (M_s) and the coercivity (H_c) values of the sample are found to be 1.8 emu/g and 251.1 Oe, respectively.

The Mössbauer spectra of FeS nanocompound were taken at various temperatures ranging from 4.2 to 295 K to understand localized nearest neighbor effects on effective field, as shown in Fig. 3. We notice that the Mössbauer absorption spectrum shows 2-sextets at room temperature, while it shows a clear 1-sextet at 4.2 K. We conclude that FeS nanocompound shows ferrimagnetic behavior at room temperature as pyrrhotites (Fe_{1-x}S) by analysis of Mössbauer spectrum. This is consistent with the result of hysteresis loop obtained by VSM measurement, too. The isomer shift value at room temperature is found to be $(0.60 \sim 0.64) \pm 0.01 \text{ mm/s}$, relative to the Fe metal, which are consistent with the Fe^{2+} valence state. The ferrous character of the Fe ions is also manifested by the magnitudes of the magnetic hyperfine fields: the magnetic hyperfine field of FeS nanocompound is approximately $327 \pm 5 \text{ kOe}$ at 4.2 K, which corresponds to ferrous ion.

Metal-oxide ferromagnetic granular films, such as Co-Al-O, Fe-Si-O, and Co-Sm-O, exhibit high electric resistance and high permeability at high frequencies; therefore, these films have the potential to be used for integrated thin-film inductive elements and electromagnetic shielding films. We reported that Co-Ce-O [1] and Fe-Ce-O [2] films were successfully deposited by the electrochemical method. In this study, ferromagnetic metal-insulated polymer composite films were synthesized from the reaction solution containing metal cation and water-soluble resin by a newly developed electrochemical method called the "metal-polymer co-electrodeposition method". Ferromagnetic metal cobalt (Co) is deposited by an ordinary metal reduction reaction. $\text{Co}^{2+} + 2\text{e}^- \rightarrow \text{Co}$. On the other hand, polymer resin is deposited combined with hydroxide ions near the cathode, which is generated by the electrolysis reaction of the water. $2\text{H}_2\text{O} + 2\text{e}^- \rightarrow \text{H}_2 + 2\text{OH}^-$. $(\text{Resin})_3\text{NH}^+ + \text{OH}^- \rightarrow (\text{Resin})_3\text{N} + \text{H}_2\text{O}$. Metal-polymer composite film was deposited galvanostatically at -1.3 mA/cm² from the reaction solution containing 10 - 50 mM cobaltous acetate, 20 - 100 mM glycine, 2.5 ml/l water-soluble resin, adjusted pH 7.0 by DMAE and maintained at 333 K. It became clear that uniform stirring of the reaction solution was important to obtain an even film. The FT-IR spectrum (Fig. 1) of the deposited composite films matched that of the film deposited from the reaction solution containing only water-soluble resin. Electric resistance of the films deposited from Co concentration less than 30 mM showed over 30 MΩ. The deposited films showed the ferromagnetic hysteresis loop. Figure 2 shows the coercivity dependence on the Co concentration in the reaction solution. Coercivity decreased by increasing the Co concentration below 20 mM. On the other hand, coercivity increased by increasing the Co concentration above 30 mM. Figure 3 shows the X-ray diffraction pattern of the deposited films. Diffraction peaks attributed to hcp Co, and In₂O₃ (ITO substrate) were observed from the films deposited from the Co concentration above 35 mM. However, only In₂O₃ peaks were observed from the films deposited at a Co concentration less than 30 mM. These results suggest that the microstructure of the Co-polymer films changed at around Co concentration 30 mM. Figure 4 shows the XPS profile of Co 2p for the film prepared from the reaction solution containing Co concentration 30 mM. The Co 2p_{3/2} peaks that coincided with Co in metallic Co were observed. This result suggests that films containing ferromagnetic metal and polymer resin with high electric resistance were successfully prepared using the electrochemical method.

Soft magnetic composites are becoming competitive for applications in electrical machines and actuators, due to the improvement of their magnetic properties [1]. These materials are constituted of insulated iron powders, compacted through high compressive stress, leading to heterogeneous media having a granular nature. The presence of intergranular induced currents can affect the material behaviour and, particularly, the magnetic losses.

The analysis of devices including soft magnetic composites requires the knowledge of their effective electric and magnetic properties, which are influenced by the properties of the constituents, the interaction between them and the geometrical configuration. Well-known rules for determining the effective properties are the Maxwell–Garnett and the Bruggeman formula, valid under the assumptions of elliptical and spherical inclusions, and of linear magnetic properties [2]. Approaches based on energetic considerations have been also proposed and extended to nonlinear magnetic properties [3]. A more general framework consists in the application of the multiple scale expansion technique to the Maxwell equations, without limitation to inclusion shape and constituent properties. A homogenisation technique based on the multiple scale expansion theory has been applied by the authors to heterogeneous linear materials [4]. Recent extension to nonlinear media have been proposed for magnetic flux driven problems, where the role of nonlinearity is included in the right-hand side of the differential problem equation and it is handled by a simple spatial average of the magnetic nonlinear characteristics of the constituents [5].

In this paper a novel formulation is proposed and applied to a current driven electromagnetic field problem, where the nonlinearity is included as an argument of the second-order differential operator. Thus the homogenisation process leads to the evaluation of effective nonlinear magnetic characteristics, which depend on the inclusion shape and dimension. The stochastic nature of the composite material is approximated by a fine periodic structure, identifying a basic elementary cell constituted of the inclusion and the surrounding non-magnetic layer. Nonlinear field problems are solved on the elementary cell, introducing the properties of the constituents, in order to determine a tensor of homogenized equivalent magnetic curves. The result of this procedure is the definition of an equivalent homogeneous material, having effective electrical conductivity and nonlinear magnetic curve, to be used in finite element field computations, with a significant reduction of the required computational burden.

In the results here reported, the ferromagnetic particle is assumed to have a cubic shape with side s_p equal to 0.05 mm or 0.2 mm (see Fig. 1). The particle is constituted of pure iron, with electrical conductivity equal to 10 MS/m and B-H curve reported in Fig. 2. The nonmagnetic layer around the particle has low conductivity (10 S/m) and variable thickness s_{layer} (from 0.2 μm to 1 μm), leading to interparticle conductivity of the order of the experienced values [1]. The homogenized electrical conductivity σ_e is plotted in Fig. 1 against the layer thickness, and the homogenized B-H curves are reported in Fig. 2 for different values of particle size and layer thickness.

In the full paper, the mathematical formulation will be described in details and applied to the analysis of the influence of the inclusion shape and dimension on the effective electrical conductivity and nonlinear properties of the soft magnetic composite.

Hexaferrites have physical and chemical properties that make them very attractive for some technological applications. They have high saturation magnetization, high magnetic anisotropy and good chemical stability. Strontium hexaferrite $\text{SrFe}_{12}\text{O}_{19}$, in particular, exhibits high coercivity due to the existence of a large magnetocrystalline field in this material. The coercive field H_C does also depend on the microstructure of the material which, in turn, is influenced by the techniques used to prepare the sample. Therefore, a good control of the structural properties of the samples are necessary to optimize their magnetic properties. Furthermore, there are applications that require nanoparticles within the single magnetic domain regime and with a narrow particle size distribution. Strontium and barium hexaferrite, for instance, has been used in the preparation of permanent magnets and in plastic-ferrite materials, in magnetic recording media and in microwave devices [1,2]. The conventional solid state reaction route used to prepare powders of hexaferrite make use of heat treatments at temperatures above 1000 °C [3]. This technique yields particle size distributions that are coarser than those obtained using the ionic coordination reaction (ICR) technique, for instance.

In the present work, the formation of nanocrystalline strontium hexaferrites $\text{SrFe}_{12}\text{O}_{19}$ using a new route of an ICR technique was carefully investigated. In this processing, the biopolymer chitosan was used as a nanoreactor. Chitosan is an aminopolysaccharide extracted by a deacetylation procedure from chitin, the most abundant biopolymer in nature after cellulose. It is characterized by a high nitrogen content in the amino group which is mainly responsible for its ability to react with several types of metal ions through ionic coordination processes. The ICR technique is also attractive because of its low-cost, low-temperature synthesis, high homogeneity and a simple processing. The obtained precursor powders were calcined at temperatures in the range 600-900 °C. The amount of the hexaferrite phase present in each sample was determined using X-ray diffraction and from Mossbauer data. It was observed that the average particle size increases as the calcination temperature T_0 is increased. In particular, the Rietveld refinement analysis yielded 41.6 nm for the sample calcined at 900 °C. This value is in good agreement with the one obtained from the SEM images.

The Mossbauer spectra were fitted to Lorentzian curves using a least-squares computer program. Five Lorentzian sextets corresponding to five non equivalent sites in the hexaferrite phase and one Lorentzian sextet corresponding to hematite were used to fit the samples calcined at 800 and at 900 °C. For the sample calcined at 600 °C, it was also necessary to add two Lorentzian sextets corresponding to the maghemite phase. For the sample calcined at 700 °C, it was only necessary to add one maghemite Lorentzian sextet to fit the spectrum. The observed isomer shifts are in the range 0.10-0.28 mm/s relative to metallic iron indicating that the ionic state of iron ions on the five sites is ferric Fe^{3+} . In the M-type hexagonal structure of $\text{SrFe}_{12}\text{O}_{19}$ the Fe^{3+} ions occupy five different crystallographic sites: three are octahedral sites, one site is tetrahedral and one is trigonal bi-pyramidal. The point symmetry of these sites is consistent with an asymmetry parameter $\eta=0$, and

an electric field gradient tensor with its principal axis parallel to the c-axis. The quadrupole splitting of the trigonal bi-pyramidal site was found to be substantially large because of its strongly distorted environment.

The hysteresis loop for the sample calcinated at 600 °C showed a behavior characteristic of a mixture of hard (Sr-hexaferrite) and soft (maghemite) magnetic materials. However, the magnetization measurements yielded squared hysteresis loops for the samples annealed at and above 700 °C. The overall results indicate that the particles in these samples are in the single domain regime. This is also supported by the theoretical models used to describe uniaxial single domain particle systems. For Sr-hexaferrite, the critical diameter D_{crit} of a spherical single domain particle is 940 nm. Moreover, the value for H_C at room temperature for a system of randomly distributed single domain $\text{SrFe}_{12}\text{O}_{19}$ particles under reverse magnetization is 6.70 kOe. This value is based on the coherent rotation Stoner-Wohlfarth model. As reported above, the values for the average particle size obtained for our samples are much less than the D_{crit} for an ensemble of $\text{SrFe}_{12}\text{O}_{19}$ particles. Besides, the theoretical value for H_C is close to the values obtained experimentally from our magnetization data (6.48 kOe). Furthermore, the ratio M_r/M_s ($= 0.58$) for the samples annealed at and above 700 °C does also agree with the theoretical ratio ($=0.5$) calculated for a system of randomly distributed single domain particle. These results are also in good agreement with the ones obtained from transverse susceptibility measurements. Thus, based on experimental results and on the framework of Stoner-Wohlfarth based models one can conclude that the magnetization reversal in these particles is mainly due to coherent rotation.

Tunnel spin-polarization of low-work-function ferromagnets.

R. Patel, B. Min, S. Dash, M. de Jong, R. Jansen

MESA+ Institute for Nanotechnology, University of Twente, Enschede, Netherlands

The magnetic tunnel junction (MTJ) is a central element in many spintronic devices and applications. As such, it is crucial to be able to control the tunnel spin-polarization (TSP), while simultaneously achieving a proper resistance area (RA) product matched to a particular application. The requirement for low resistance MTJs pushes the tunnel barrier thickness to the limit where pinholes become an issue. Also, in spin tunnel junctions to semiconductors, for example for spin-injection and detection in spin-transistors, it is paramount to obtain contacts that have a high tunnel spin-polarization, as well as the proper resistance. In order for a spin-MOSFET to exhibit any sizeable magnetoresistance, the RA product of the magnetic source and drain contacts needs to be in a rather narrow window, and it was recently shown that Schottky barrier formation is a severe obstacle in achieving the proper RA product in contacts with conventional transition-metal ferromagnets [1,2]. To solve this issue, a novel approach to control the RA product of spin-tunnel junctions was recently developed [1], involving the introduction of an ultrathin (sub-nm) interlayer of a ferromagnetic material with a low-work-function at the tunnel interface of FM/Al₂O₃/Si spin tunnel contacts.

Here, we further examine the effect of such a low-work-function interlayer on the TSP using metal MTJs of the form Co/Al₂O₃/X/Ni₈₀Fe₂₀, where X is a material with low-work-function for which we have used Gd (3.1eV), Gd/Co bilayers, or Yb (2.6eV). These studies provide valuable insight into the effect of such an interlayer on the TSP, and simultaneously allows one to probe the interaction of the (spin of the) conduction electrons of rare-earth elements with transition-metal ferromagnets.

In figure 1 we see that the TSP for Al₂O₃/Gd/Ni₈₀Fe₂₀ interfaces decays with Gd thickness, but is always positive. The situation is different for the junctions with a Gd/Co bilayer of total thickness of 1 to 1.2 nm introduced between the Al₂O₃ and the Ni₈₀Fe₂₀. In that case, depending on the relative thickness of the Gd and Co in the bilayer, the TMR was found to be either positive (for large Co content) or inverted to a negative sign (at large Gd content, bottom right panel of figure 2). Since for Gd the 5d and 6s conduction electrons, rather than the localized 4f electrons, are expected to dominate the tunneling process, the difference reflects the nature of the coupling between the 5d/6s conduction electrons of Gd with Ni₈₀Fe₂₀ or Co, respectively. The negative TSP observed in figure 2 is consistent with an antiferromagnetic coupling of the Gd 5d and 6s electrons to Co. Figure 3 shows the TSP versus temperature for MTJs with an Al₂O₃/Yb(0.8nm)/Ni₈₀Fe₂₀ top electrode. The Yb was chosen because of its very low work-function, but also because it has a closed 4f shell with no magnetic moment. We find that the TMR decreases with insertion of the Yb interlayer, but more rapidly in comparison with a Gd interlayer. At 10K, the TMR is reduced to 15% for 0.8 nm of Yb, while for thicker Yb layers the TMR rapidly decays to zero.

Strain dependence of magnetoresistance in magnetostrictive magnetic tunnel junctions.

J. G. Deak

Advanced Technology, NVE Corporation, Eden Prairie, MN

The strain (ϵ) dependence of magnetoresistance (MR) was studied in various magnetic tunnel junctions (MTJ) utilizing magnetostrictive freelay materials. The MTJs had similar bottom pinned layers and Al_2O_3 tunnel barriers. The freelayers differ in composition (CoFeB and Co70Fe30) and thickness (5 nm to 10 nm). The films were deposited on SiN coated Si wafers, which were flexed in order to induce ϵ , similar to a ϵ sensor. [1-3] $R(H)$ was measured under tensile stress (σ) applied parallel to the easy-axis. MR was found to increase by a maximum of about 1% in the Co70Fe30 and 0.5% in the CoFeB devices as the ϵ exceeded 300 ppm. For all devices tested, resistance decreased in the parallel (Rp) and anti-parallel (Rap) orientations as tensile ϵ increased. This effect has not been explained. Various causes for the effect including improved domain alignment and thinning of the tunnel barrier under tensile ϵ due to Poisson's ratio (ν) were studied. Magnetic modeling shows domain reorientation does not produce the correct dependence of resistance on ϵ . Results suggest that the modification of the barrier thickness as σ is applied in the plane of the film must be taken into account.

Figure 1 shows representative $R(H)$ loops for a CoFeB MTJ as a function of applied σ . Note that both Rp and Rap decrease and MR increases as σ is increased. Similar data was acquired on 60 devices, and measured average trends in MR, Rap, and Rp are given in Table 1.

Figure 2 shows a Stoner-Wohlfarth (SW) model including magnetostriction used in an attempt to explain the resistance and MR ϵ dependences. Similar plots were created for varying degrees of misalignment. Here, Rap decreases, Rp increases, and MR decreases as σ is increased. These trends in the magnetic simulation are a result of changing alignment in the layers as ϵ -anisotropy increases. They do not agree with measurement.

In an attempt to better predict the affect of ϵ on the magnetostrictive MTJs transport behavior, the change in the thickness of the tunnel barrier (d) under ϵ was taken into account, and included in a modified Simmon's model. [1,4] Figure 3 shows a plot of Rap, Rp, and MR showing that the correct trends are reproduced using this model.

Although the model could be improved, it does seem to reproduce the correct behavior. The ϵ -dependence of the elastic and inelastic tunneling conductivity should be taken into account in order to further linearize MTJ ϵ sensor response. [1] A better understanding of ϵ -dependence of MTJ transport characteristics might also be used to develop techniques for utilizing ϵ applied during the manufacturing process to improve MTJ performance.

Measurement Summary A summary of the normalized dependence of Rap, Rp, and MR on ϵ .

R(H) MEASURED for an MTJ with 5 nm thick CoFeB freelay. The inset details the relative change in Rap, Rp, as ϵ is increased.

R(H) SIMULATED using SW model with $\lambda=10^{-5}$, $M_s = 1600$ emu/cc, $P=0.5$, and tensile stress applied at 10° to the easy-axis. A pinning field of 500 Oe is assumed. The inset shows normalized changes in Rap, Rp, and MR as ϵ is increased. Magnetic simulation alone cannot reproduce the measured behavior.

A plot of the calculated change in Rap, Rp, and MR for a MTJ using a Simmon's model modified to account for the strain's reduction of barrier thickness. The ν dependent change in the barrier thickness produces the correct trends in Rp and Rap. MR increases less strongly than measurement, but it is consistent with measurement.

Broadband Ferromagnetic Resonance Linewidth Measurements of Magnetic Tunnel Junction Multilayers.

J. Sierra¹, F. Aliev¹, R. Heindl², S. Russek², W. Rippard²

1. Condensed Matter Physics, UAM, Madrid, Spain; 2. NIST, Boulder, CO

Magnetic tunnel junctions (MTJs) are being developed for a large range of applications including magnetic recording sensors, low-field magnetic sensors, magnetic random access memory, and high-frequency spintronics devices [1,2]. The quality of the MTJs depends sensitively on interfacial properties [3,4]. These properties include interfacial roughness, intermixing, oxygen content, which in turn depend on materials used in the stack, deposition conditions, and annealing conditions. Ferromagnetic resonance (FMR) has been shown to be an effective tool to get insight into both the magnetization dynamics and the quality of single ferromagnetic layers, multilayers and MTJs. Here we present broadband FMR measurements in MTJs over a frequency range of 0 to 20 GHz to characterize their dynamic properties.

Our MTJ were fabricated using Al₂O₃ tunnel barriers and CoFeB/NiFe free layers and underwent a sequence of anneals at various temperatures. We have used VNA-FMR technique to determine FMR resonance position and FMR linewidth [5]. We put MTJs covered with a thin layer of photoresistive material on top of a coplanar wave guide (CPW). In this way, FMR of the free layer of the MTJ has been excited in the presence of a permanent in-plane magnetic field (H_b) and by sweeping frequency of the excitation signal from the port 1 of the VNA, that creates the perpendicular RF component of the magnetic field (H_{rf}). The FMR signal was detected by measurements of the transmission to VNA port 2 through the CPW with the specimen on top. All experiments were done at room temperature.

It was found that the FMR linewidth of the free layer is considerably larger than that of an isolated free layer and that the linewidth increases in the regions of the free layer reversal and the fixed layer reversal. The increase in FMR linewidth was correlated with both the magnetization hysteresis curves in unpatterned films and low frequency noise in patterned devices. The large increase in free layer linewidth and its subsequent change upon annealing indicates that considerable disorder, originating in the exchange-biased fixed layer, is transferred to the free layer [6]. In addition, we have found that the regions of increased linewidth, as with the regions of increased $1/f$ noise, are history dependent, i.e. depend on the starting magnetic state of the MTJ. We show that the increase in FMR linewidth is a simple and effective method of monitoring the disordered magnetic structure, interfacial roughness, and the improvement during the annealing process. Hence, the study of FMR linewidth of the free layer of MTJs may be a useful diagnostic on the quality of the MTJs being developed for a variety of applications.

Introduction:

A double barrier magnetic tunnel junction (DMTJ) has been introduced to suppress the bias voltage dependence of tunneling magnetoresistance (TMR) ratio. Because in the DMTJ, the voltage is divided between two tunnel barriers, and thus, the reduction of the TMR ratio at a given bias is smaller than that in the single barrier MTJ. In the DMTJ, however, top barrier flattening is one of the most important issue because the metallic polycrystalline free layer over the bottom tunnel barrier is difficult to grow uniformly, and consequently, the top barrier interface became rough [1]. To resolve this problem, we introduced an amorphous magnetic CoFeSiB to retard the columnar growth resulting in a wavy interface.

Experiment:

The DMTJ structure consisted of Ta 45/Ru 9.5/IrMn 10/CoFe 7/AlOx/free layer 7/AlOx/CoFe 7/IrMn 10/Ru 60 (nm). Various free layers such as CoFe 7, CoFeSiB 7, and CoFe 1.5/CoFeSiB 4/CoFe 1.5 were prepared by a six-target rf magnetron sputtering system under typical base pressure below 5×10^{-8} Torr. A magnetic field of 100 Oe was applied during deposition to induce the uniaxial magnetic anisotropy in ferromagnetic layer. Tunnel barriers were formed by oxidizing 1.0 nm thick Al layers under rf plasma environment in a load lock chamber. The $10 \mu\text{m} \times 10 \mu\text{m}$ junctions were fabricated by a photolithographic patterning procedure and ion beam etching.

Results and Discussion:

In order to make a close examination of the morphology of the DMTJs, the samples were examined by high-resolution TEM (HRTEM) focusing on the tunnel barriers. Fig. 1 shows the HRTEM images of the DMTJs consisting of (a) CoFeSiB 7 (b) CoFe 1.5/CoFeSiB 4/CoFe 1.5, and (c) CoFe 7 (nm) free layer. The top tunnel barrier of Fig. 1 (a) and (b) were smoother than that of Fig. 1 (c). The absence of grain boundary in amorphous CoFeSiB layer appeared to retard the columnar growth that would otherwise resulted in wavy barrier interface, therefore in comparison with the CoFe-used one it offered smoother surface roughness.

The magneto-transport properties of DMTJs depending on the free layer structure are summarized in Table 1. The normalized TMR ratio at applied voltage of ± 0.4 V and V_h (voltage where the TMR ratio becomes half of its nonbiased value) values in CoFeSiB 7 nm free layered DMTJ are larger than that of the other structure. By using the CoFeSiB layer, the asymmetry of the normalized TMR curves at ± 0.4 V became smaller compared to the CoFe used one and in case of the full CoFeSiB free layer, the asymmetry was negligible. This result can be attributed to the fact that the top portion of the DMTJ structure, including the top barrier, was more uniform and less defective due to the amorphous layer.

When the CoFeSiB layer thickness increased, the interlayer coupling field (H_i) decreased. Because the H_i is relevant to the ferromagnetic interaction across the tunnel barrier, a junction with smoother barrier interfaces would offer a lower H_i .

The presence of the amorphous layer appears effective in terms of achieving flat and uniform top tunnel barrier. For reducing the H_i and suppressing the bias voltage dependence of the TMR ratio, the smooth free layer/tunnel barrier is indispensable.

Appearance of a tunneling spectrum peak by electrical breakdown of tunneling junction.

K. Horikiri, K. Shiiki

Applied Physics and Physico-Informatics, Keio University, Yokohama, Japan

Recently, there has been considerable interest in using tunneling junctions in applications such as magnetic disk storage systems,[1] magnetoresistive random access memories,[2] Josephson junctions.[3] However, the very thin insulator of tunneling junctions suffers from electrical breakdown by voltage stress. Thus, reliability is an important issue for device applications. Although it is known that the tunnel resistance of a junction is reduced by an electrical breakdown,[4,5] the mechanism of electrical breakdown is not clear. Inelastic electron tunneling spectroscopy is a powerful tool for detecting very small changes in current-voltage (I-V) characteristics of devices.[6, 7] In this present study, the breakdown mechanism of tunneling junctions was investigated by obtaining tunneling spectra.

Tunneling junctions of Co (10 nm) /AlOx /Co (50 nm) and Al (100 nm) /AlOx /Al (100 nm) were fabricated on a glass substrate by ion-beam sputtering. The bottom electrode was deposited in the shape of a stripe using a metal mask. A 2.5-nm-thick Al layer was then deposited on the electrode. The insulator AlOx was formed by thermal oxidation in pure O₂ at 200 °C for 24 h. The top electrode was deposited on the AlOx crossing for the bottom electrode. The I-V characteristics of the junction were measured by the four-probe method. When the applied voltage reached the critical voltage, the tunnel resistance of the junction decreased sharply and electrical breakdown occurred. d^2I/dV^2 spectrum of before and after breakdown junction was measured using a modulation method in liquid N₂. [8]

Figure 1 (a) shows the d^2I/dV^2 spectrum of an as-made junction. A peak was observed near 0.03 V. No other peaks were observable up to 0.3 V. Figure 1 (b) shows the d^2I/dV^2 spectrum of a junction after breakdown. A peak appeared in the spectrum after electrical breakdown. This peak is very sharp and it appears to be made up of several combined peaks. After breakdown, all junctions exhibited a similar peak between 0.07 V and 0.09 V, irrespective of the way in which the voltage was varied. This peak was reproducible. Figure 2 shows d^2I/dV^2 spectra of an Al /AlOx /Al junction at 77 K after breakdown. Before breakdown, the only peak near 0.03 V was observed as same as a Co /AlOx /Co junction. After breakdown, a peak appeared near 0.07 V, as Fig.2 shows. It was confirmed that this peak appeared independent of the electrode and the Al oxide layer of the junction. This peak suggests that a level was created in AlOx by electrical breakdown. When the applied voltage was 0.09 V, an additional current starts to flow through the level. It is thought that this conduction channel is not a band but a level, since the peak is very sharp. It is generally thought that a pinhole is created in an insulator by inducing electrical breakdown in a tunneling junction, and that the current flows through the pinhole.[3, 4, 9] However, a pinhole current does not contribute a sharp peak to the d^2I/dV^2 spectrum. Thus, the results of our experiments suggest that a pinhole mechanism cannot explain electrical breakdown in this case.

Abstract

Mechanical and electrical properties of magnetic tunnel junction (MTJ) are interesting because the right combination of low magnetostriction (λ_s) and high tunneling magnetoresistance (TMR) of a certain type of MTJ can be applied in the read head sensor and magnetoresistance random access memories (MRAMs) fields [1]-[2]. However, those properties of the Co/AlO_x/Co MTJ were less reported before. In this work, the top configuration Co/IrMn was inserted to study λ_s and TMR of the Co/AlO_x/Co junction.

The cross-strip MTJs were fabricated following this sequences: Si(100)/Ta(30Å)/Co(75Å)/AlO_x(δt_o)/Co(75Å)/IrMn(90Å)/Ta(100Å) deposited under an in-plane deposition field (h) = 500 Oe, where δt_o = 12, 17, 22, 26, and 30 Å is the thickness of the AlO_x layer. TMR increases initially from 21% to 36% and then decreases to 24%, as to increases monotonically. This means the spin tunneling is weakened eventually, as to 26 Å. Moreover, λ_s of Co/AlO_x/Co MTJs shows the concave-up feature [3]. We used the nanoprobe energy dispersive x-ray (EDX) equipped in high-resolution sectional transmission electron microscopy (HR X-TEM) to analyze Co, Al, O concentrations across each AlO_x layer. The different concentration dependence along δt_o causes the λ_s feature. In addition, the microstructure of each Co/AlO_x/Co MTJ observed with HR X-TEM (Fig. 1) shows that the interfaces between Co/AlO_x and AlO_x/Co are quite smooth. λ_s of Co/AlO_x/Co MTJs is in general in the range from -23 ppm to -12 ppm. Finally, we find the optimal MTJ in this series has the following properties: TMR = 36% and λ_s = -15 ppm.

Magneto-transport in a single nano-object with a conductive AFM.

P. Zermatten, G. Gaudin, A. Schuhl
SPINTEC, CEA/CNRS, Grenoble, France

Transport measurement is one of the most efficient tools to get insight into the electronics properties of a sample: for example band structure properties in semiconductors or GMR effect in a magnetic stack. When the dimensions of the sample decrease to the nanometer scale, new physics could be involved like coherent electronic properties, enhanced tunnel magnetoresistance, spin transfer effect, In order to perform these measurements, the nano-object must be connected to two electrodes separated by an insulating layer embedding the object. The fabrication process involved is always complicated, expensive and time-consuming. It implies different and successive electronic lithography, etching and planarization steps. Moreover, when nanoparticles are obtained in a dense array, contacting a single particle is often impossible with such a fabrication technique. The particles are too close to each other compared to the size of the electrode so that the measurement is an average over different particles.

We developed a new technique based on the direct contact of a single nano-object by a conductive AFM tip. A commercial AFM has been modified: an external electronic set-up (stable current source and high resolution acquisition cards) is added as well as magnetic coils. A wide range of current from 10nA to 10mA can be applied with magnetic fields up to 1.5kOe and 400Oe respectively for out-of-plane and for in-plane direction. The noise in the detection is mainly due to the stability of the contact. Voltages as small as 10 μ V can be resolved. Two advantages can be outlined. Because the top electrode is directly the metallic tip, the fabrication process is much simpler and involves only one step of e-beam lithography followed by an ion beam etching step. We were able to contact nanopillars as small as 50nm diameter. Moreover, the spatial resolution is given by the tip apex which can be decreased down to some nanometers by FIB machining [1]. Contacting a single nanoparticle inside a dense array is then possible as the distance between the nanoparticles is larger than the tip apex.

First measurements have been performed on nanofabricated pillars. Full epitaxial Fe/MgO/Fe stacks [2] presenting high TMR values were patterned. We clearly evidenced the presence of surface states in the Fe density of state at the interface between the bottom Fe layer and the MgO layer. These interfacial states only appear for the minority electrons and they drastically modify the behavior of the TMR as a function of the applied bias voltage. They are responsible for example of the change of sign of the TMR for a certain bias voltage which could be very interesting for applications. Experiments were also performed on TMR stack with a very thin MgO layer in order to test the sensitivity of the technique. We were able to measure a small TMR signal 0.25% on these very low R.A. structures 0.3 Ohm $\cdot\mu$ m².

One of our goals is to be able to directly contact nanoparticles obtained for example by a chemical way. The behavior of a single particle, not damaged by any fabrication step should give a great understanding on the magneto-transport properties at the nanometer scale. These particles can be very small, less than 10nm diameter, and packed in a dense array. Beside our results on nanofabricated Fe/MgO/Fe pillars we will present the different improvements of our technique to achieve such a goal: optimization of the stability of the AFM head and FIB-machining of the metallic tips to achieve the desired spatial resolution.

The X₂YZ (X, Y = transition metal, Z = main group element) Heusler compounds have attracted scientific and technological interest for their potential use as materials for magneto-electronic devices. Reason is the exceptional electronic structure found in particular in the Co₂YZ Heusler compounds (see [1, 2] and references there). Those compounds are predicted to be half-metallic ferromagnets.

One major research area, where Co₂ based Heusler compounds are used, is on tunnelling magnetoresistive (TMR) junctions. For materials with complete spin polarization, an infinite TMR ratio is expected.

From a TMR junction with both electrodes consisting of Co₂MnSi films, Sakuraba et al measured a TMR ratio of 570% at low and 67% at high temperature [3] compared to 159 % [4] for a Co₂MnSi/AlO_x/CoFe junction at 2 K and about 70% at 300 K. Overall, the drop of the ratio at room temperature

suggests that still an improvement with respect to the temperature stability of the TMR is necessary. This work reports on the detection of the valence band of buried half-metallic ferromagnets by means of hard X-ray photo emission spectroscopy (HAXPES). The measurements have been performed on "half" tunnel junctions that are thin films of Co₂MnSi underneath MgO. Starting from the substrate, the structure of the samples is: MgO(buffer) - Co₂MnSi - MgO(z) - AlO_x(1-2 nm) with a thickness z of the upper MgO layer of 2 nm and 20 nm. The topmost AlO_x layer is for protection of the MgO. Core level and valence band X-ray photo emission have been excited by hard X-rays of about 6 keV energy. Both, core level and valence band spectra have been used to estimate the mean free path of the electrons through the MgO layer to be 19 nm at kinetic energies of about 6 keV. In particular it is shown that the buried Co₂MnSi films exhibit the same valence density of states like bulk samples that is typical for half-metallic ferromagnets.

However, for magnetic materials such as spintronics devices the measurement of the spin and charge is necessary for fully understanding of these materials.

Therefore it is necessary to develop spin polarized high resolution HAXPES.

With the spin dependent measurement one can investigate the spin diffusion length of the materials depending on the barrier and spacer layer material and thickness.

The observation if and how the spin polarisation of the bottom electrode is retained through the MTJs and GMR devices will be possible with this technique.

In summary, this means that spin polarized high resolution HAXPES is a powerful and necessary tool to investigate different materials for tunneling barriers and spacer layers to optimize the structure, configuration and composition of the MTJs and the GMR devices to achieve sophisticated properties and results.

The ability to achieve close to 100% spin-polarised materials is currently a major challenge in the area of ‘spintronics’ research. Such materials will have a huge impact on applications such as MRAM technology and sensors. Recently, large TMR values of 570% at low temperature have been obtained in structures incorporating Heusler alloy electrodes such as Co₂MnSi [1]. These alloys have been predicted to possess a gap in the minority-spin density of states (DOS) at the Fermi level and thus be 100% spin-polarised, i.e. they are said to be ‘half-metallic’ ferromagnets.

The techniques of x-ray absorption spectroscopy (XAS), x-ray magnetic circular dichroism (XMCD), and x-ray magnetic linear dichroism (XMLD) provide an element-specific probe of electronic and magnetic interface states. Here we discuss the results of some recent experiments performed on Co₂MnX/alumina structures (where X is Si, Al), at the Advanced Light Source, Lawrence Berkeley Laboratory. The gap in the minority-spin states leads to a local exclusion of the minority spin electrons around a given atom in half-metallic ferromagnets, i.e. the formation of an ‘ideal’ local moment system despite the delocalised electronic character of the material [2]. In recent work we provided the first experimental evidence of local moments on both Mn and Co atoms in Co₂MnSi/alumina structures as distinct multiplet features in x-ray magnetic circular dichroism (XMCD) spectra [3].

In figures 1 and 2 are shown the XMCD spectra recorded around the Co and Mn L_{2,3} absorption edges for Co₂MnSi (CMS) and Co₂MnAl (CMA) films. From Fig.1 it can be seen that the multiplet features (indicated by arrows) are only observed in the CMS Co spectrum, whilst the CMA Co XMCD more closely resembles that from a Co/Al reference film. However the strongest multiplet feature found in the Mn XMCD spectrum from the CMS film was also observed in the CMA sample, although perhaps reduced in intensity (see Fig.2). Thus, if indeed these multiplet features are evidence of local moment formation then it appears that the Co moments are only localised in the CMS system, whilst the Mn moments are at least partially localised in both CMS and CMA films. Band structure calculations reveal that a minority-spin band gap only occurs for the Co LDOS in the CMS material, whereas both materials have a gap in the Mn LDOS [4,5]. This is entirely consistent with our XMCD results that indicate a more itinerant magnetic character of the Co atoms in the CMA sample, as can be seen by comparison of the XMCD from this sample with a standard metallic Co film.

In contrast to XMCD, the x-ray magnetic linear dichroism (XMLD) is weak in itinerant magnets (around 2% for Co), but many times larger when local moments exist [6,7]. Thus XMLD is an ideal probe of local moment formation in half-metallic ferromagnets. Our preliminary measurements of the XMLD in CMS films showed a substantial effect (~7%) at both the Co and Mn L_{2,3} absorption edges indicating the formation of local moments at both atomic sites. However the effect was substantially reduced at the Co L_{2,3} absorption edge for the CMA sample. This is consistent with the explanation given above for the more itinerant nature of Co in the CMA sample.

Fabrication of magnetic tunnel junctions with Co₂FeSi Heusler alloy and MgO crystalline barrier.

W. Lim, G. Choi, T. Lee

Department of Materials Science and Engineering, KAIST, Daejeon, South Korea

Recently half-metallic Heusler alloys have been studied to achieve higher TMR ratios. Among the predicted half metallic Heusler alloy, Co₂FeSi is an attractive material for spintronic devices due to high Curie temperature of 1100K, high spin polarization and no Mn containing composition[1]. Inomata[2] and Miyazaki[3] already reported 41% for Co₂FeSi/Al₂O₃/CoFe MTJs and 90% for CoFeB/MgO/Co₂FeSi at RT, respectively. In this study, we have obtained high TMR ratio up to 158.4% at RT in CoFeB/MgO/Co₂FeSi MTJs by coherent tunneling.

MTJs with the structure of Ta(5 nm)/Ru(90 nm)/Ta(5 nm)/CoFeB(3 nm)/MgO(2 nm)/Co₂FeSi(5 nm)/(top pinned layers) were deposited by a magnetron sputtering method in the UHV chamber of below 2×10^{-9} torr. Highly-oriented crystalline MgO(001) barrier was deposited by an rf method and examined by x-ray diffraction. Conventional photolithography and ion milling technique were used to fabricate the junctions of $10 \times 10 \mu\text{m}^2$. All the samples were deposited at room temperature and annealed at T_{ann} (200~430°C) for 1 hour in the vacuum chamber of below 3×10^{-6} torr with a magnetic field of 1kOe.

Fig. 1(a) shows annealing temperature dependence of TMR ratio and RA product in CoFeB/MgO/Co₂FeSi MTJs. TMR ratio of CoFeB/MgO/Co₂FeSi MTJ increases gradually up to 350°C. Maximum TMR ratio is 158.4% at 350°C annealing and TMR ratio drops to 78% after 430°C annealing. RA products of the junctions were several $\text{M}\Omega\mu\text{m}^2$. To compare Co₂FeSi electrode with CoFeB electrode in MgO-based MTJs, we fabricate four types of MTJs with alternating stacking sequence of CoFeB and Co₂FeSi electrodes at both sides of MgO barriers. All the samples were annealed at 400°C after depositing at room temperature except the CoFeB/MgO/Co₂FeSi MTJ which showed the best results at 350°C annealing. As shown in Fig. 1(b), annealed CoFeB/MgO/CoFeB MTJ showed very high TMR ratio by coherent tunneling. However, TMR ratio and RA product decrease by using Co₂FeSi electrode even in one side. Furthermore bottom Co₂FeSi electrode shows lower TMR ratio and higher RA product than top Co₂FeSi electrode. This means bottom Co₂FeSi electrode makes some structural problems at both interfaces with the barrier. To analyze this structural difference in MTJs with Co₂FeSi electrodes, we use cross-sectional HRTEM images of annealed MTJs(Fig. 2). CoFeB/MgO/Co₂FeSi MTJ showed CoFeB[100](001)/MgO[110](001)/Co₂FeSi[100](001) epitaxial relationship between both electrodes and barrier and lattice misfit between both electrodes is about 3.5%. This epitaxial relationship made high TMR ratio by coherent tunneling. On the contrary, Co₂FeSi/MgO/Co₂FeSi MTJ showed large lattice misfit (about 6.7%) between both electrodes through Co₂FeSi[110](001)/MgO[100](001)/Co₂FeSi[110](001) epitaxial relationship. The reason of this large misfit may be caused by the fact that the growth of bottom Co₂FeSi electrode follows Cr-buffered MgO substrate but the growth of top Co₂FeSi electrode follows crystalline MgO barrier. This implies that epitaxial relationship between bottom Co₂FeSi electrodes and MgO barrier is locally broken and non-coherent tunneling through the MgO barrier degrades TMR ratios. This part will be discussed in more detail. Similarly very low TMR ratio of Co₂FeSi/MgO/CoFeB MTJ can be also caused by broken epitaxial relationship between bottom Co₂FeSi electrode and MgO barrier. Another reason for the lower TMR ratio for Co₂FeSi electrode may be high degree of antisite disorder in 350°C annealed state[4].

In this study, we have fabricated MTJs with Co₂FeSi Heusler alloy electrode and MgO barrier. Co₂FeSi is predicted to be a highly spin-polarized material, but has shown worse results than amorphous CoFeB electrode with crystalline MgO barrier. In addition, the growth of bottom Co₂FeSi electrode broke epitaxial relationship between electrodes and barrier. Further studies are required to reduce lattice misfit and improve TMR characteristics of Co₂FeSi/MgO/Co₂FeSi MTJs.

Recent research in spintronics has been focused in the fabrication of magnetic tunnel junctions (MTJs) using highly spin-polarized conductive materials as the half-metallic manganites. For achieving this purpose, La-manganites ($\text{La}_{1-x}\text{A}_x\text{MnO}_3$, being A an alkaline divalent earth), with the optimal composition at $x=1/3$, have been integrated into epitaxial heterostructures with (001) cubic orientation, typically grown on SrTiO_3 (STO) substrates. However, it has been demonstrated that intrinsic problems as electronic phase separation and chemical segregation develop in (001) electrodes and (001) multilayers, depressing their magnetotransport properties [1]. The substrate-induced strain and the breakdown of the perovskite plane stacking and polarity discontinuity are claimed to cause these effects which are mostly located near the manganite-substrate interface [2]. Interestingly, heterostructure growth with orientation other than (001) one may suppress these problems and eventually improve device functionality, as both elastic properties and atomic termination (and thus charge) of the corresponding planes will be different. It has been shown that after capping $\text{La}_{2/3}\text{Ca}_{1/3}\text{MnO}_3$ (LCMO) electrodes with STO insulating layers, the depletion of electronic and magnetic properties of (001)LCMO electrodes increases whereas those of (110)LCMO are less sensitive to the STO capping layer. Besides, the magnetic properties of the (110) LCMO are found to be similar to those before capping [3]. Thus, MTJs based on (110)LCMO manganites appear to be promising candidates for obtaining improved magnetotransport properties.

To enhance the functional properties of MTJs based on manganite electrodes, we have fabricated MTJs based on bilayer epitaxial heterostructures of (110) STO/LCMO grown on (110) STO substrates. The magnetization dependence of bare electrodes with (001) and (110) orientation (Figure 1a) show an increase of the Curie temperature and the overall magnetization in (110) ones. We have grown (110) STO/LCMO heterostructures and verified the tunneling transport across nanometric STO barriers using conducting atomic force microscopy (CAFM) [4], determining the tunneling barrier energy along [110] direction. Nanojunctions on the STO//LCMO/STO structure have been fabricated by a nanolithographic process [5] using a CAFM tip to drill nanoholes in a photoresist layer spinned onto the STO surface. Filling the holes with cobalt, the junction top ferromagnetic electrodes are defined, and after oxidizing a thin layer of Co into CoO (to control the Co magnetization via antiferromagnetic coupling between them), these CoO/Co electrodes were subsequently capped by sputtered Au layers for electric contacting. In Figure 1b we show the bias dependence of the tunneling current I (main panel) and conductance G (inset) across the Au/CoO/Co/STO/LCMO//STO(110) heterostructure measured at 4.2 K. The conductance of the junction changes depending on the relative orientation of each electrode: (i) with parallel (P) magnetized electrodes at 6 kOe, GP is low, and (ii) with anti-parallel (AP) magnetized electrodes at -1.2 kOe, GAP is high. Thus, a negative tunnel magnetoresistance [$\text{TMR} = (\text{GP}-\text{GAP})/\text{GAP}$] is observed, which is expected on the basis of the positive and negative spin polarization of LCMO and Co electrodes, respectively [6]. The value of TMR (-11%) allows calculating the spin polarization of LCMO electrodes using Jullière model [7] and taking as the spin polarization of Co $\text{PCo}=37\%$ [8]. Thus, $\text{PLCMO}=+14\%$. This value is surprisingly lower than expected for half-metallic ferromagnets but it could be related to intrinsic problems such as symmetry matching between spin-dependent wave functions in Co electrodes and (110) STO barriers, although other

non-intrinsic effects could also contribute. Further experiments are underway to measure other nanojunctions and obtain with better statistics the value of PLCMO.

We will report on the temperature, magnetic field and bias dependence results of these (110)LCMO based MTJs and discuss their perspectives for practical implementation in spintronic devices.

Introduction

To reduce the magnetization switching field (Hsw), in our previous study, we introduced a synthetic antiferromagnet (SAF) free-layered magnetic tunnel junction (MTJ) comprising amorphous ferromagnetic Co_{70.5}Fe_{4.5}Si₁₅B₁₀ layers [1]. The amorphous CoFeSiB SAF free-layered MTJs showed both reduced TMR ratio and Hsw than those of the single free-layered MTJs. Despite the undesired low TMR ratio, the CoFeSiB SAF free-layered MTJs exhibited much lower Hsw values than that of the single free-layered MTJs. Therefore, in the present study, we attempted to develop a new SAF free-layered structure to improve the magneto-transport properties while maintaining the low Hsw by controlling the free-layer thicknesses.

Experiment

The MTJs consisting of Si/SiO₂/Ta 45/Ru 9.5/IrMn 10/CoFe 7/AlO_x 1.5/CoFeSiB 7-t (F1)/Ru 1.0/CoFeSiB t (F2)/Ru 60 (in nm) were prepared using a six-target dc magnetron sputtering system under the typical base pressure of less than 5X10⁻⁸ Torr. A photolithographic patterning procedure, including ion beam etching, was used to fabricate the 10 x 10 μm² of MTJs.

Results and Discussion

Before we implement the CoFeSiB-used SAF layer into a full MTJ structure, we have characterized the magnetic hysteresis of various SAF structures including Ta 5/CoFeSiB (t₁ = 3.5, 4.0, 4.5, 5.0)/Ru 1.0/CoFeSiB (7-t₁)/Ta 5 (nm). As shown in Figure 1, a well-defined anisotropy and antiparallel alignment is occurred during the magnetization reversal at (a) t₁ = 3.5, (b) 4.0, and (c) 4.5 nm. However, the SAF characteristic was not observed at (d) t₁ = 5.0 nm. Therefore, to observe the SAF characteristics in our system, the thickness difference between the lower and upper part of the layers must have a critical range. And moreover, an increment in the M_s is observed by increasing the t₁ thickness. For example, the sample (d) CoFeSiB 5.0/Ru 1.0/CoFeSiB 2.0 (nm) has a four times higher M_s value than that of the sample (a) CoFeSiB 3.5/Ru 1.0/CoFeSiB 3.5 (nm). Because in the SAF structure, magnetic flux forms closed loop and can reduce the magnetostatic energy in the free layer separated by nonmagnetic space layer. However due to poorly defined SAF characteristics in the (d) SAF structure, it has higher M_s value than that of the (a), (b), and (c) SAF structures.

To investigate the SAF effects on the magnetotransport properties, various SAF free-layered MTJs were fabricated on Si/SiO₂ wafers including Ta 45/Ru 9.5/IrMn 10/CoFe 7/AlO_x 1.5/CoFeSiB 7-t (F1)/Ru 1.0/CoFeSiB t (F2)/Ru 60 (nm). As summarized in Table 1, the junction resistance (R), interlayer coupling field (H_i), TMR ratio, and Hsw all showed a dependence on F1 and F2 thickness. In the SAF-MTJ structure, when the amorphous F1 layer (a lower ferromagnetic layer in the SAF structure) was thinner than the amorphous F2 layer (an upper ferromagnetic layer), it is unable for the F1 layer to perfectly cover the tunnel barrier. As a result, more defective and rough points may exist at the tunnel barrier/free layer interface. The R and H_i are relevant to the tunnel barrier/ferromagnetic free-layer interface conditions, the junction with rougher barrier interfaces induces a lower R and a higher H_i. Because in the rough junctions, the tunnelling current preferentially shunts through the electrically weakest points and the ferromagnetic interaction across the

tunnel barrier becomes stronger, respectively. On the contrary, when the amorphous F1 layer becomes thick enough, the tunnel barrier can be perfectly covered, and, as result, the population of electrically weak points gets lowered. And moreover, by increasing the F1 layer thickness, the decrement of the surface roughness of the tunnel barrier/free-layer interface was observed. Because of this, when F1 layer became thick, it exhibited a higher R and a lower H_i values.

For the cell comprising (a) CoFeSiB 3.5/Ru 1.0/CoFeSiB 3.5 nm SAF free layer, the magnetization reversal was completed at the applied field of 3 Oe. For the (d) CoFeSiB 5.0/Ru 1.0/CoFeSiB 2.0 nm SAF free layered MTJ, however, it required 11 Oe of Hsw. We think that the reasons of exhibiting relatively lower Hsw were due to a lower magnetostatic energy in the free layer and well-defined SAF characteristics as previously shown in Fig. 1.

Half-metals, which have 100% spin polarized conduction electron band, is an ideal material for spintronics devices, such as spin MOSFETs [1] and high density nonvolatile memory devices. Recently, Co-based full-Heusler alloys [2-3], whose structures are Co_2XY type L_{21} , have attracted great attention as promising candidates of the half-metals since the fully spin-polarized band structures are predicted and they show high Curie temperatures above room temperature (RT). Very recently, a large tunnel magnetoresistance (TMR) ratio as high as 220% at RT (390% at 5 K) has been reported in a MgO(001)/Cr-buffer/ $\text{Co}_2\text{FeAl}_{0.5}\text{Si}_{0.5}$ (CFAS)/MgO/CFAS magnetic tunnel junction (MTJ) [4]. However, Cr buffer impedes a highly L_{21} -ordered structure due to the Cr interdiffusion by post-deposition annealing at a high temperature [5]. In this study we achieved a highly L_{21} -ordered CFAS layer using an MgO buffer layer instead of a Cr buffer layer, and investigated structure and magnetic and TMR properties as a function of post-deposition annealing temperature. Multilayers were prepared on MgO(001) single crystal substrates using ultra-high vacuum magnetron sputtering system at RT. CFAS (30 nm) layer was deposited on MgO (20 nm) or Cr (40 nm) buffer layer. Post-annealing was carried out after the CFAS layer deposition. The multilayers were characterized by x-ray diffraction (XRD), vibrating sample magnetometer (VSM) and atomic force microscopy (AFM). MTJ structures of MgO buffer/CFAS/Mg/MgO/CFAS/CoFe/IrMn/Ru were deposited on MgO (001) substrates and patterned using electron-beam lithography and Ar ion-beam etching. TMR curves are measured by a 4-probe method.

Figure 1 shows the XRD pole figures of (111) superlattice line for a CFAS film on an MgO buffer layer for different post-annealing temperatures (T_a). The distinct peaks with 4-fold symmetry indicate the L_{21} structure of CFAS on the MgO buffer layer, of which intensity increases with increasing T_a . The (111) superlattice line was not observed for below $T_a = 400^\circ\text{C}$, which indicates B2 structure of CFAS. Figure 2 shows saturation magnetization (M_s) and coercivity (H_c) for both MgO- and Cr-buffered CFAS (30 nm) films measured at RT as a function of T_a . The Cr-buffered film shows a rapid M_s drop and a H_c increase above 450°C , indicating the interdiffusion of Cr atoms into the CFAS layer significantly. This tendency is similar to the report demonstrated by Tezuka *et al.* [5]. Meanwhile, M_s starts to increase above 450°C without changing H_c for MgO-buffered film, suggesting L_{21} ordering without any interdiffusion. We plot T_a dependence of both R_a (average surface roughness) and $P-V$ (peak-to-valley) values of MgO-buffered CFAS layer in Fig. 3. Even as-deposited sample shows very small R_a of 0.15 nm. The surface roughness is improved by the post-annealing process. A remarkable flat surface with both R_a of 0.1 nm and $P-V$ of 1.0 nm was achieved by 500°C post-annealing as shown in the inset of Fig. 3. These facts indicate the use of the MgO-buffer for CFAS layer is a promising approach for achieving a higher TMR ratio. Detailed TMR properties will be presented and discussed.

The authors thank Prof. Tezuka for discussion. This study was supported by NEDO.

The analytical treatment of electron transport processes in spintronics layered nanostructures is commonly restricted to classical or semi-classical framework [1,2], where the equilibrium Fermi distribution $f(\epsilon, T) = [e^{(\epsilon - \mu)/T} + 1]^{-1}$ (with energy ϵ , chemical potential μ , and temperature T) is perturbed in each i -th layer by the trade-off between the external field E and the mean free path l_i , accordingly to the Boltzmann equation for diffusive transport regime. However, in highly perfect epitaxial junctions [3,4], an essentially ballistic regime is expected at distances closer than l_i from the junction. We show that in this condition a new specific perturbation of electronic distribution can appear, either in equilibrium and out of equilibrium, which can be important for the spintronics performance. A similar effect was already discussed for electrons near atomic point contacts [5]. To model the junction, we consider two ferromagnetic leads 1 and 2 with dispersion laws $\epsilon_{i\sigma}(k)$ ($i=1,2$ and $\sigma=\pm$ for majority and minority carriers) linked by a thin non-magnetic barrier (Fig. 1). The steady state distributions far from the barrier, $f_{i\sigma}^{\infty}(k)$, are defined by the respective $f_{i\sigma}^{\infty}$, but close to the barrier they are defined by the transmission and reflection coefficients, $|T_{\sigma\sigma}(k)|^2$ and $|R_{\sigma\sigma}(k)|^2$ (at conserved energy and transversal momentum) as given in Eqs. (1). The second pair of equations relates to the current conservation in each (k, σ) channel. Eqs. (1) fully define the functions $f_{i\sigma}(k)$ near the barrier, and the result essentially depends on the relative magnetic configuration (parallel, P, or antiparallel, AP) of the junction. For the P case (symmetric barrier with $|T(k)|^2 + |R(k)|^2 = 1$), one has trivially $f_{i\sigma}(k) = f_{i\sigma}^{\infty}(k)$, but a non-trivial effect appears for the AP case, as can be already seen in the equilibrium state ($E=0$, $f_{i\sigma}(k) = f_{i\sigma}^{\infty}(k)$). Then the explicit solution for simple parabolic dispersion $\epsilon_{i\sigma}(k) = \epsilon_0 - \sigma \Delta - \hbar^2 k^2/2m$ and $T=0$ (when $\mu = \epsilon_0$) is: $f_{i\sigma}(k) = 1, f_{i\sigma}(k) = k/\sqrt{(k^2 - k_A^2) - k_A^2} \ln[(k + \sqrt{(k^2 - k_A^2) - k_A^2})/k_A]$ for $k_0 < k < k_m$ and $k_A = \sqrt{(4m\Delta)/\hbar} < k$. Since $f_{i\sigma}(k) < 1$, there appears an additional deficit of minority spins, that is enhanced polarization and charge accumulation near the barrier, compared to the bulk leads. At finite field E , the conservation of equal spin currents requires a bigger shift of $f_{i\sigma}(k)$ than of $f_{i\sigma}^{\infty}(k)$, which should enhance the AP resistance and so the magnetoresistance of the device. The relaxation of accumulated charge and spin on scales $\sim l_i$ and $\sim l_{i\sigma}$ from the barrier also contributes to this enhancement. A more involved analysis for the intermediate case between P and AP permits to estimate a similar effect for the spin torque performance of a perfect junction.

Spin Transport in a Double Magnetic Tunnel Junction Quantum Dot System with Non-collinear Magnetization.

M. Ma, M. Jalil

Department of Electrical and Computer Engineering, Information Storage Materials Laboratory, Singapore, Singapore

The spin polarized transport through a magnetic tunnel junction(MTJ) has attracted much research interest in recent years [1,2], due to its high tunneling magnetoresistance (TMR) for potential spin-based devices. In a MTJ system consisting of a quantum dot(QD) sandwiched between two ferromagnetic leads, i.e., an QD-MTJ system, the current through the system depends on the intrinsic polarization and the magnetization orientation of the two leads. If the QD is sufficiently small, its energy levels become quantized and discrete. Most previous models of discrete QD transport consider only a single energy level and neglect the substantial contribution due to hole transport in the QD [1].

In this paper, we propose a theoretical model to describe the spin transport in a noncollinear QD-MTJ system, with θ being the angle between the magnetizations of the leads. The model considers two discrete energy levels of the QD, i.e., the highest occupied(HO) energy level ϵ_h and lowest unoccupied(LU) energy level ϵ_c [2]. In our model, the QD can be occupied by at most two (excess) electrons or holes of opposite spins with intra-level Coulomb correlation energy of U_ξ ($\xi = e/h$ for electrons/holes). The relaxation of an electron (hole) in the dot is denoted by Γ_ξ^σ , where $\sigma = \uparrow/\downarrow$ for up/down spin. A bias voltage V_b is applied between the two leads, i.e. the potential of left/right lead is $\mu_l=0$ and $\mu_r=-eV_b$, respectively. The QD energy levels are given by $\epsilon_\xi = \epsilon_{\xi 0} - 0.5eV_b$, where $\epsilon_{\xi 0}$ is the initial energy level at zero bias. The spin polarization of the lead is denoted by $p_v = (\gamma_v^\uparrow - \gamma_v^\downarrow)/(\gamma_v^\uparrow + \gamma_v^\downarrow)$, where $v=1,2$ signifies the lead, and γ_v^σ is the line width function. The total current I and TMR at equilibrium were obtained by formulating the master equation. In the following calculations, we assume $p_v = p$ and $\Gamma_\xi^\sigma = \Gamma$.

We first investigate the I - V_b characteristic. As shown by Fig.1a, there are three distinct regions in the I - V_b characteristic, i.e., the low-bias Coulomb Blockade (CB) region with zero current, an intermediate single occupancy(SO) region, and a high bias double occupancy (DO) region. In the CB region, the sequential tunneling current is suppressed. In SO region, the QD could be occupied by only one electron or one hole. In DO region, the bias voltage is sufficiently large for the QD to be occupied by up to two electrons or two holes, which results in more tunneling channels, and hence an increase in the current.

Next we study the angular(θ) dependence of I - V_b characteristic (Fig.1a) and TMR (Fig.1b). We find that θ -dependence of current is much stronger in SO region compared to that in DO region. For instance, in SO region, the tunneling current is suppressed by 90% when θ changes from 0 to $\pi/2$; while in DO region, the corresponding reduction in tunneling current is only about 20%. Similarly, we found that θ -dependence of TMR is greater in SO region than that in DO region (Fig.1b). For example, when θ changes from 0 to $\pi/2$, the TMR in SO region increases from 0 to 0.84; while that in DO region reaches only 0.2. The smaller θ -dependence in DO region is due to the possibility of spin mixing in the tunneling current.

In Fig.2, we study the effect of spin flip in the dot on the tunneling current and TMR for both SO and DO regions. We found that a finite spin flip rate Γ enhances the current for $\theta \neq 0$ case, leading to a suppression of the TMR for both SO and DO regions, with the suppression in the SO region being more pronounced. Thus, in general, the angular dependence of current and TMR is reduced by spin flip in the QD.

Finally, we study the dependence of the current and TMR on the intrinsic spin polarization p of the leads, as shown in Fig.3. We find that in contrast to the spin flip effect, an increase in the lead polarization enhances the angular dependence of current and TMR, especially in SO region. Additionally, we find that the TMR in both bias regions increases nonlinearly with p (Fig.3e), with the p dependence of TMR being greater as p increases (see Fig. 3f). Note that when the p value exceeds 0.775, the differential change in TMR with p for DO region exceeds that of the SO region. Thus, to achieve maximum sensitivity, the operating bias conditions should be set to the SO or DO regions, depending on whether the lead polarization p is smaller or larger than this critical value.

Spin torque effects in magnetic nanostructures.*R. Buhrman**Cornell University, Ithaca, NY*

The initial predictions and subsequent definitive demonstrations of the ability of a spin-polarized current that impinges onto a thin film nanomagnet to reversibly switch the orientation of the magnetic moment and/or to excite it into microwave precession by the torque exerted through the transfer of spin angular momentum from the incident conduction electrons have catalyzed what is now a quite broad and very active area of spin torque research. Since that initial work, there has been remarkable progress in advancing the fundamental understanding of this new spintronics phenomenon, and in successfully moving it towards technological implementations, particularly spin-torque MRAM and spin-torque microwave oscillator applications, that have the potential for broad impact. In this presentation I will discuss the basics of the spin torque effect and briefly survey the various approaches that can be employed to demonstrate and study it in both all-metallic, spin-valve-type nanostructures and magnetic multilayers, and in nanoscale magnetic tunnel junctions (MTJs). I will also briefly discuss some of many challenges that remain to be overcome before spin-torque based technologies can be successfully realized. After this survey of the basic phenomenon and some of its possible implementations, I will discuss some recent work that has sought to contribute to the rapidly advancing spin-torque research effort, by helping both to better understand quantitatively the details of the phenomenon and to understand and enhance the efficiency of the effect I will summarize results from studies of spin-transfer switching and microwave excitation in magnetic tunnel junctions (MTJs) which include the use of the spin transfer phenomenon to quantitatively determine, through spin-torque-excited ferromagnetic resonance (ST-FMR), both the bias dependent efficiency of the spin torque in high quality MTJs and the magnetic damping of individual free layer nanomagnets. I will conclude by briefly describing some recent work that has been examining spin torque effects in nanoscale structures with distinctly non-uniform magnetization, including the case where persistent dynamics of an individual magnetic vortex can be excited and detected. These studies are giving us some new information regarding magnetic dynamics in nanoscale structures. The results are also pointing to ways by which it may be possible to make better or more versatile spin-torque driven microwave oscillators, and, most significantly, to reduce the spin polarized current needed for the short-pulse switching of a thermally stable nanomagnet for MRAM applications.

The development of magnetic tunnel junction memory: from first devices to Mbit MRAMs to emerging spin-torque transfer MRAMs.

W. J. Gallagher

IBM Watson Research Center, Yorktown Heights, NY

This talk will review the development of and outlook for magnetoresistive random access memory (MRAM). It will begin by explaining why the magnetic tunnel junction device in particular is an attractive device for high-speed memory [1]. The device and design choices that have been made for current Mbit-level MRAMs will then be described. While enormous advances have been made in magnetic tunnel junction materials for getting higher read signal, it has been developments to make writing more reliability that have been more important for the first MRAM products. Existing Mbit-level MRAMs all rely on x- and y- magnetic fields for bit selection within sub-arrays. This selection scheme necessarily involves the exposure of many half-selected bits on the x- and y-lines to half-select write fields. Furthermore, nearest neighbor bits feel the vector addition of stray write-fields plus the half-select fields. Particularly the latter combination (a nearest neighbor to the bit being written, which both feels a stray field and is subjected to a half-select field) leads to a non-negligible probability for bits to be accidentally written. A toggle writing scheme, which involves the rotation of magnetic storage layers rather than threshold switching, has been one successful approach to avoiding half-select upsets [2]. When combined with magnetic liners added to the x- and y-write wires to increase and concentrate the magnetic flux delivered to selected bits while lower that applied to neighboring bits, the probability of nearest-neighbor magnetic half-select write upset errors is reduced to a negligible level. This combination of approaches works well for eliminating unintended bit writing, and toggle MRAM products up to 4-Mbit [2] in capacity are in commercial production utilizing 180nm minimum feature sizes technology. Larger prototype toggle MRAM chip capacities, for example up to 16Mbit in 180nm technology, have also been demonstrated.

For scaling MRAMs to smaller feature-size technologies, bit thermal stability requirements lead to a need to increase write fields to a level that eventually becomes impractical. Fortunately in smaller devices, the direct injection of spins starts to become a more dominant effect for rotating magnetic moments. Thus spin-torque transfer devices [3] in their tunnel junction form [4] become an attractive alternative approach to MRAM. With these devices, write-selection is done through an access transistor in each cell, thus eliminating the magnetic half-select issue. The challenge remaining today is to lower the required write current so that smaller selection transistors can deliver sufficient current, thus enabling smaller cells. Producing spin torque transfer devices with lowered required writing currents is the focus of considerable present research and development efforts. In the final part of this presentation, the properties of existing and emerging MRAM approaches will be compared to those for other existing and other emerging nonvolatile memory technologies. For example phase change memory which offers potential for random access and multibit storage [5], seems a better approach for high density, but not necessarily so if high endurance or very high speed is also required. In those cases, MRAM would be preferred. Other situations in which one memory type or another would be a preferred solution will be described.

The spin torque effect enables new possibilities for magnetoelectronic devices such as a high density, low power spin torque memory (ST-MRAM) and spin torque nano-oscillators (STNOs). The spin torque effect is dominant at bit sizes of $0.1\mu\text{m}$ or less, making it ideal for high density memory. However, maintaining a good bit shape at such dimensions is challenging using optical lithography. We fabricated MTJ nanopillars as small as 80nm with good pattern fidelity using optical lithography on 200mm diameter wafers. (Fig. 1.)

Since the programming current passes through the MTJ, a low resistance is needed to prevent dielectric breakdown. We fabricated low resistance area (RA) product MgO barriers using various oxidation techniques. (Fig. 2.) Natural oxidation is superior to radical oxidation for low RA barriers. For an optimized natural oxidation process, an MR% of over 100% was achieved at an RA as low as $5\Omega\mu\text{m}^2$ with a CFB free layer.

We patterned similar films into $0.1\times 0.2\mu\text{m}$ bits and measured the quasistatic (0.1s pulse duration) spin-transfer switching currents (I_c) of several hundred bits across-wafer. (Fig. 3.) The average I_c for a $0.1\times 0.2\mu\text{m}$ bit with CFB free layer was 0.6mA with a cross wafer relative standard deviation of 11%. To determine the high speed I_c , we measured I_c for different pulse duration and fit the standard formula for thermal activation to the data. (Fig. 4.) We found a high-speed switching current density of $J_{c0}\approx 6\text{MA}/\text{cm}^2$ along with a thermally-stable energy barrier $E_b\approx 50k_B T$. While the results are promising, we estimate that reducing J_{c0} by $\geq 2\times$ while maintaining $E_b > 40k_B T$ will be required to realize a practical ST-MRAM.

The spin torque effect can also cause free layer oscillations at GHz frequencies. An STNO is of applied interest because it has small size, high Q, and is tunable over a wide range. We fabricated giant magnetoresistance point contacts having diameters ranging from $d < 50\text{nm}$ to $d \approx 300\text{nm}$ using either e-beam or optical lithography. The spin torque resonance was measured over a frequency range from $< 8\text{GHz}$ to $> 26\text{GHz}$. The slope of the resonance frequency versus current decreased as d increased and was fit by a phenomenological spin-transfer model where the effective d extends $\approx 50\text{nm}$ past the contact edge into the surrounding magnetic film¹. Also, phase locking between the resonances of two STNOs was demonstrated when the intercontact spacing between them $\leq 200\text{nm}$.² Such phase locking offers a way of controlling arrays of STNOs and thereby increasing the output power to levels useful for applications.

I. Introduction

Most of spin torque works used MTJs with shape anisotropy[1],[2]. However, the anisotropy fails to keep non-volatility at small size. A solution is to use perpendicular magnetization[3]. In this paper, the potentials are discussed.

II. Potential for small switching current, I_c

Analytic expressions of I_c are given in figure 2. The I_c for perpendicular is small by the second term in (i)-b. In perpendicular, both switching paths by spin torque and by thermal agitation are the same. In longitudinal, only spin torque makes the magnetization perpendicular and the I_c gets large.

III. Scalability of the non-volatility

Perpendicular materials with about 7nm diameter used in HDD have non-volatility. $F=7\text{nm}$ gives the $8F^2$ footprint of $0.00001\mu\text{m}^2$ (figure 3) which corresponds to 50 Gbit.

IV. Scalability of the switching speed

The work memory switching time must be about 10 nsec.. The analytic expression is given in figure 2. It gives several nano-seconds for $F=60\text{nm}$. The Landau-Lifshitz-Gilbert simulation and the experiments also gave less than 10 nano-seconds (figure 3). The expression says the speed scales.

V. Scalability of the switching current

Table 1 summarizes demonstrations[2], [4], [5], [6], [7]. While perpendicular elements have larger coercivities, I_c s don't differ much. I_c/Δ takes the small value for TbCoFe and CoFe super lattice. Further reduction in I_c can be made by smaller damping and higher spin polarization[7]. CMOS drivability gets worse at small size, but the switching current gets smaller (figure 5). The I_c scales.

VI. Conclusion

Perpendicular MRAMs have good scalabilities.

The generation and detection of spin currents are important issues for the further development of spin-electronics. Direct and inverse spin Hall effects (SHEs) in nonmagnetic semiconductors or metals, which convert charge current into pure spin current and vice versa, respectively, enable us to inject or detect spin current without ferromagnetic materials. Thus, it is expected that SHE provides a new functionality of materials for spin-electronic devices. The theoretical predictions of the SHE have stimulated scientific interests, and the optical detection of SHE was demonstrated in nonmagnetic semiconductors. Recently, the electrical detection of SHE was also reported in nonmagnetic metals such as Al [1] and Pt [2]. However, the complicated device structures or the sophisticated measurement techniques were required to detect SHE, and the small magnitudes of spin Hall signals limit the possibility of device applications of SHE.

Here, we present “giant SHE” at room temperature in perpendicularly spin-polarized FePt/Au devices [3]. We fabricated a multi-terminal device with a nano-sized Au Hall cross and a FePt perpendicular spin injector through the use of electron beam lithography and Ar ion etching. Perpendicularly magnetized FePt generates or detects the perpendicularly polarized spin current without external magnetic field, which allows us to simplify the device structure. Furthermore, the present multi-terminal device enables us to measure three kinds of Hall effects, that is, direct SHE, inverse SHE, and local Hall effect (LHE) using the same device.

We employed the non-local spin injection technique to detect the direct and inverse SHEs. In the case of the inverse SHE, the spin-polarized electric current is injected from FePt to Au, the spin current flows in Au due to the spin accumulation, and the non-local Hall voltage induced by SHE is detected by the Au Hall cross. For the direct SHE, on the other hand, the electric current flows in the Au cross, the spin current is generated by SHE, and the generated spin current is detected by the FePt spin injector. An important point is that the SHE is detected even at zero external magnetic field owing to the perpendicular magnetization of FePt.

Clear hysteretic transitions of the non-local Hall resistance were observed in both direct and inverse SHE geometries with sweeping the external magnetic field, and the shapes of the hysteresis loops were the same as that of the LHE. Since the LHE results from the anomalous Hall effect in FePt, the hysteresis loops observed in the SHE geometries reflect the magnetization reversal of FePt. In addition, the sign change of the spin accumulation in Au led to the polarity reversal of the hysteresis loops of the non-local Hall voltage, which is interpreted as the change of the direction of the spin current in the Au Hall cross. Those results clearly indicate that the non-local Hall resistance originates from the SHE in Au. With increasing the distance between the FePt spin injector and the Au Hall cross, the magnitude of the SHE exponentially decreased and the spin diffusion length in Au was obtained to be about 86 nm at room temperature.

From the resistance change of SHE, the spin Hall angle, which is the ratio of the spin Hall conductivity to the electric conductivity, was calculated to be 0.113. This large spin Hall angle in Au is interpreted by the skew scattering mechanism. The spin Hall angle showed the weak temperature dependence, which supports that the skew scattering contribution is dominant in the present Au.

The maximum value of the resistance change in the multi-terminal devices is 2.7 m Ω at room temperature, which is significantly larger than those in previous reports [1,2]. We believe the large spin Hall signal opens a way of new writing and/or reading techniques for magnetic storage devices. Electrical Generation, Modulation and Detection of Spin Currents in Silicon in a Lateral Transport Geometry.

B. Jonker, O. van 't Erve, G. Kioseoglou, A. Hanbicki, C. Awo-Affouda, M. Holub, C. Li, P. Thompson
Naval Research Laboratory, Washington, DC

The electron's spin angular momentum is one of several alternative state variables under consideration on the International Technology Roadmap for Semiconductors for processing information in the fundamentally new ways which will be required beyond end-of-roadmap CMOS technology (1). Electrical injection / transport of spin-polarized carriers is prerequisite for developing such an approach. While significant progress has been realized in GaAs (2), little has been made in Si, despite its overwhelming dominance of the semiconductor industry.

We report successful injection of spin-polarized electrons from an Fe /Al₂O₃ tunnel barrier contact into Si(001) n-i-p doped heterostructures (Figure 1), and spin transport across the Si/AlGaAs interface (3). The circular polarization of the electroluminescence (EL) due to radiative recombination in the Si tracks the Fe magnetization, confirming that the electrons originate from the Fe. The polarization reflects Fe majority spin, consistent with the common delta₁-symmetry of the Fe majority and Si(001) conduction band (CB). The electron spin polarization in the Si is ~30% at 5K, with significant polarization extending to at least 125K. In Si/AlGaAs/GaAs quantum well (QW) structures, the spin polarized electrons drift under applied field from the Si and recombine in the GaAs QW, where the polarized EL can be quantitatively analyzed, yielding an electron spin polarization of 10%. Spin transport occurs despite the poor crystalline quality of Si epilayers on GaAs, the 0.3 eV CB offset (Si band lower), and the fact that the sample surface was exposed to air before growth of the Si on the AlGaAs/GaAs and of the Al₂O₃ on the Si. Lateral transport structures and non-local detection techniques (Figure 2) are used to create a spin current which flows separately from the spin-polarized charge current (4). This spin diffusion current is sensitive to the relative orientation of the magnetization of the injecting and detecting contacts. Hanle effect measurements demonstrate that the spin current can be modulated by a perpendicular magnetic field, which causes the spin to precess and dephase in the transport channel. This effect is clearly manifested in the signal at the detector contact.

The realization of efficient electrical injection and detection using contacts compatible with "back-end" Si processing should greatly facilitate development of Si-based spintronics. This work supported by the Office of Naval Research and core programs at NRL.

Ferromagnetic contacts to Si are recently studied for spin-polarized current injection and detection in hybrid devices [1],[2],[3],[4]. The inclusion of an insulator (I) as tunnel barrier between the ferromagnet (FM) and the semiconductor (SC) results to an interfacial resistance, necessary for a significant spin polarization of the injected current [5]. The resistance value should lie within a narrow window, its upper limit determined by a necessary discontinuity of the electrochemical potentials at the interface and its lower by the amount of spin-flip events in the SC [5]. The latter is sensitive to the doping type and density. Low-doped, n-Si should give rise to a larger spin-flip length [5], but on the other hand, due to the extended Schottky barrier, it results to a forbiddingly large contact resistance for spin injection [1]. The electron spin relaxation time in p-Si is expected to be smaller due to the additional electron-hole interaction [6]—nevertheless experimental evaluation is lacking.

In this digest we present the properties of FM contacts to p-Si, using MgO as tunnel barrier. We concentrate on the influence of the tunnel barrier thickness and wafer doping density on the contact resistance for spin injection and detection.

Micrometer and sub-micrometer size trenches were patterned by deep-UV lithography on p-doped Si wafers, with a doping density of $\rho=10^{15}$ to 10^{18} cm⁻³, covered with a 42 nm-thick oxide layer. The trenches were subsequently opened down to the Si surface with a combination of reactive and HF wet chemical etching. MgO(x=0.5, 1, 1.5, 2.5 nm)/Co₇₀Fe₃₀(1 nm)/Ni₈₁Fe₁₉(4 nm)/Ta contacts were sputter-deposited on the freshly etched Si. Finally, Al top contacts were fabricated and temperature-dependent, DC current-voltage (I-V) characteristics were measured.

A cross section, transmission electron microscopy (TEM) image of the multilayer with x=2.5 nm is shown in Fig. 1. The MgO layer appears amorphous, and the FM bilayer polycrystalline. A SiO_x layer is formed between the MgO and Si with an estimated thickness below 1 nm.

Elements of 0.5 to 8 μm^2 were measured and the current was found to scale satisfactory with the area, suggesting a homogeneous current flow through the element. In Fig. 2(a) we show room temperature (RT) I-V curves, measured for 6 μm^2 contacts with different tunnel barrier thickness, on a wafer with $\rho=10^{17}$ cm⁻³. Forward (negative) bias corresponds to the spin injection case, i.e. electron current flows from the FM to the SC, while the latter is in accumulation. Reverse bias corresponds to the detection case, i.e. electron current flows from the SC to the FM. The forward bias current density for x=0.5 nm is in some cases more than 2 decades higher than for x=2.5 nm. Even though considerable, the dependence of the current density on the barrier thickness is much weaker than the one observed in magnetic tunnel junctions. This is due to the existence of the Schottky barrier at the I/SC interface, contributing to the electrical transport characteristics.

In Fig. 2(b) we present RT I-V curves for elements with x=1.5 nm, for different wafer doping densities (normalized to the current value at -1.5 V). Interestingly, no rectification is observed for $\rho=10^{15}$ cm⁻³, while it increases by more than a factor of 1000 for $\rho=10^{18}$ cm⁻³. This increase of the rectification with increasing doping density is in sharp contrast to the case of identical contacts deposited on n-doped Si, in agreement with what is reported in the literature [1]. The observed

behaviour can be explained by a suppression of the minority carrier (electron) current by electron-hole recombination in the bulk of the SC for larger doping densities. The reverse bias current (corresponding to detection) is greatly influenced, while the effect on the forward bias current is much less significant. The above argument is also supported by the enhanced temperature dependence of the I-V curves for higher doping.

In conclusion, we present the properties of FM contacts with MgO tunnel barrier on p-doped Si for spin injection and detection. The current is considerably increased with decreasing barrier thickness, while the rectification is minimal for low doping densities, in contrast to the case of n-doped wafers. This makes such contacts potentially interesting as injectors and detectors of spin polarized current in a two-terminal local measurement.

Spin Coulomb Drag: a Limitation for Spintronics?

I. D'Amico¹, C. A. Ullrich²

1. Physics, University of York, York, United Kingdom; 2. Physics and Astronomy, University of Missouri-Columbia, Columbia, MO

An intense research effort is underway to improve our understanding of spin dynamics, especially related to nanocircuits and their components, with the aim of building novel (spin)electronics devices. In this context the theory of spin Coulomb drag (SCD) was recently developed[1]. It analyzes the role of Coulomb interactions between different spin populations in spin-polarized transport, showing that Coulomb interactions are an intrinsic decay mechanism for spin currents, a measure of which is given by the spin-transresistivity. As confirmed by experiments[2], SCD can be substantial in semiconductors, and it is bound to become one of the most serious issues in spin polarized transport, since, due to its intrinsic nature, it cannot be avoided even in the purest material. More recently the frequency dependence of SCD has been considered[3]: this is important for AC spintronics applications, optical spin-injection and spin-resolved optical experiments.

A critical issue for potential spintronics devices has been pointed out, namely the power loss in spin transport and dynamics due to SCD[3]. We have estimated that for three dimensional GaAs ac spintronic devices operating at terahertz frequencies, the power loss due to SCD can be of the order of several mW/cm³. This can be a large fraction of the power loss due to the Drude resistivity, between 22% and 44% when considering densities between 10¹⁶ and 10¹⁸ cm⁻³ and mobilities of 10⁴ cm²/Vs. As the SCD becomes stronger in low dimensional structures, we expect the corresponding power loss to be even more relevant in such structures.

Another important aspect of SCD in the frequency domain is its effect on optical spin excitations[3]. A related issue is its interplay with the spin-orbit coupling[4]. Our calculations show that SCD may contribute substantially to the linewidth of spin optical excitations. Results for the intersubband spin plasmon in a parabolic quantum well are reported in Fig.1. In two dimensional structures spin-orbit coupling effects may also become important. In particular a threefold splitting of the intersubband spin plasmon mode has been predicted[5]. In Fig.2 we show that such a splitting would be very small in parabolic quantum wells. Let us compare the effects due to spin-orbit coupling and SCD by considering quantum wells corresponding to the maximum value of the SCD linewidth. We see then that the dispersion relation splitting due to the spin-orbit coupling becomes a negligible effect.

This suggests the possibility of a purely optical quantitative measurement of the SCD effect by means of inelastic light scattering. The proposed experiments would establish unequivocally the influence of and the limitations imposed by SCD on optical excitations.

Fig.1: Linewidth of the intersubband spin plasmon due to SCD versus characteristic width of the parabolic quantum well calculated for different sheet densities, as marked. The figure shows results for $q=0$. Corrections due to a finite value of the in-plane wave vector q are negligible (not shown).

Fig.2: Maximum splitting of the intersubband spin plasmon due to spin-orbit coupling versus in-plane wave vector q for a parabolic quantum wells with sheet density $N_s=10^{10} \text{ cm}^{-2}$ and different characteristic widths (as marked). Notice that the peak value of the SCD linewidth for the same density (Fig.1) is almost two order of magnitude bigger than the corresponding spin-plasmon splitting.

Organic spintronics: on the spin injection at the CuPc/GaAs interface.

Organic semiconductors (OSC) have considerably attracted the interest of the scientific community due to the possibility of implementing very-low-cost and versatile electronic devices based on organic thin-film materials [1]. Recently, different pioneering experiments suggested that OSC represent as well a major opportunity for application in the growing field of spintronics [2,3]. In fact, OSC usually consist of elements with small atomic numbers, such as carbon and hydrogen, and thus intrinsically weak spin-orbit coupling is expected. This leads to long spin-polarization relaxation times that are particularly important for spintronics devices.

Spin injection from an active medium (AM) into OSC thin films is a fundamental prerequisite for the implementation of OSC-based spintronics devices. All experimental studies done so far to demonstrate the feasibility of spin injection into OSC are based on magnetoresistance or electroluminescence measurements, which result in a spin-dependent signal integrated over the whole spintronics device. According to the results presented in [4], great care has to be taken in the search of spin-injection in such experiments, since stray fields may mimic the spin effects. Spin- and time-resolved two-photon photoemission (2PPE) allows collecting direct experimental information about the efficiency of spin injection and the microscopic spin-flip mechanisms governing spin injection. Using this experimental technique we have studied a model system constituting the main ingredient of every OSC-based spintronics device, namely the heterojunction between an AM (in this case p-type GaAs) and copper phthalocyanine (CuPc).

In a first step, we have studied the formation of the CuPc/GaAs interface by means of ultraviolet photoemission spectroscopy (UPS). The energy band alignment of the interface as derived from the measurements is depicted in Figure 1. After having characterized the interface, we employed spin- and time-resolved 2PPE measurements, following the excitation scheme depicted in Figure 1: a circularly polarized pump pulse with photon energy of 1.56 eV (denoted with R in the picture) creates spin polarized carriers in the GaAs substrate by optical orientation. Due to the large penetration depth of red light in GaAs these electrons are excited into the conduction band mainly outside the band bending area. Subsequently, some of these electrons will be accelerated towards the interface in the band bending potential and finally cross the CuPc/GaAs interface to end up in intermediate states above the LUMO of CuPc. Since the probing depth in the photoemission process is limited by the short inelastic mean free path of the photoelectrons, the probe pulse with photon energy of 3.12 eV (denoted with B) finally photoemits these electrons from the very surface region (and thus mainly out of CuPc) into a final state above the vacuum level. Figure 2 shows the efficiency of spin polarization injection for hot electrons with 1.4 eV to 1.6 eV energy above the Fermi level of the system, as a function of CuPc coverage. The efficiency is defined as the ratio between the spin polarization of the electrons originating from the bare GaAs substrate and of those which overcame the deposited CuPc film. The results show a highly efficient spin injection of hot electrons from GaAs into CuPc, with values even above 100% for CuPc coverages up to 10 ML. This fact demonstrates beyond doubt that spin-injection takes place without any substantial spin-flip scattering at the interface.

In further measurements, we studied the temporal evolution of the spin polarization injected into the organic layer in the range from 10 fs up to 1 ps after injection from the GaAs substrate for dif-

ferent hot electron energies. The results indicate that the degree of spin polarization of electrons injected through the CuPc/GaAs interface into molecular orbitals just above the LUMO onset of CuPc is preserved longer than for electrons injected in energetically higher lying states. Thus, we can conclude that in order to achieve high efficiency in organic-based spintronics devices based on CuPc, injection of spin-polarized electrons energetically close to the LUMO onset of CuPc should be implemented by a careful choice of the bias potential.

Francis Bitter Magnet Laboratory, Massachusetts Institute of Technology, Cambridge, MA

Spintronics is an emerging technology to overcome some of the physical limitations of conventional charge based electronics. Effective spin injection from ferromagnetic metal into semiconductors is prerequisite for the development of spin field effect transistor (spin-FET). Poor electrical spin injection is a major obstacle in the realization of spin-FET, which is attributed to the intrinsic conductance mismatch between metal and semiconductor. Tunnel contact is known to be a useful way to overcome the mismatch.[1] With the purpose, Schottky or Al_2O_3 tunnel contacts have been extensively studied to enhance spin injection, but the possible maximum spin polarization might be limited by the tunneling spin polarization from the ferromagnetic metal. An alternative approach to increasing spin polarization is to use a crystalline $\text{MgO}(100)$ tunnel barrier. It was found that the majority electrons decay slowly and the minority electrons, on the other hand, decay rapidly in the MgO barrier.[2]

Here we present a manifest evidence of purely electrical detection of spin injection and accumulation in In-As quantum wells through MgO tunnel barrier. Spins injected from a Fe thin film accumulate and diffuse out in the InAs quantum well, with the spins being electrically detected by a neighboring Fe electrode. The injected spin polarization of the current crossing the Fe-InAs interface was increased, and the spin signal was much clearer than the previous experiment without MgO barrier.[3]

We have fabricated a mesoscopic lateral spin valve on InAs semiconductor. The device consists of two ferromagnetic Fe electrodes and an InAs high-electron-mobility transistor (InAs HEMT). A scanning electron microscope (SEM) image of a fabricated device is shown in Fig. 1(a). The essential parts of the device are 8.6- μm -wide InAs HEMT mesa and two ferromagnetic electrodes that work as the spin injector and detector. The ferromagnetic electrodes have different aspect ratio to give distinguishable magnetization-switching fields. A thickness of 30 nm was removed from the top surface by Ar-ion milling and then 2.2 nm MgO / 0.3 nm B / 28 nm Fe film has been epitaxially grown by molecular beam epitaxy subsequently. Lastly, the film was capped by 12-nm-thick Au layer. Fig. 1(b) shows a schematic diagram of the cross section of InAs HEMT where the ferromagnetic electrode was deposited.

Spin injection can be detected electrically by measuring correlations of the magnetization of two ferromagnetic electrodes. Fig. 2 shows the nonlocal spin signal as a function of magnetic field applied along the easy axis of ferromagnetic patterns. For nonlocal measurement, the voltage is not measured directly where the charge current flows; instead, only the chemical potential that is sensitive to spin accumulation is measured using a ferromagnetic detector. The chemical potential in the parallel (antiparallel) magnetization makes an additive (subtractive) contribution to the nonlocal voltage.

Most of all, the regions where the magnetizations of ferromagnetic electrodes are parallel and antiparallel are evidently distinguished, since the resistance dips are much clearer and the plateaus are observed compared to the previous experiment without MgO tunnel layer.[3]

Purely electrical spin injection and detection in a semiconductor are important for constructing a spin-FET. Our layer structure is very similar to the previously reported structure except MgO

layer.[3] Comparing to the previous experiment, we observed much clearer spin injection qualitatively and quantitatively. These experimental results will contribute significantly to the realization of a practical spin-FET. The introduction of MgO layer at the interface is proved to enhance spin injection from ferromagnetic metal to semiconductor as predicted by theoretical calculation.

Giant magnetoresistive sensors can have their field sensitivity enhanced by manyfold if located in the gap of two magnetically soft flux-guides [1]. These can detect magnetic fields in the picoTesla range [2-3] and nanosize magnetic beads, labeling biomolecules of medical interest[4].

A spin valve film, prepared by ion beam deposition, with the physical structure of Ta 2nm/Ni₈₀Fe₂₀ 2.5nm/Co₈₀Fe₂₀ 2.5nm/Cu 2nm/Co₈₀Fe₂₀ 2.5nm/Mn₇₇Ir₂₃ 6nm/Ta 2nm/Ti₁₀W₉₀(N₂) is patterned into a long and narrow (3 microns wide) stripe. The sensor exhibits a Barkhausen-noise and hysteresis free response to uniform transverse (to the stripe length) applied magnetic fields, with a saturation field mainly limited by the free-layer demagnetizing field.

Thin films of an amorphous alloy of Co_{88.4}(Zr_xNb_y)_{11.6} (CZN), with a thickness of 300 nm, were patterned by a lift-off process into long poles (80 microns wide, 104 microns long), and larger square yokes (150 microns by 150 microns) to form two identical flux guides, having their poles separated by 10 microns (gap width). A spin valve sensor centred in the gap of the flux guides exhibit a linear magnetoresistive response, characterized by a coercivity of 0.7 Oe, as shown in Fig. 1. In this device, a factor of 12 of field amplification is obtained and the sensor sensitivity is 50 mV/Oe.

Focused beam magneto-optic Kerr effect (MOKE) in the longitudinal geometry was used to measure hysteresis cycles of the yoke and pole regions of the CZN flux guides.

The MOKE curves show small hysteresis characterized by a coercivity of 0.7 Oe, similar to that typically obtained in the spin valve sensors coupled to the CZN flux guides.

Identical shape magnetic flux guides, integrating a multilayer film of (Ni₈₁Fe₁₉ 35nm/Ru .65nm)x10, having an antiferromagnetic coupling field of about 40 Oe, exhibit MOKE curves that overlap those of the CZN flux guides, in the range of ± 10 Oe, but with no detectable hysteresis (Fig. 2). This result indicates that the magnetization processes in the multilayer flux guides mainly occur by uniform rotation. Anisotropic magnetoresistance measurements in wide stripes of the multilayer films also indicate single-domain rotation processes.

Micromagnetic simulations indicate that spin valve sensors with 80% of the full linear signal in a field range of ± 2 Oe can be attained by adding to the previously described flux guides of CZN, a thin antiferromagnetically (AFC) coupled bilayer of CoFeB but having longer poles.

Thin films of Co₇₀Fe₃₀B_{20at%} (CoFeB), prepared by ion beam deposition have as-deposited a spontaneous magnetic moment of 1200 emu/cm³ and amorphous crystalline phase. Upon annealing at 320 °C, the films exhibit a crystalline phase.

A crystalline phase is also obtained by growing bilayers and multilayers of CoFeB 10nm/(Ru .9nm/CoFeB 10nm)xN on a buffer of Ta 2nm/Ru 1nm as indicated by XRD analysis. Furthermore, they exhibit an oscillatory antiferromagnetic coupling upon the Ru thickness with a maximum around $t_{Ru} = 0.9$ nm.

To integrate this higher magnetic moment trilayer film of CoFeB 10nm/Ru .9 nm/CoFeB 10nm, having an antiferromagnetic coupling field of 20 Oe, we use a self-alignment process, defining a gap with nearly the same width as the sensor.

The AFC trilayer, in turn, is magnetostatically coupled to recessed poles (gap width of 10 to 15 microns) of CZN.

The presence of that higher moment AFC trilayer in the previously described CZN flux guides effects the sensor response, reducing its coercive force from 0.7 Oe to less than 0.3 Oe while enhancing the sensitivity by a factor of 3.

Gate Controlled Magnetoresistance in a Ballistic Nanodevice.

S. Kumar^{1,2}, S. Tan¹, M. Jali²

1. SMI, Data Storage Institute, Singapore, Singapore; 2. ISML, ECE, National University of Singapore, Singapore, Singapore

Giant magnetoresistance (GMR) [1-3] refers to a large fractional change in resistance induced by an external magnetic field which changes the magnetization orientations of the two ferromagnetic (FM) layers separated by a non-magnetic (NM) spacer, from the parallel to the anti-parallel configuration. Magnetoresistance (MR) is a property of the multilayer device which depends on its material and geometry. Device MR cannot be modified once the device is fabricated.

Here, we propose a ferromagnetic (FM) transistor, in which the device MR can be modified by simply applying the gate voltage [4,5]. Our device is made of a high-electron-mobility-transistor (HEMT) structure with electrical gates fabricated on top of the electron conduction channel [Fig. 1]. The source and the drain of the device are made of FM materials. For magnetoresistive measurement, the source's magnetization is fixed in one direction, while the drain's magnetization is free to rotate. The electron conduction channel is shorter than the electron's mean free path in GaAs 2DEG, so as to ensure electron transport is ballistic in the 2DEG.

We studied the variation of MR and spin injection (SI) in the semiconductor by varying gate voltage under different conditions. The effects of following the device parameters were studied: 1) channel length, 2) 2DEG and FM material choice, and 3) multiple gates vs. single gate. We define MR as $(G_p - G_{ap}) / (G_p + G_{ap})$, where G_p and G_{ap} are conductance of parallel and antiparallel configurations, respectively. Conductance is obtained by assuming the continuity of electron wave function and electron flux through out the device. SI is defined as the ratio of majority and minority spin in parallel configuration.

Fig 1 and Fig 2 show the results for a single and a triple gate device, respectively. The results show an oscillating MR and SI trend with varying gate voltage. The oscillation frequency increases with the increase of the channel length. Therefore device with longer channel becomes more sensitive to the gate voltage. The effective mass of the 2DEG material too has an effect on MR oscillation similar to channel length, i.e. in this case, the frequency of oscillation increases with increasing effective mass. These show that the stability of the device can be improved by using smaller channel length as well as 2DEG material with smaller effective mass. The magnetic exchange energy, h_0 in the FM electrodes also affects the device performance. Higher h_0 results in a larger magnitude of MR and SI. However the frequency of the oscillation remains the same. Fig. 2 shows that the magnitude of MR and SI as well as the stability of the device can be improved drastically by using a triple gate device structure.

In conclusion we have designed a semiconductor based MR device that could perform the function of a metal spin valve, but with the advantage that its MR can be optimized (post-fabrication) and its stability enhanced by controlling the applied gate voltage.

Magnetic-tunnel-junction-based programmable logic devices by spin transfer torque switching.

X. Yao, Y. Zhang, H. Meng, J. Wang

MINT Center & Electrical and Computer Engineering Department, Univ. Of Minnesota, Minneapolis., MN

GMR and MTJ element based programmable logic devices[1-6] and a Full Adder[7] have been proposed for future reconfigurable and non-volatile computation devices and systems. A single-MTJ based full-function programmable logic device[5] has been experimentally demonstrated. Till now, all logic device designs use the magnetic field generated by a current line to switch the free layer magnetization. However, the fringe magnetic field from the current line can make the adjacent elements instable. Spin transfer torque (STT) or so-called current-induced magnetization switching (CIMS) has advantages in the device scaling compared to the field-switching mechanism. In this work, a single MTJ based logic device using STT switching mechanism is proposed and tested. Logic functions, such as AND, OR, NAND, NOR, and XOR, can be realized.

Fig.1(a) shows the device design for logic functions AND and OR. The MTJ element locates between the top and bottom electrodes. Each electrode has two inputs. For functions AND and OR, inputs A and B are used; and inputs C and D are grounded. Logic "1" (logic "0") is defined as positive (negative) current passing through the input terminals. The current density of each input is 67% (2/3) of the critical switching current density (J_c) of the MTJ. Nano-second current pulse can be used in the real application so that $J=67\%J_c$ is safe, which cannot switch the free layer by itself. For AND operation, the device is pre-set to parallel status. At this parallel state, the free layer can only be switched when both inputs are logic "1". When the inputs have mixed "1" and "0", there is no net current passing through MTJ. When both inputs are logic "0", the device prefers keeping parallel state. When operating OR function, the device is first set to high resistance state. For functions NAND and NOR, the inputs C and D are used and inputs A and B are grounded fig.1(b). logic "1" for the inputs is also defined as the positive current passing through the input terminals. The device is pre-set to antiparallel state and parallel state for function NAND and NOR, respectively. XOR is one of the most important logic functions. Here we propose a design of a double-MTJ device to realize the XOR function. As shown in fig.1(c), the two free layers locate at the two sides of the fixed layer separated by the barriers. Because the critical switching current density of the free layer is proportional to its saturation magnetization(M_s)[8], free layer 1 which has smaller M_s has lower critical switching current density (J_{c1}) than that (J_{c2}) of free layer 2, which has larger M_s . The input current density, J , is in between of J_{c1} and J_{c2} . This double-MTJ device has four resistance states, shown in the table of fig.1 (c). We define the highest resistance state (state d) is logic "1", and the other three low resistance states (state: a, b, c) are logic "0". For XOR function, the device is first set to antiparallel state (logic "1"). When both input A and B are "1" or "0", only one of the free layers switches. Therefore, the device shows low resistance state, "0". Otherwise, the device keeps logic "1".

To operate function AND, OR, NAND, NOR, the amplitude of each operating input is set to 67% (2/3) of the critical switching current density, which guarantees that single input current cannot switch the free layer by itself. Fig.2 (a) shows the experimental result of the current-induced switching in the MTJ device. The sample structure is: Si substrate/SiO₂/bottom electrode/Ta₃/CoFe₂/FeSiO₃/CoFe₁/Al 0.65+oxidation/CoFe₃/Ru0.8/CoFe₃/IrMn15/Ta₂₀/top electrode (Unit:nm). The device was patterned into 180 nm*250 nm ellipse shape by phase shift photo-lithography. The average critical switching current is 4.5×10^6 A/cm². So, in our design, the

current density for each input is 3×10^6 A/cm². When both operating inputs have the same direction, the total current density is 6×10^6 A/cm², which has capability to switch the free layer magnetization. Fig.2(b) lists the actual input and output values for AND operation and their corresponding logic states.

Transport properties of fully epitaxial magnetic tunnel transistor with a MgO barrier.

T. Nagahama¹, H. Saito^{1,2}, S. Yuasa¹

1. AIST, Tsukuba, Japan; 2. PRESTO, Japan Science and Technology Agency, Kawaguchi, Japan

Magnetic tunnel transistor (MTT) is a hot electron transistor consisting of semiconductor as collector, ferromagnetic layer as base, and ferromagnetic layer and tunnel barrier as emitter [1]. When the bias voltage (V_{eb}) is applied between emitter and base, the hot electrons traverse the base layer ballistically and pass over the Schottky barrier between the collector and the base layers, which is called collector current (I_c). The I_c heavily depends on the relative configuration of magnetizations of emitter and base. The change of collector current is called as “magnetocurrent effect (MC effect)”; MC ratio is defined as $I_P - I_{AP} / I_{AP}$.

In previous reported MTTs, the AlO_x has been used as a tunnel barrier. However, its amorphous structure gives rise to many scattering events during the tunneling, which prevents the transport of hot electrons for device operation. Consequently, the transfer ratio (TR ratio), which is the ratio between emitter and collector currents (I_c/I_e), and MC ratio become significantly small. On the other hands, in 2004, single-crystal MgO barrier was found for the magnetic tunnel junctions (MTJ), which has shown extremely high MR ratio coming from coherent-tunneling [2]. In the same way, employing MgO barrier is considered to improve the performance of MTT, e.g. MC ratio and TR ratio.

In order to realize high performance MTT, we prepared the MTT of GaAs(001)/Fe(20nm)/MgO(2.5nm)/Fe(5nm)/Co(10nm)/Au(20nm). After the growth of n -GaAs ($n=1.8 \times 10^{18} \text{ cm}^{-3}$), MgO tunnel junction was deposited in metal-MBE chamber at room temperature without breaking the vacuum. The films were fabricated into three terminal junctions with Schottky junction of $90 \times 40 \mu\text{m}^2$ and MgO-tunnel junction of $10 \times 10 \mu\text{m}^2$.

In figure 1, I_c and MC ratio are shown as a function of V_{eb} . Clear increase of both of I_c and MC are observed above threshold V_{eb} of 0.7 V. The maximum MC ratio is 208% at 40 K, which is 6 times larger than that for AlO-MTT of CoFe/AlO/Fe(001)(20nm)/ n -GaAs [3]. Regarding the TR ratio, I_c/I_e is 1.8×10^{-5} at $V_{eb}=1.0$ V. This is 2 orders larger than the value for the AlO-MTT. These results indicate that the MgO tunnel barrier is very favorable for MTT emitter.

In order to achieve MgO-MTT's potential, the scattering in the base layer should be suppressed. We have done two approach to solve this problems. The first is the reduction of the thickness of the base, and the second approach is a use of Ga-rich surface of GaAs collector. Ga-rich surface was obtained by annealing after GaAs growth at 800 K for 1 hour, and 2×6 reconstruction was observed by RHEED.

Table 1 shows typical values of MC ratio and TR ratio in the present MTTs at 40K. All the MTTs show MC ratios of larger than 200 %. MTT with 10 nm base made on Ga-rich surface shows the largest MC ratio of 288%, implying that the Ga rich surface and thin base layer are efficient for large magnetic signal. With respect to the TR ratio, it seems to be almost independent of the GaAs surface. The As atoms still exist at GaAs/Fe interface and diffuse into Fe(001) base layer. While it depends on the thickness of base layer. At $V_{eb}=1.0$ V, the TR ratio for MTT with 10 nm is twice of that for 20 nm base. In higher V_{eb} , TR ratio for 20 nm base-MTT has the maximum at 1.4 V, and decrease in $V_{eb} > 1.4$ V. On the contrary, the 10 nm base-MTT keeps increasing of TR ratio beyond 2.0 V. As a result, MTT with 10nm base have much larger TR ratio maximum compared to 20 nm base. The different V_{eb} dependence of TR ratio is considered to relate to the band structure of Fe(001) layer and GaAs. More detail experiments and advanced theory are necessary to understand the V_{eb} dependence of I_c .

In summary, we study the magnetic tunnel transistor with single crystal MgO tunnel barrier. The MTT shows high-performance in magnetocurrent ratio and transfer ratio compared to MTT with AlO barrier. The transport characteristics are independence of GaAs surface and strongly depend on the thickness of base layer.

A Planar Magnetic Content Addressable Memory Cell.

W. Wang, Z. Jiang

Electrical Engineering, University of Wisconsin - Milwaukee, Milwaukee, WI

Magnetic Content Addressable Memory (MCAM) simplifies CAM cell from ten CMOS transistors to one Magnetic Tunneling Junction (MTJ) by exploring both data storage and XOR logic function inside MTJ [1]. However, the original proposed MCAM cell structure contains a vertical ring, which poses challenges in both material and fabrication of the MCAM. In this paper, we propose a planar MCAM cell design where the top and bottom magnets are programmed by two different programming mechanisms so that the programming process of one magnet won't disturb the magnetic state of the other magnet in the same MTJ.

Fig. 1(a) is the cross-section view of the MTJ cell. The top magnet of MTJ is a SAF structure, which is programmed by cross-bar current lines in toggle mode. The bottom magnet is a simple magnet programmed by fringe magnetic field from the domain wall motion in a programming line underneath it. The magnetic domain wall inside the bottom programming line is driven by the spin polarized current.

Fig. 1(b) is the top view of the proposed cell. The bottom programming line has an obtuse angle in the middle and enlarged pieces at both ends. The obtuse angle is to produce a head-to-head domain wall after initialization process when a large external magnetic field is applied along the angle bisector. This domain wall will be driven bi-directionally by the spin polarized current during bottom magnet programming. The enlarged end pieces are designed to pin the domain wall motion. Although the current pulses generated by CMOS circuits are very well defined, the domain walls may still have significant drift after millions of repeated programming cycles. The domain wall motion stops when the spin polarized current density drops below a minimum threshold level [2]. The enlarged end pieces are designed to reduce the spin polarized current density below the threshold level, so that the domain wall is pinned at the junction of the thin and thick portions of the magnet.

In the proposed planar MCAM implementation, the top SAF magnet requires relatively low programming field, which is too weak to disturb the magnetization states in the bottom magnet. In contrast, the bottom programming line demands current density in the order of 10^8 A/cm^2 . Such high current density will induce a strong magnetic field. Fortunately, the induced is perpendicular to the easy axis of the top SAF structure. The magnetization states inside the SAF structure is in scissor state [3] around the applied magnetic field. After the external field is removed, the SAF magnetization states return to their original states in parallel to its easy axis. Therefore, the magnetization states in the top SAF structure are not disturbed.

In order to demonstrate the feasibility of the proposed operation, we used LLG micro-magnetic simulator to investigate the programming margins for toggle mode SAF switching fields. Fig. 2 (left axis) shows the deviation of the final magnetization orientation from the expected direction. There is a clear jump between 80Oe (corresponding to 166 degree) and 100Oe (corresponding to 17 degree). Therefore, the switching field for the SAF structure is between 80Oe and 100Oe. Above mentioned final magnetization orientations deviate from the expected orientation (0 or 180 degree) due to some magnetization curling at the edges.

The programming field for SAF structure has an upper limit due to SAF saturation. Fig. 3 (right axis) shows the smallest angle between two magnetization orientations inside the SAF structure during toggle mode process. If we choose 10 degree as the minimum allowed angle for reliable

operation, the upper limit of the SAF programming field is around 180Oe. Therefore, there is about $2\times$ programming margin in SAF programming field.

In summary, we proposed a novel spin based planar CAM cell design. LLG simulation was performed to demonstrate the operation feasibility and the programming margin of $2\times$ in the programming field.

Carrier injection, carrier separation at metal/organic (M/O) interfaces and carrier transport in the organic films are key processes in the organic semiconductor devices.[1,2] The understanding of the electrical properties at M/O interfaces is of great importance to improve device performance as well as to design novel organic devices.

In order to study the interfacial properties of M/O films, Cu-phthalocyanine(CuPC) films of a thickness ranging from 10 to 100 nm were deposited on nonmagnetic and magnetic layers such as Au, Al and permalloy(Py). Surface potential formed in the M/O films was measured by Kelvin probe method in vacuum.

Figure 1 shows that the variation of the surface potential could be related to not only the ionization potential of the organic film but also the apparent work function of the metal surface. For the CuPC on Py layer, as the thickness of the film increases, the surface potential was positively charged due to the displacement of holes from the Py surface to the CuPC film, whereas the negatively charged surface potential was observed for the CuPC on the Au and Al electrodes. This implies that the carrier injection (electrons or holes) at the M/O interface could strongly depend on the electronic structure of the interfacial region of the M/O bilayers. These results led us to investigate electromagnetic properties in M/O interfaces by using the electroluminescent (EL) and tunneling devices with different metallic electrodes.

EL devices with CuPC and Alq3 organic films were prepared beyond the Al and Py surfaces by the vacuum-deposition at a base pressure of 10^{-8} Torr. Figure 2 shows a schematic of the EL device structure.

In Figure 3, for the EL devices with the Py electrode, we observed a larger magneto-optical effect ($\sim 4.4\%$) at 300 K than that ($\sim 0\%$) of the EL devices with the Al. For both of EL devices with Al and Py, the magnetic field effect on the transport properties was not shown in the current range which is large enough for the electroluminescence. However, for the tunneling devices with Py electrode (Py/CuPC/Py), the magnetic field effect at room temperature was more pronounced in the low current range (a few nano-amperes range).

According to our x-ray results, the high resistance of the EL and tunneling devices with Al could result from the poor crystallinity of the CuPC film grown on the amorphous Al layer. The good crystal structure was observed in the CuPC film grown on the FCC(111) Py layer.

These results point out the importance of electromagnetic properties at the interfaces in the M/O heterostructure films for spintronics applications.

Magnetoresistance (MR) effects including giant MR, colossal MR etc. exhibit large changes in electrical resistance according to magnetic field, which has led to great interest of scientists due to improvements in the magnetic information storage, sensors and magnetoelectronics. Specially, in manganite system showing colossal MR effect the dramatic switching of resistive states can be achieved not only by a magnetic field, but also by an electric field [1]. This current switching of resistive state has received considerable attention because of their interesting physical phenomenon and potential applications as nonvolatile memories [2]. On the other hand, magnetoresistive switch effect with large MR had been reported in the Sb/MnSb nanoclusters/GaAs system [3] and Au/GaAs Schottky diode [4].

In this report, we have studied a switching of resistive states in a semiconductor npn junction structure based on Hg_{0.79}Cd_{0.21}Te. Our device shows more than three orders of MR change and threshold magnetic field can be tunable by a bias voltage on the device.

Figure 1 (b) magnetic field dependence of current measured at various bias voltages. It shows abrupt change of current at a threshold field whose value is determined by the bias voltage. Thus, the conducting state of our device is convertible from low resistive state to high one and this change is governed by magnetic field. All of the observed curves are successfully recovered when sweep direction of magnetic field is reversed. Current in this device can be increased more than 10X10⁻⁶A, but the amount of current is limited to 100nA in this data to protect the device from high-current damage. Switching effect may be caused by avalanche multiplication process in p-type region. This electrical switching device can be good candidate for a future reprogrammable electronic device.

Micromagnetic Investigation of Interaction between Spin-Polarized Current and Spin-wave.

S. Seo, K. Lee
Korea University, Seoul, South Korea

I. Introduction

Excitation and propagation of spin-wave (SW) in a confined magnetic system have attracted a considerable interest because of its potential application for the logic device [1] as well as fundamental physics. Since the SW is a spin texture consisting of non-collinear magnetizations, it is possible to modulate the characteristics of SW by current injection. In order to study the interaction between a spin-polarized current and the SW in such a slowly varying magnetic environment, the adiabatic and non-adiabatic spin-transfer torque terms can be used. Here, we show the effect of spin-transfer torque on the characteristics of SW propagating along a wave guide.

II. Micromagnetic Simulation

We carry out micromagnetic simulations by solving the phenomenological Landau-Lifshitz-Gilbert (LLG) including the adiabatic and non-adiabatic spin torque terms; $\partial \mathbf{M} / \partial t = -\gamma (\mathbf{M} \times \mathbf{H}_{\text{eff}}) + \alpha / M_s (\mathbf{M} \times \partial \mathbf{M} / \partial t) - b_j / M_s^2 (\mathbf{M} \times (\mathbf{M} \times \partial \mathbf{M} / \partial x)) - c_j / M_s (\mathbf{M} \times \partial \mathbf{M} / \partial x)$, where \mathbf{H}_{eff} is the effective field consisting of the anisotropy, exchange, magnetostatic, and external field (\mathbf{H}_{ext}), M_s is 800 emu/cm³, Gilbert damping constant $\alpha = 0.01$, the exchange constant $A = 1.3 \times 10^{-6}$ erg/cm, the anisotropy constant $K = 0$, and $b_j (= P_j \mu_B / e M_s)$ and $c_j (= \beta b_j)$ represent the magnitude of the adiabatic and non-adiabatic spin torque, respectively. The Permalloy nanostrip is selected as a wave guide. The geometry of the nanostrip is $2000 \times 120 \times 6$ (length (l) \times width (w) \times thickness (t)) nm³ (Fig. 1.). To absorb reflected SWs from edges, an enhanced damping constant is adopted at both sides of the nanostrip ($x = 0 \sim 50, 1950 \sim 2000$ nm). Upon applying AC bias field along the y -axis, i.e., $H_y = H_{\text{ext}} \sin(2\pi\omega_0 t)$ where $H_{\text{ext}} = 100$ Oe, and $\omega_0 = 2 \sim 20$ GHz, the magneto-static surface wave is generated.

III. Results and Discussions

The dispersion relation of SW as a function of the current density (J_c) is shown in Fig. 2(a). As theoretically predicted [2, 3], the adiabatic spin torque provides the spin wave *Doppler* shift. However, the dispersion relation is obtained at relatively higher wave vectors (k_x s) than those predicted by theories. Interestingly, the splitting energy ($\Delta\epsilon \propto \Delta k_x$ in Fig. 2(a)) show a different dependence on the ω_0 depending on the sign of current. The $\Delta\epsilon_{(-)e}$ is proportional to the ω_0 whereas the $\Delta\epsilon_{(+)e}$ is almost the same in the range of calculated frequency (ω_0). Note that the β term measures the relative magnitude of non-adiabatic spin torque with respect to the adiabatic one. The effect of the non-adiabatic spin torque on the SW mode is also studied. It is found that the β term does not affect the dispersion relation, but efficiently changes the amplitude of SW.

Fig 2. (b) shows the FFT power (P_{FFT}) over a temporal window for $t = 30$ ns as a function of k_x . The P_{FFT} increases or decreases depending on the sign of J_c and the magnitude of β term. When $\beta < \alpha$, the P_{FFT} increases (decreases) when the J_c is positive (negative). It means that the amplitude of SW is enhanced or damped depending on the relative directions of SW propagation and electron flow. When $\beta = \alpha$, the P_{FFT} is the same regardless of J_c . When $\beta > \alpha$, the P_{FFT} increases (decreases) when the J_c is negative (positive). The enhancing or damping rate of SW increases with the J_c and β term.

IV. Conclusion

We perform micromagnetic investigation of interaction between spin-polarized current and spin-wave. It is confirmed that only the adiabatic spin torque contributes to the current-induced spin-wave *Doppler* shift. The non-adiabatic spin torque has a negligible effect on the dispersion relation, but significantly affects the amplitude of spin-wave.

Oxides are being intensively investigated as candidates for a new generation of electronic and magnetoelectronic devices. Of particular interest is the obtention of fully polarized spin sources as they could allow larger magnetoresistance values in magnetic tunnel junctions thus allowing further miniaturization of magnetic components. For this purpose, half-metallic ferromagnetic oxides have been intensively investigated in the last decades but so far, materials for room-temperature operation have not been obtained. However, during the last few years, spin filtering has emerged as a very powerful tool to obtain a large magnetoresistance in magnetic tunnel junctions, circumventing intrinsic materials limitations. Effective room-temperature spin filtering has been achieved with the so-called orbital symmetry filtering, as illustrated in magnetic tunnel junctions made using epitaxial MgO barriers, and record values of tunnel magnetoresistance have been obtained. A promising alternative to spin filtering is by using the so-called magnetic spin filtering as occurs in ferromagnetic tunnel barriers. Magnetic oxides are ideal candidates for this purpose and recent results suggest promising perspectives. We will review the status and perspectives of magnetic spin filtering. We will show that epitaxial engineering of oxides allows to design artificial sources of spin polarized electrons and we shall report on recent results suggesting that indeed these materials could offer for progress and opportunities for spintronics. Other alternatives for electric manipulation of magnetic elements will also be discussed.

The planar Hall effect (PHE) is an interesting phenomenon in magnetic materials which allows the study of magnetization processes and has applications in sensitive low-field detection [1, 2]. This effect stems from the anisotropy of the resistivity tensor and, as a consequence, its magnitude is proportional to the anisotropic magnetoresistance (AMR) and to the absolute value of the resistivity [3]. Fe_3O_4 seems to be a promising material to produce giant PHE values due to its large resistivity compared to magnetic metals and its relatively large AMR values [4]. Previous studies on Fe_3O_4 thin films suggest potentiality for giant PHE at room temperature [5].

We have investigated the planar Hall effect in epitaxial Fe_3O_4 thin films with thickness ranging from 5 to 150 nm grown on MgO (001) substrates. Previous studies indicate the epitaxial growth and high crystalline quality of our Fe_3O_4 thin films and describe the optical lithography procedure [6]. In summary, the current flows through a micrometric electrode along the [100] direction and Hall contact pads are patterned in order to minimize offset voltages. The magnetic field is applied in the film plane forming a fixed angle (Θ) with the current direction. The maximum PHE is expected when the current and the magnetization are at $\Theta=45^\circ$ (135°) degrees.

In figure 1 the result obtained at room temperature for the 40 nm film is shown. The absolute value of the PHE (ρ_{xy}) at maximum field is quite large (a few $\mu\Omega\text{cm}$) compared to the values observed in metallic magnetic thin films (typically 100 times smaller). We attribute this giant PHE effect to the high resistivity of the film together with a relatively large AMR value. This is corroborated by the set of measurements performed in all the films at room temperature and shown in figure 2. As the film thickness decreases, the longitudinal resistivity (ρ_{xx}) increases due to the influence of antiphase boundaries [7], which reflects in the enhancement of the PHE for the thinnest films. We have obtained a record value at room temperature of $\rho_{xy}=60\mu\Omega\text{cm}$ for the 5 nm film under 10 kOe. Our investigation as a function of temperature indicates a substantial enhancement of the absolute value of the PHE when crossing the Verwey transition ($T_v \approx 120$ K), which is a consequence of the increase of resistivity at T_v whilst keeping a significant AMR. As shown in figure 3, colossal values of PHE are observed below T_v , never attained before. A change in the sign of the PHE effect has been found in the film with thickness 20 nm at $T \approx 150$ K, which seems to be correlated with the change in the sign of the AMR previously observed [4]. Our results demonstrate the potentiality of the PHE in Fe_3O_4 thin films for studies of magnetization processes as well as for sensitive low-field detection in a wide range of temperature.

1. Physikalisches Technische Bundesanstalt, Braunschweig, Germany; 2. CRANN and School of Physics, Trinity College, Dublin, Ireland

The half metallic character of magnetite with a predicted 100% spin polarization and its high Curie temperature (≈ 850 °K) [1] makes it an attractive candidate for a variety of spintronics applications. Furthermore, magnetite nanoparticles are interesting for bio medical applications like hyperthermia cancer treatment [2]. In both fields the ultra fast precessional magnetization dynamics and especially the dissipation of magnetization precession due to Gilbert damping is of major importance. However, detailed studies are not available. Here we investigate time resolved precessional magnetization dynamics of sputter deposited Fe₃O₄ thin films using pulsed inductive microwave magnetometry (PIMM) [3]. The field dependence of the precession frequencies and the Gilbert damping parameter α is studied. We find a large Gilbert damping parameter which could be of advantage for magnetite based spin transfer torque applications.

The samples were prepared by DC magnetron sputtering on Si (111) substrates in a deposition system with a base pressure of 10^{-7} mbar. The deposition results in a strongly oriented f.c.c. thin film as observed by x-ray diffraction. The 50 nm thick magnetite film under investigation has a saturation magnetization of $\mu_B M_s \approx 0.5$ T with out-of-plane anisotropy. The temperature dependence of the magnetization shows a Verwey transition around 120 K (Figure 1) proving the correct stoichiometry consistent with the inverse spinel lattice structure.

For PIMM measurements the Fe₃O₄ films are placed onto a 50 Ω coplanar waveguide connected to a pulse generator and a sampling oscilloscope with 18 GHz bandwidth. Ultra short current pulses (rise time 50 ps, pulse width 100ps) from the pulse generator propagate in the coplanar waveguide and generate transverse magnetic field pulses ($H_p \approx 0.02$ mT) at the magnetite thin film. The field pulses excite a precessional motion of the magnetization (M) which in turn induces a voltage signal into the waveguide that can be detected by the oscilloscope.

During PIMM experiments static in-plane fields up to 20 mT are applied in different in-plane field orientations. A time resolved trace of the magnetization dynamics is shown in Figure 2 (b). By fitting the time resolved data by an exponential damped sinusoid (b) or by fitting the Fourier transform of the precessional data by a Lorentzian (c) the field dependent precession frequency and Gilbert damping parameter α are obtained. As shown in Figure 3 the precession frequency increases with static fields as expected for ferromagnetic resonance. A Gilbert damping parameter of $\alpha = 0.13 \dots 0.08$ is found. The value of α is thus about a factor of 10 higher than in high quality metallic thin films like permalloy. A decrease of α with increasing bias field is observed which could be due to a dispersion of anisotropy field [3,4].

The measured high Gilbert damping could be useful for spin transfer torque applications. Here a high damping [5] could allow an efficient spin angular momentum transfer from the magnetite to a neighbouring ferromagnetic free layer by a high density current. The high Gilbert damping together with the out-of-plane anisotropy could thus make such thin films an interesting candidate for perpendicular spin polarizers in spin transfer torque MRAM or spin transfer oscillators [6].

Angular dependence of the magnetoresistance measured across a single-grain boundary.

L. B. Steren, G. Alejandro, J. C. Rojas Sanchez, E. N. Monteblanco Vines, H. Pastoriza
Physics, Centro Atómico Bariloche, S.C. Bariloche, Argentina

Bicrystalline substrates are appropriate devices to investigate the low field magnetoresistance (LFMR) of manganite compounds, by isolating a unique artificial grain boundary (AGB). During the last years a large experimental effort has been devoted to study the electronic and magnetic properties of these systems. The LFMR of ferromagnetic perovskites, its temperature and field dependence, and the non linear character of the I-V curves have been studied on (La, Ca)MnO₃, (La, Sr)MnO₃ and Sr₂FeMoO₆ (1) bi-crystalline films by using different lithographed patterns of diverse size, shape and complexity.

In this work we present magnetoresistance measurements in Wheatstone bridges of La_{0.75}Sr_{0.25}MnO₃ thin films crossing a single grain boundary. The films of 120 nm thickness, were deposited by dc-sputtering on 0.5x0.5cm bi-crystalline SrTiO₃ substrates, at a temperature of 760°C. X-ray diffraction (XRD) patterns, obtained from a four-circle diffractometer, allows us to identify the orientation of the La_{0.75}Sr_{0.25}MnO₃ bi-crystal.

The Wheatstone bridges were lithographed onto the La_{0.75}Sr_{0.25}MnO₃ films in order to measure the magneto-transport properties of the manganite compound. Two arms of the bridge crosses the AGB while the other two sense only single-crystalline regions. The magnetoresistance measurements were performed at 77K. The angular variation of the resistance has been measured by rotating the magnetic field in the plane of the films.

The angular dependence of the DC magnetization of the samples was measured in a vibrating sample magnetometer. The anisotropy of the manganite films, deduced from the magnetization data serves us to identify the crystal anisotropy contribution to the magnetoresistance from that of the AGB.

The magnetoresistance has been measured simultaneously in two arms of the Wheatstone bridge. The SC that traverse the single-crystalline region and the GB, that crosses the artificial grain boundary. Typical curves measured for the GB arm are shown in Fig. 1. The high field component is associated to the colossal magnetoresistance effect observed in ferromagnetic manganites. The magnetoresistance is hysteretic at low field and it is strongly dependent on the field direction.

The low field magnetoresistance curves can be analysed in terms of two contributions. One of them, present also in the SC magnetoresistance curves, is anisotropic and clearly dependent of the crystalline symmetry of the crystal. This effect has been already reported in Ref. 2 for La_{0.7}Ca_{0.3}MnO₃ films. The other one, has a two-fold symmetry with the easy axis oriented along the AFG direction.

The distinction between the two low field components is difficult when the peak position of both effects are close, as shown in Fig. 1. In order to better examine the origin of both effects we perform a different experiment. We measured the angular dependence of the resistance of the SC and GB arms at different magnetic fields. We noticed that the intensity of both effects are strongly affected by the magnetic field. Above 5kOe, the magnetoresistance arising from the crystalline anisotropy of the samples has almost disappeared while the component associated to existence of the AGB is still present.

Antiferromagnetic Heusler compounds with high spin-polarization.

G. Liu, X. Dai, G. Fecher, C. Felser

Institution for Inorganic and Analytical Chemistry, Johannes Gutenberg University of Mainz, Mainz, Germany

Half-metallic antiferromagnets are the ideal materials in spintronic devices since such a material would not give rise to great stray flux and thus would lead to smaller energy losses. In the last decades, only several materials have been theoretically predicted to be half-metallic antiferromagnets, including ternary Heusler MnCrSb , binary Heusler Mn_3Ga_2 and quaternary Heusler MnCoVAI and $\text{Mn}_{1.5}\text{Co}_{0.5}\text{VSi}$ compounds³. Unfortunately, up to now, none of these alloys has been successfully synthesized in the desired structure. Therefore, many researchers turn to search for the half-metallic ferrimagnets with low magnetic moments. Some significant results have been achieved. However, in these half-metallic ferrimagnets, the magnetic moment are impossible to achieve the smaller value than $1 \mu\text{B}$. In this work, we will turn to another route, that is, to develop antiferromagnets with high spin-polarization (but not 100% spin-polarization), which will be easy to design and fabrication, and can also do well work in realistic applications.

The Co_2CrZ ($Z=\text{Al, Ga}$) compounds with L21 structure have been predicted to be half-metallic ferromagnets, but they have a magnetic moment of $3\mu\text{B}$. In order to decrease the magnetization, we substitute a Cr atom for a Co atom in these compounds. So, a series of Cr_2CoZ ($Z=\text{Al, Ga, In}$) compounds with CuHg_2Ti -type structure were achieved. Based on this structure, their electronic structures with different lattice constants were calculated by the first-principle calculations as shown in Fig.1. The detailed parameters were listed in table I.

For Cr_2CoAl alloys, one can see that its spin-polarization ratio at the Fermi level increases with the increasing lattice constant. The maximum of 42.3% occurs when the lattice constant is 5.82 \AA . When the lattice constant is the optimized one of 5.74 \AA , the Fermi level is at the edge of a pseudogap. So, we can understand the sharp increase of the spin-polarization ratio with the increasing lattice constant results from the upshift of Fermi level due to the extension of the lattice. For the Cr_2CoGa compound, the optimized lattice constant is 5.75 \AA where the maximum spin-polarization ratio of 45.07% was observed. The corresponding magnetic moment is about $0.3\mu\text{B}$. The larger or the smaller lattice constant will lead to the destruction of antiferromagnetism which is nonsensical to our work. As to the Cr_2CoIn compound, from the table I, it can be seen that the ratio of spin-polarization is up to 70.1% at the lattice constant of 5.7 \AA . The larger lattice constant will result in the disappearance of the antiferromagnetism. Although the optimized lattice of 5.99 \AA is in the range where ferromagnetism occurs, we can expect to obtain the proper lattice constant by some methods such as the epitaxial technique which will not be difficult.

Furthermore, we must emphasize that these alloys are easy to crystallize in the CuHg_2Ti -type structure and we have successfully synthesized them. In the absence of half-metallic antiferromagnets with 100% spin-polarization, these alloys will be a good candidate for the realistic application in spintronic devices.

In addition, based on the investigation of the Cr_2CoZ system, we also found a rule to search for the new antiferromagnets with high spin polarization ratio: the CuHg_2Ti -type Heusler alloys containing transition-metal atoms with less number of d electrons than eight is a rich field to develop such materials. The detailed discuss will be presented in the formal paper.

In summary, in this work we reported a new series of Heusler compounds: Cr_2CoZ . These compounds crystallize in CuHg_2Ti -type structure, and exhibit a high spin-polarization at the Fermi level and a magnetization close to zero, which make

these compounds become a good candidate for spintronic devices. The electronic structures, magnetic structure, transport properties and the spin-polarization of these compounds will be detailedly investigated in experiments and theory, which will be shown in the formal paper.

Co₂-based Heusler compounds are promising candidates for spintronics devices with the potential to provide 100% spin polarization. Here, we report on the determination of magnetic anisotropy, exchange interaction and magnetization reversal in Co₂FeSi, Co₂Cr_{0.6}Fe_{0.4}Al (CCFA), Co₂MnSi and Co₂MnAl_xSi_{1-x} Heusler compounds using Magneto-Optical Kerr Effect (MOKE) magnetometry and Brillouin light scattering (BLS) spectroscopy. The samples are studied as a function of composition, ordering and thickness [1-3].

Examples of BLS spectra of CCFA and Co₂FeSi are presented in Fig. 1a. CCFA, as well as all Heusler compounds studied here except Co₂FeSi, provide BLS spectra with several well-resolved BLS peaks, corresponding to different spin-waves modes. On the other hand, the BLS spectra of epitaxial L₂1 ordered Co₂FeSi does not provide sharp peaks, as they are smeared out to a wide, single peak (Fig. 1a). It is a fingerprint of a random distribution of the internal field in Co₂FeSi, with a distribution width of about 4 kOe. We have attributed this random internal field to a presence of Dzyaloshinskii-Moriya (DM) exchange which is described by a Hamiltonian $H = \mathbf{D} \cdot (\mathbf{S}_i \times \mathbf{S}_j)$, different from ordinary Heisenberg exchange Hamiltonian $H = J \mathbf{S}_i \cdot \mathbf{S}_j$. The presence of the random field distribution is also supported by constanteness of the coercive field H_C as a function of the in-plane angle of the applied field, found in epitaxial Co₂FeSi films, smearing out the expected 4-fold anisotropy [3], which was found for example in CCFA films [1].

From the frequencies of the spin-waves modes we have determined the exchange constant A , the saturation magnetization M_S and the magnetocrystalline cubic volume anisotropy K_1 of the investigated Co₂-based Heusler compounds (Tab. 1) and compared them with phases of Co and Fe. The exchange constant A of the investigated Heusler compounds is about 0.4-0.6 $\mu\text{erg/cm}$, i.e. about 4-5 times smaller than A of Co and Fe. M_S of Heusler compounds ranges between 500-1000 emu/cm^3 , whereas typical value of Co and Fe is 1400 emu/cm^3 . Exchange stiffness D of Heusler compounds is about 2-3 times smaller than those of Fe and Co.

In Co₂MnSi films, we have studied the dependence of M_S , A and K_1 on the annealing temperature T_a , which provides different degrees of the L₂1 order (i.e. B2 or L₂1). The change of M_S and A with change of crystallographic order is less than 10% (see Tab. 1). On the other hand, K_1 drops by more than a factor of 10 during B2 to L₂1 transition (Fig. 1b). Similar results are provided by the dependence of Co₂MnAl_xSi_{1-x} on the nominal composition x (Fig. 2). Although M_S and A depend weakly on x (Fig. 2a,b), K_1 depends expressively on x (Fig. 2c).

The project was financially supported by the Research Unit 559 "New materials with high spin polarization" funded by the Deutsche Forschungsgemeinschaft, by the NEDO International Joint Research Grant Programm 2004/T093 and by the Stiftung Rheinland-Pfalz für Innovation.

Spin transitions in DyCoO₃ investigated by measuring the electric quadrupole interactions.

F. H. Cavalcante, A. W. Carbonari, G. A. Cabrera-Pasca, J. Mestnik-Filho, R. N. Saxena
CRPq, IPEN, Sao Paulo, Brazil

Rare earth Cobaltites with perovskite structure RCoO₃, where R = rare-earth element, form a family of compounds in which magnetic transitions are associated to spin states of Co³⁺ ion. In the perovskite structure R³⁺ and Co³⁺ metal ion sites have twelve fold and six fold oxygen coordination, respectively. In this family, LaCoO₃ has been studied intensively due to two spin-state transitions of Co³⁺. The first is associated with the transition from a nonmagnetic low spin state (LS) ($t_{2g}^6 e_g^0$) to a paramagnetic intermediate spin state (IS) ($t_{2g}^5 e_g^1$) at around 50-100 K and the second transition (an insulator-metal character transition) from IS to high spin state HS ($t_{2g}^4 e_g^2$) at 500-550 K. However, this interpretation has been criticized, first, because theoretical calculations indicate that IS state is energetically more favorable than HS state and second, a Jahn-Teller distortion is expected for a IS state as the degenerate orbital e_g^1 is partially occupied which is not compatible with the R-3c symmetry [1,2]. Differently from LaCoO₃, which presents a rhombohedral crystallographic structure and where the spin transitions are relatively easy to observe by magnetic measurements, the other compounds of the RCoO₃ family exhibit a orthorhombic structure, and Co spin transitions are difficult to determine by magnetic susceptibility measurements due to large magnetic moment of R ions. In particular, DyCoO₃ shows a large distortion of the CoO₆ octahedron and has been very little studied so far. A microscopic technique, in which local changes can be easily followed, is therefore very useful to investigate spin transitions in RCoO₃ family. Hyperfine interactions techniques offer a high sensitivity to local structure variations in the crystal lattice and, consequently, can be used to follow changes such as bond distances, symmetry, defect trapping etc. on a microscopic scale.

In the present work, the perturbed angular correlation (PAC) technique was used to measure the temperature dependence of quadrupole interaction (QI) in DyCoO₃ compound using ¹¹¹In → ¹¹¹Cd and ¹⁸¹Hf → ¹⁸¹Ta nuclear probes. These radioactive probes were introduced in the oxide lattice through a chemical process during the sample preparation. The PAC measurements with ¹¹¹Cd and ¹⁸¹Ta probes were made in the temperature range of 10 K to 1200 K.

The temperature dependence of the quadrupole frequencies for ¹¹¹Cd at Co and Dy sites show unexpected behavior. Instead of decreasing with temperature as a result of thermal expansion of the lattice, the quadrupole frequencies (ν_Q) for ¹¹¹Cd at both Dy and Co sites show discontinuities at two different temperature regions: 200-350 K and 600-800 K. Above 800 K the quadrupole frequency increases with increasing temperature, as can be seen in figure 1. The second discontinuity in the temperature dependence of quadrupole frequency is clearly seen in the measurement taken with ¹⁸¹Ta.

The asymmetry parameter measured with ¹¹¹Cd at Co sites shows high values in the temperature range of 100 K to 400 K, which indicates a strong distortion of the CoO₆ octahedron. However, above 400 K the asymmetry parameter decreases almost linearly with temperature. These results are discussed in terms of spin-state transitions and distortions in the crystal structure and compared to results previously published for PAC measurements in LaCoO₃ [3], GdCoO₃ [4] and TbCoO₃ [4]. With these results it was possible to observe a systematic behavior of the temperatures assigned to the spin transitions as a function of the rare-earth ion radius.

1. Introduction

FES is the therapy for rehabilitate lost movement function to apply electrical stimulation to paralyzed extremity. We adapt implanted direct feeding method for the FES (Fig. 1). One of the specific FES need is synchronizing all stimuli in order to rehabilitate function correctly. TDMA allows stimulus signals to multiplex, but a outer unit and inner units are separated in the way. So we must pick up the information from inner units to make reparation for receiving data and stimulate correctly. In addition, based on downsized inner units, it is not undesirable to make large coils of inner units. We realized two-way communication system by magnetic connection between voltage resonance and current resonance.

2. Principle of Communication Coils between Inside and Outside of Body

It is important to resonate current for transmit signal with coil. On the other hand, it is important to resonate voltage for receive signal with coil. In generally, the former is constructed by connect capacitance in series against coil and the latter is constructed by connect capacitance in parallel against coil. But it is difficult to transmit signal from voltage resonance system so that two-way communication is not realized in simply. So we show communication system we suggest in Fig. 2. Because there are power coils out of body, we decided that the part that a number of coils is fewer is outer unit. When communicate from inner to outer, magnetic flux generated by L_p interlinks L_s and transmit signal with current resonance. In the receive side, it is able to get high voltage in order to voltage resonance with C_{po} and L_{sp} . At the same time, when communicate from outer to inner, C_{so} is enable to make current resonance state at lower frequency (f_{oi}) than the frequency from inner to outer (f_{io}). Though the magnetic flux interlinks each inner coil, L_s side resonates at f_{io} and different from f_{oi} so that inner unit is free of influence form L_s and C_{si} . L_p and C_{pi} make voltage resonance at f_{oi} and inner unit can get high voltage. In this way, we could realize communication antenna system between inside and outside of body.

3. Result

In FES, we can think magnetic connection between outer unit and inner units is very few. The values of each capacitance are shown in Table. 1. Based on the expressions, we experimented communication with this antenna. Input voltage is 10 Vp-p, f_{io} is 2MHz and f_{oi} is 1.6MHz. The characteristic of the distance of coils and voltage is shown in Fig. 3. From this result we can recognize this system allows two-way communication.

Bone Tissue Engineering using Magnetically Oriented Collagen.

T. Shinohara¹, T. Saito², D. Saito¹, A. Nakahira³, M. Aoki⁴, M. Kotani²

1. Research Institute for Advanced Technologies, Tokyo Denki University, Inzai-shi, Japan; 2. Graduate School of Engineering, Tokyo Denki University, Kanda, Japan; 3. Graduate School of Engineering, Osaka Prefecture University, Sakai, Japan; 4. Neomax, Hitachi Metals, Ltd, Oomachichou, Japan

Introduction

As the life span of human being is becoming increasing, people with bone problems is also increasing. Ceramics and metals are used as the biomaterial for repair and reconstruction of diseased or damaged bones [1]. However the mechanical and biocompatible characteristics of these materials are different to those of natural bones. Therefore, the development of biomaterials with characteristics similar to those of natural bones is expected.

As natural bones are consisted with collagen and hydroxyapatites, so that is an organic/ceramic hybrid composite material. In natural bones, the collagen is highly oriented in one direction, leading to the achievement of a mechanically strong material. To obtain structures similar to natural bones, it is necessary to orient collagen. Therefore, to develop artificial bone similar to natural bones, highly oriented collagen scaffolds for osteoblast cells are required, and the preferred orientation of collagen is a key technology. For this purpose, we developed magnetic circuit using permanent magnets, without using superconducting magnet, which showed magnetic field strength around 3 T, and collagen oriented clearly [2]. In this paper, fundamental bone formation by osteoblasts cultured on oriented collagen is reported.

Experiments

Collagen (type 1 from pig) provided by Nippon Ham was used as a starting material.

The collagen solution 0.5 wt% 2ml, 1.5 mol NaCl solution 0.2ml, and Dulbecco's Modified Eagle medium (α -MEM, Gibco provided), with 10% fetal bovine serum (FBS, BioWhittaker provided) were mixed, and cooled 0 Celcius degree, and then warmed to 22 Celcius degree then applied magnetic field 3 T by permanent magnet circuit for 24 hr, then warmed again to 37 Celcius degree, and kept for 1.5 hr, then the materials were observed by optical microscope.

Mouse osteoblast MC3T3-E1, provided by Riken cell bank, 1.6×10^6 cells/ml, 0.5ml, were seeded on mixture of collagen, NaCl solution and MEM, then, warmed to 22 Celcius degree for 24 hours and then warmed to 37 Celcius degree and cultured in incubator with 5% CO₂ for 50 days. The specimens were observed every 24 hr by optical microscope and SEM. The α -MEM solution changed every four days. After 50 days cultured, the specimens were observed by SEM, and then analyzed by EDS and X-ray diffraction.

Results and Discussions

The collagen oriented by permanent magnet circuit is shown in Fig 1. The orientation degree was more than 0.9. The shape of collagen fiber was straight, longer, and oriented clearly. The osteoblast cells seeded on collagen gel shrank with cultured days. The shrinkage of collagen-gel was formed by the mutual interaction of collagen and osteoblasts, and related to the activity and mineralization of cells [3]. The surface area of collagen-gel dependence on culturing time was observed. The shrinkage of collagen-gel saturated 14days after cultured. From the results, it was considered that the mineralization process of osteoblasts began after collagen shrinkage completed.

The SEM photograph of osteoblasts cultured 42 days is shown in Fig 2. The small round bolls, diameter around couples of microns meter, covered over all of collagen fibers. These materials were analyzed by EDS. It clarified that was composed with Ca and P. The X-ray diffraction measurement

result is shown in Fig 3. The material was identified to be hydroxyapatite which is main component of natural bones.

Modification of motor evoked potentials caused by electrical peripheral nerve stimulation in transcranial magnetic stimulation.

O. Hiwaki¹, M. Odagaki¹, F. Hiroshi¹, A. Kodabashi², T. Fujimoto²

1. Graduate School of Information Sciences, Hiroshima City University, Hiroshima, Japan; 2. Fujimoto Hayasuzu Hospital, Miyakonojo, Japan

1. Introduction

Transcranial magnetic stimulation (TMS) can evoke localized excitation of nerve cells in the motor cortex non-invasively. A cortical motoneuronal activation by TMS produces efferent signals going down through cortico-spinal tracts, thereby motor evoked potentials (MEPs) are observed at muscles which are innervated by the motor neurons. On the other hand, an electrical stimulus of peripheral nerves generates nerve potentials in sensory neurons going up to the primary somatosensory cortex. The potentials reached at the primary somatosensory cortex can be observed as electrical potentials or magnetic fields, which are named as somatosensory evoked potentials (SEPs) or somatosensory evoked fields (SEFs) respectively. It is supposed that the afferent sensory inputs into the sensorimotor cortex reached before TMS can influence the excitability of neurons in the motor cortex. The aim of the present study is to investigate whether the modification of the motor function is caused by the electrical peripheral nerve stimulus prior to the TMS. We analyzed MEPs evoked by the TMS following the electrical stimulus of the median nerve. SEFs were also measured in order to evaluate the afferent signals in the primary somatosensory cortex.

2. Materials and Methods

Four right-handed subjects (males aged 23-24 years) with no known neurological abnormalities participated in this study. Study procedures were approved by the ethics committee of Hiroshima City University. Informed consent was obtained from all subjects. The TMS stimulator was a Magstim Model 200 magnetic stimulator (Magstim, Whitland, UK) with a 70-mm figure-of-eight coil (2.2 T maximum output at the coil surface; monophasic pulse; duration, 1ms). The subjects lay supine on a medical chair and were instructed to maintain a slight contraction of the muscles of the right hand. The position of the coil on the left side of the subject's head was adjusted until visible contraction of the right hand muscle occurred. The coil was fixed at this site with a rigid multi-articular arm system. The median nerve at the right wrist was stimulated electrically prior to the TMS with interstimulus intervals (ISIs). The strength of the electrical stimulus was so adjusted that slight movement of the thumb was observed. ISIs were between 0 to 50 ms at 5 ms step. MEPs were measured at hand muscles: first dorsal interossei muscles (FDI), abductor pollicis brevis muscles (APB), abductor digiti minimi muscles (ADM), and forearm muscles: brachioradialis muscles (BR), extensor carpi radialis longus muscles (ECRL), flexor carpi ulnaris muscles (FCU) with Ag-AgCl electrodes on the bellies of these muscles. At each ISI, 10 successive trials were conducted, and the average of integral EMGs (iEMGs) in the period of 10 ms to 100 ms after the onset of TMS was calculated.

SEFs were measured in all subjects during right median nerve stimulation at the wrist by using a whole-head 160 channels axial SQUID gradiometer system (PQ1160C, Yokogawa Electronic, Tokyo, Japan). The passband of the bandpass filter was set at 1-500 Hz. Up to 400 responses were averaged. Single equivalent current dipoles (ECDs) were estimated in local regions at 20 ms and 30 ms after the stimulus.

3. Results and Discussion

The electrical stimulus of the median nerve was found to influence the iEMG of MEPs evoked by TMS. The MEPs of FDI was attenuated when ISI was 20 ms. This attenuation of MEPs was

observed at ADM as well (Fig.1). Furthermore, the iEMGs of MEPs at FDI and ADM were enhanced when ISI was longer than 25 ms.

The ECDs of the SEFs measured with 160 channels SQUID at 20 ms and 30 ms after the peripheral nerve stimulus were located in the posterior wall of the central sulcus (area 3b in the primary somatosensory cortex). The direction of the ECD at 20 ms was the postero-anterior, whereas that of the ECD at 30 ms was the antero-posterior direction which was approximately opposite direction of ECD at 20ms.

These results indicated that the attenuation and enhancement of MEPs observed at ISI of 20 ms and beyond 25 ms respectively was probably caused by the excitation of the neurons in the area 3b. The direction of the estimated ECD at ISI of 30 ms was in opposite to that of 20 ms, though both the estimated ECDs were located in the area 3b in the primary somatosensory cortex. Therefore, it is likely that the area 3b of the primary somatosensory cortex is involved in the motor responses from peripheral inputs, and the direction of the electrical dipole in the area 3b is concerned with the modification of the motor function.

Fig. 1. Integral EMG of motor evoked potentials (MEPs) changing with interstimulus interval (ISI) between TMS and electrical stimulation of the median nerve at the wrist

Detection of the terrestrial magnetism in migrating birds: Is it a question of vision?

The ability of birds to migrate over huge distances with outstanding accuracy is, in part, based on their capacity to use the earth's magnetic field for orientation. However, the "sensor" responsible for geomagnetic orientation is still unknown. It has been hypothesised [1, 2] that geomagnetic directional information is encoded by the birds' visual system. One explanation of the involvement of light as a possible transducer of magnetic field information is the "radical pair process theory" [2]. Photons of light striking the retina induce a chemical reaction within the photoreceptors. According to this theory, the yield of this reaction can be altered by the alignment of the ambient magnetic field with respect to the axis of the photoreceptive cell. Retinal activation is then processed further in the bird's brain, providing sufficient information to orient precisely. Support for the theory is given by studies showing that magnetic orientation in birds is disrupted by magnetic fields with resonance frequencies of 1.315 MHz [3] and 7 MHz [4]. Moreover, cryptochromes, which have been suggested as a possible centre of magnetic sensing in the eye, were found in the eye of migratory birds, and cryptochrome activity was increased during magnetic orientation [5].

It has been shown that migratory orientation in birds is preceded by head scanning, which is thought to calibrate the magnetic compass [6]. In this paper, head movements were studied to investigate homing pigeon behaviour with respect to different magnetic field conditions. An artificial magnetic field, equivalent to the earth's magnetic field, was generated with the help of a set of Helmholtz coils that are capable of producing static as well as sweeping magnetic fields, or the absence of any field. The constructed system is also equipped with a camera and, together with the equipment devoted to the generation of an artificial magnetic field, is fully automated by computer software. It is essential to ensure a high level of magnetic shielding when working with such low magnetic fields. Therefore, a specially designed shielding device, with a shielding factor of 850, was used. In this system, homing pigeons (*Columba livia*) were investigated using a novel approach: they were exposed to a sequence of several different magnetic field conditions, including a moving field, in the course of one experimental trial. Their behaviour was video recorded and analyzed to determine if their head movements were temporally correlated with changes in the field, indicating some kind of visual response to changes in the field.

Results showed that the birds tended to be especially active when experiencing a zero magnetic field, which presumably they had never experienced before. Particularly striking head movements and changes in postures were also observed during transitions to a sweeping field. Figure 1 depicts typical behavioural responses that occurred after a field transition to a sweeping field. In addition, increased eye movement during a sweeping field was noted. However, as eye movements can happen independently of the head movements, they are not recorded by our current software. Nevertheless, the eye movements may carry important information about the visuomotor origin of magnetic field detection in birds, and will be an important part of future analyses.

The data suggest that the different head movements and postures observed are indeed correlated to changes in the ambient magnetic field. Consequently, this finding, together with the indication that eye movements are involved in the response, implicates the homing pigeon's head as a location of the magnetic field sensor. However, further research is needed to determine whether changes in the

artificially produced magnetic fields lead to statistically reliable changes in head movements, and whether these movements are visuomotor in nature.

Looking to the future, establishing a reliable behavioural assay for magnetic field responses in homing pigeons would serve as a basis for identifying the location and nature of the magnetic sensor, the neurobiological and psychophysical properties of magnetic field perception, as well as the behavioural responses related to such perception.

Introduction: Electroconvulsive therapy (ECT), in which electric current are applied to the brain through scalp electrodes, improves severe mental illnesses [1]. Transcranial magnetic stimulation (TMS) is another neurophysiology method to stimulate cerebral tissue non-invasively using eddy currents generated by impulses of magnetic field [2][3]. Both TMS and ECT have been employed for treatment of psychiatric disorders such as depression and Parkinson's disease etc. In addition to their widespread application in humans, TMS and ECT have been also applied to the animals experimentally. Zyss et al. presented the comparison of the effect of treatments of TMS and ECT in rats [4]. Ogiue-Ikeda et al. investigated the effect of TMS on long term potential in the rat hippocampus [5]. These experimental studies have well shown us the different effects of TMS and ECT in rat tissues. However, the current distributions in rat brain by TMS and ECT are still to be elucidated.

Models: In this paper we use a 3D rat model obtained from Brooks Air Force Laboratory, USA. For TMS case, a special figure-eight-shaped coil has been designed according to the rat dimensions and placed on the surface of the rat head as shown in Fig. 1. For ECT case, the ear clip electrodes are placed on the tip of rat ears. Current is injected into one ear and extracted from another ear. The electrical properties of rat tissues are modeled using the Four-Cole-Cole method.

Impedance Method: The rat model is composed of small cubic voxels and is represented as a 3D network of impedances. Kirchhoff voltage law around each loop in this network generates a system of equations for the loop currents. These loop currents are driven either by Faraday induction for the TMS applicator or the injected current from the ECT electrodes. Details implementation of the impedance method can be found in literature [6].

Results: By employing the 3D impedance method, the current density distribution in the rat model are calculated for both TMS and ECT cases. Fig. 2 and Fig.3 show the current density distributions in rat head at slice layer of $y = 44$ mm by TMS and ECT, respectively. From Figs. 2 and 3, we know the maximum value of current density in rat head are presented in CSF for TMS case and in muscle for ECT case. In rat brain, current density by TMS can be comparable to that by ECT. Detailed results will be presented in the extended paper.

Center LNESS, Politecnico di Milano, Como, Italy

In the past few years we assisted to a continuously growing interest in magnetic field sensors for biological applications and, in particular, for biomolecular recognition. Examples of recognitions are DNA-DNA hybridization, antibody-antigen recognition and general ligand-receptor binding. [1] This research field is becoming more and more important for areas such as healthcare, pharmaceutical industry, environmental analysis, and generally in biotechnological applications.

Generally the detection involves the use of a known biomolecule that probes a testing sample looking for a specific target analyte. Hence they are given the name of probe and target biomolecule, respectively. A common approach to detect biological molecules is to attach to the target molecule a label producing an externally observable signal. The label may be a radioisotope, enzyme, or a fluorescent molecule, as in the case of LIF techniques. Recently, magnetic beads have also been used as labels for biosensing, due to their advantages over other labels. The magnetic properties of the beads are stable over time, because the magnetism is not affected by reagent chemistry or subject to photo-bleaching (a problem with fluorescent labelling). There is also no significant magnetic background present in a biological sample and magnetic fields are not screened by aqueous reagents or biomaterials. In addition, magnetism may be used to remotely manipulate the magnetic particles. Finally, a number of very sensitive magnetic field detection devices have been developed during recent years, such as giant magnetoresistance (GMR) and spin-valve [2] magnetic sensors that enable the measurement of extremely weak magnetic fields, like those generated by a single magnetic microbead. Besides GMR sensors, measurements of single magnetic beads have been demonstrated using miniaturized silicon Hall sensors [3] and planar Hall effect sensors based on permalloy thin films [4]. More recently tunnelling magnetoresistance (TMR) sensors based on magnetic tunnelling junctions (MTJs) have been applied to biomolecular recognition due to their superior sensitivity and stability with temperature. A group from Brown University fabricated 2 micron x 6 micron MTJ sensors to detect single superparamagnetic M-280 Dynabeads. [5] Nevertheless MTJ based on MgO barriers display the highest values of magnetoresistance ever measured at room temperature (410 %) [6] and show the promise of being spintronic transducers capable of detecting magnetic field in the pT range. This can enable detection of single 10 nm magnetic particles and, consequently, of single biomolecular reaction even for very small molecules. With these performances spintronic biochips show potential to become very powerful tools for molecular biology, and many groups are now working on spintronic biosensors employing MgO based MTJs. The spintronic group of Center LNESS has recently developed the capability of fabricating state of the art MTJ based on MgO barriers with TMR comparable with the highest values reported in literature. Fully epitaxial Fe/MgO/Fe(001) heterostructures are grown by MBE in UHV conditions and patterning is achieved by shadow masks (junction area of 200x200 microns) or optical lithography (down to the micron size). No exchange bias is required thanks to the action of properly designed magnetic anisotropies in the layers, while an in plane bias field of 18 Oe is needed in order to work in the linear region of the TMR. In these conditions a sensitivity of 3.5% / Oe (see Fig. 1) has been obtained on prototypical junctions with 200x200 microns area, which represents one of the best values reported up to now in literature.

The sensor surface is then passivated with a SiO₂ capping layer and then probe molecules are immobilized via well defined protocols and conventional micro-spotting. Preliminary tests of DNA recognition, with the double magnetic and fluorescence label, are currently under development. In

the paper we will present the first experiments of biomolecular recognition with great attention to the biological sensitivity of the biosensor.

In the last few years, biochips based in magnetoresistive sensors have been used for biomolecular recognition assays [1-3]. In these assays biological probes are immobilized on the chip surface and complementary target biomolecules can be detected using a magnetic label. The detection of the magnetic label fringe fields is accomplished by a magnetoresistive sensor. An emerging interest in using magnetic tunnel junctions (MTJ) as magnetoresistive sensors is arising due to its higher magnetoresistance (up to 70% with AlOx barrier and 350% with MgO barrier) and its potential increase in sensitivity. However, due to its current-perpendicular-to-plane (CPP) configuration which increases the distance between the sensing layer and the particles, in similar sensor architectures, MTJs show lower particle sensitivity when compared to spin valves sensors (with current-in-plane configuration) [4].

In this work, a new architecture using MTJs with gold contacts and without passivation on top of it (as proposed in [5]) was fabricated. Since the passivation on top of the sensors was removed, the distance between the particles and the sensing layer is reduced to 1000 Å (thickness of the Au electrode) and a higher signal should be observed in the MTJ response. The inset of figure 1 shows a cross section of the chip. As observed, the biological probes will be immobilized on top of the gold contact.

MgO-barrier MTJs with linear response were successfully fabricated. The linear response was obtained by shape anisotropy (30x2 μm²). As observed in figure 1, the MTJ shows a tunneling magnetoresistance (TMR) of 78%, a sensitivity of 1.89%/Oe and a resistance of 2000 kΩ. The signal-to-noise ratio (SNR) in function of the MTJ bias current was measured in order to determine the optimum working current (figure 2). The maximum SNR was attained for a current bias of 300 μA which will be used in the particles detection.

Figure 3 shows the MTJ voltage variation due to the presence of magnetic particles. The detection was made applying an external in-plane transverse 30 Oe + 15 Oerms magnetic field. The signal was acquired using a lockin technique. A volume of 10 μl of 250nm superparamagnetic particles (~10¹¹ particles/ml) was put over the chip and let to settle down during 10 minutes. A saturation signal of 860 μV was obtained. After washing, the signal came back to the baseline value meaning that all the particles were removed from the sensor (see fig. 3). It is important to note that these experiments with particles demonstrated that neither the Au contacts nor the MTJs were corroded by the liquid used in the experiments. Further experiments with different particles concentrations and with biological probes immobilized over the Au contact will be performed.

Hematopoietic stem/progenitor cells (HSC) have vast potential for use in medical applications and the separation of these cells from blood has an important role in the stem cells research [1]. However, the most usual techniques, MACS and FACS, have some drawbacks like being cell-loosing or very time-consuming.

In this work a device based on magnetophoresis is being developed using microfluidics and in-situ magnetic fields, generated by current lines, in order to separate stem cells from blood in a more efficient and easy way [2],[3],[4],[5]. In the same device Spin Valve sensors are used to measure the efficiency of the separation (by counting the cells as they are separated).

The geometry of the separator makes it possible to change only the path of specific stem cells, that are magnetically labeled with 50nm magnetic beads functionalized with monoclonal antibodies, instead of separating all the magnetic elements in the fluid (which is vital to keep count of the stem cells).

The fluidic system consists in 2 micro-channels (150 μ m wide, 14 μ m thick and 40 μ m apart) joined over two gaps of 2.5mm and disposed in an “H”-type geometry (fig.1 and fig.2). The laminar flow is generated in the y-direction, from the inlet to the outlet. The fluidic system is bonded to the separator platform which consists in two successive lines (7 μ m wide and 500nm thick), deviated from the y-direction by an angle of 5 degrees, starting in one channel and ending in the other. At the end of each line there are three spin valves in both channels to count the cells that have been separated and those that might fail to be separated [6],[7].

To prove the concept and test the design, preliminary tests were made passing 2 μ m magnetic particles through the channels. These particles ($\chi=0.22$ and $\rho=1.1 \times 10^{-3}$ kg/m³) feel a magnetic force of 9.5pN when passing over the current lines (due to a magnetic field of 6kA/m and a gradient of 2.2×10^6 kA/m when applying 100mA), which force them to be deviated in the x-direction. With velocities between 75-300 μ m/s, particles were observed to follow the line path, moving from the beginning of the line (in the first channel) until the end of it (in the second channel) (fig.3). When any particle fail to feel the first line (due to agglomeration for e.g.) it can be separated when passing over the next line. These measurements were made for a concentration of 1×10^5 particles/ μ l to make the optical inspection easier. The real experiment will be made with human hematopoietic stem/progenitor cells (CD34+ enriched cells), from umbilical cord blood samples.

We demonstrate the functionality of spin-wave logic gates and report on the first steps towards the implementation of all-spin-wave on-chip logic devices.

The proposed concept of a spin-wave (SW) logic gate is based on a Mach-Zehnder interferometer approach as it is shown in Fig. 1-a. The gate mainly consists of a splitter that divides the power of the applied SW pulses into two channels (called the interferometer arms), two controllable phase shifters and switchers integrated into the arms, as well as a combiner where the signals modified in the arms interfere. Logical input signals are applied to the gates which vary either the phase or the amplitude of the spin waves in the interferometer arms. The logical output corresponds to the amplitude of the interference signal. By controlling the accumulated phase in one of the arms and keeping the phase at the output of the second arm constant one can implement a NOT gate [1]. The possibility to shift the phases in both arms by π allows the implementation of the XNOR operation [2]. With the additional ability to quickly manipulate the wave amplitudes using SW switches it is possible to create a NAND gate [2].

In our work the interferometer arms are realized as longitudinally magnetized SW waveguides made from a single-crystal yttrium-iron-garnet (YIG) film (Fig. 1-b). Travelling spin waves are excited and received by microstrip antennae. An additional microwave phase shifter is used for a preliminary adjustment of the SW phase difference $\Delta\phi$ between the arms. The necessary phase or amplitude variations of the spin-wave pulses in the arms are produced due to dynamic inhomogeneities of the magnetizing field induced by dc current pulses through conductors placed near the film surface. We use the possibility to suppress the spin-wave transmission by applying a strongly localized Oersted field (stretched wires with currents I_1 and I_2 in Fig. 2-b) while the wave phase is controlled by the weakly localized Oersted field (the wire loops with currents I_3 and I_4 in Fig. 2-b). The functionality of the XNOR and NAND gate prototypes is demonstrated in Fig. 2-c, d. The structure is placed into a static magnetic field of 1885 Oe. SW packets are excited by microwave pulses of 20 ns duration with carrier frequency of 7.132 GHz.

In order to develop the on-chip SW logic gates a SW splitter and a combiner were fabricated by structuring the YIG film. The corresponding film structures have the shape of a fork and consist of two interferometer stripe-shaped arms (prongs of the fork) and a combiner/splitter part (handle). Interference of SW pulses in the structures was visualized using time-, space- and phase-resolved Brillouin light scattering (BLS) spectroscopy. Figure 2 shows a representative example of a phase manipulation procedure in the SW combiner. As before the bias magnetic field of 1885 Oe is oriented along the arm length. The control current loop is placed in the middle of the lower arm.

The upper panels demonstrate snapshots of the pulses at different times when no current is applied to the loop. In-phase interference of the two lowest-order input SW width modes, which are characterized by a maximum of the SW intensity in the middle of the stripe width, results in the formation of a similar lowest-order mode in the output waveguide. The lower panels show snapshots of SW pulses, when the phases of the spin waves, which interfere in the combiner, differ by π due to the applied current pulse. In this case one sees two distinct maxima of SW intensity in the combiner. Such an intensity profile is characteristic for the second (anti-symmetric) width mode of a SW stripe waveguide.

Thus, depending on the applied current, the combiner output pulse is carried either by a symmetric or anti-symmetric width mode which can be attributed to a logical one or zero, respectively. The output signal can easily be read out by an optical BLS probe in the center of the output part of the waveguide or by using a microwave transducer to sum up the amplitude over the complete pulse (taking into account that the two maxima of the anti-symmetric mode are exactly out of phase). In the last case the logical one (symmetric mode) will lead to a high microwave output signal while the logical zero (anti-symmetric mode) will cause a near zero microwave signal.

Most of the spin wave microwave devices existing today are based on the yttrium–iron garnet (YIG) films. Although YIG has a major advantage of a record-low ferromagnetic resonance (FMR) linewidth ($\Delta H \leq 0.5$ Oe), the practical applications of the YIG-based devices are limited due to relatively large magnitude of the bias magnetic field, low temperature stability, and relatively large size (several microns) of the elements of typical etch patterns in YIG. Most of these drawbacks can be eliminated by using metallic (e.g. permalloy (Py)) magnetic films. Unfortunately, the direct replacement of YIG by permalloy in standard passive spin wave delay lines [1] is not possible, because the spin wave propagation losses in permalloy (proportional to FMR linewidth $\Delta H \approx 25 \sqrt{50}$ Oe) are almost 100 times larger than in YIG. Thus, the dipolar spin waves (or magnetostatic waves (MSW)) in permalloy have a very low mean free path ($< 10 \mu\text{m}$).

It is possible to overcome this difficulty by using the phenomenon of parametrically stimulated recovery of spin waves excited by the input microwave signal [2]. In this process the input antenna is, also, used for the reception of the output signal, and the delay time of the output signal is determined by the time when the pulse of external parametric pumping is supplied to the device.

The experimental investigations of the parametric interaction of the pumping pulse of the carrier frequency ω_p with the input microwave pulse of the carrier frequency $\omega_s = \omega_p/2$ in a permalloy (Py) film were performed on the experimental setup shown in Fig. 1. The Py film waveguide formed on the silica substrate had the dimensions $0.5 \mu\text{m} \times 1.6 \text{ mm} \times 20 \text{ mm}$, and was placed in the opening inside the open dielectric resonator (ODR) made from a thermostable ceramics with dielectric constant $\epsilon \approx 80$. The variable magnetic field of the ODR was parallel to the bias magnetic field \vec{H}_0 , i.e. the case of parallel parametric pumping (see chapter 10 in [1]) was realized in our experiment. The wire antenna of the $50 \mu\text{m}$ diameter placed on the Py film was used for the excitation and reception of microwave spin waves. The spin waves excited by the input signal were propagating perpendicular to the direction of the bias magnetic field \vec{H}_0 , and the velocities of the excited waves were in a wide range from $v \approx 0$, corresponding to slow and almost non-propagating volume MSW, to $v \sim 10^7$ cm/s, corresponding to the propagating surface MSW [2]. The slow spin waves, selectively amplified by pumping, practically did not move away from the antenna, and they formed the amplified output signal received at the antenna. We used the following parameters of pumping and signal pulses: $\omega_p/2\pi = 2\omega_s/2\pi = 9.4$ GHz, $\tau_p = 400$ ns, $\tau_s = 300 \sqrt{400}$ ns, $P_p \leq 20$ dBW, $P_s = -27$ dBW.

When the pumping power was over 16 dBW, the delayed output signal of the duration of 100 ns, carrier frequency ω_s , and power $P_{\text{out}} \leq -50$ dBW was registered at the input antenna (see lower frame in Fig. 2). This signal was observed only if pumping was previously applied, and its delay time relative to the front of the input pulse was determined by the time at which the pumping pulse was supplied (T_p on Fig. 2).

Our experiments demonstrated that Py films can be used for the development of a microwave receiver which will allow us to perform controlled time delay with simultaneous time-compression of the input microwave pulses.

Artificial media with periodical variations of magnetic properties, so-called magnonic crystals are the magnetic analogue to photonic and sonic crystals which is suitable to work in the microwave frequency range. Spectra of spin-wave excitations in the magnonic crystals are significantly modified with respect to the uniform media and exhibit full band gaps, where spin waves are not allowed to propagate. Due to wide tunability of their characteristics magnonic crystals present excellent capability for the investigation of linear and nonlinear spin-wave dynamics. They are also promising for applications as microwave filters, switches, phase shifters, etc.

Here we present a one-dimensional magnonic crystal created by chemical etching of a surface of a single-crystal yttrium iron garnet (YIG) ferrite film. We have chosen this magnetic media because of its extremely small magnetic relaxation permitting a spin-wave path of a centimeter length. The periodic changes of the film thickness cause the variation of the spin-wave dispersion and crystal properties as well. It is obvious that stronger thickness changes result in more pronounced alteration of spin-wave propagation. However this dependence has not been covered in the literature yet. Thus we focused our efforts on experimental study of crystal characteristics as a function of the depth of the artificial periodic structure.

Photolithography and chemical etching with hot (115°C) O-Phosphoric acid were used for the YIG film structuring. The typical structure geometry is schematically shown in Fig.1. The crystal consists of 10 parallel grooves, which are perpendicularly oriented with respect to the spin wave propagation direction. The film thickness is 6 μm . The grooves width is 30 μm and the lattice constant Δ_c is 300 μm taking into account 270 μm distance between the grooves. In order to study the dependence of crystal characteristics on the groove depth the grooves were etched in 100 nm steps from 100 nm to 1.5 μm .

Two microstrip antennae placed (Fig. 1) 8 mm apart each other on each side of the magnonic crystal area were used to excite and receive the dipolar spin waves. A bias magnetic field of 1812 Oe was applied in the plane of the YIG film stripe, along its length and parallel to the direction of spin-wave propagation. Thus the geometry of backward volume magnetostatic wave (BVMSW) was realized. The measurements were performed in the frequency range 6800-7200 MHz. The typical experimental BVMSW transmission characteristic for the non-etched film is shown by the solid line in the Fig. 2. The spin-wave transmission through a magnonic crystal of depth of 300 nm is indicated by the dashed line. Spectrum rejection bands are clearly visible in this case. Their central frequencies were estimated using the simple condition $2\Delta_c = n\lambda$, where n is a number of the rejection band. The frequency values 7060 MHz, 7010 MHz, and 6960 MHz calculated for $n = 1, 2$ and 3 are in good agreements with experimental data.

The increasing of the groove depth up to 500 nm causes the pronounced widening and deepening of the rejection bands (dash-dotted line in Fig. 2). The further etching beyond 500 nm additionally decreases the transmission between the rejection bands. The structure of 1.5 μm depth does not allow any spin-wave transmission. This behavior can be explained by an increase of the interaction of a so-called “pure” magnonic crystal namely groove structure on the YIG film surface with the underlaying uniform magnetic film.

The experimental dependences of the SW rejection (in the rejection bands) and transmission (in the transmission bands) on the grooves depth are shown in Fig. 3. In addition the rejection to transmission ratio is presented. It is shown that the maximum ratio value is reached for a depth of 500 to 600 nm.

In conclusion, a one-dimensional linear magnonic crystal was designed and tested. The microwave transmission spectra were measured for different crystal geometrical parameters and, in particular, for different depth of the grooves. It was found that the rejection band width and deepness as well as the out-of-band transmission loss increase with increasing of the groove depth. The optimal groove depth has been determined.

Experimental Verification of Skin Effect Suppression in Multilayer Thin-Film Conductor Taking Advantage of Negative Permeability of Magnetic Film beyond FMR frequency.

S. Shiozawa¹, Y. Shimada¹, M. Yamaguchi¹, K. Kim², Y. Zhuang³, M. Vroubel³, B. Rejaei³

1. Electrical and Communication Engineering, Tohoku University, Sendai, Japan; 2. Physics, Yeungnam University, Gyeongsan, South Korea; 3. Electronic Components, Technology, and Materials, Delft University of Technology, Delft, Netherlands

Background: It has been a major concern of high frequency devices and circuits to suppress skin effect and the corresponding ac resistance increase in high-frequency-current carrying conductors for transmission lines, integrated inductors, antennas, etc, in order to realize high-Q and energy-saving systems. This paper demonstrates first experimental verification of skin effect suppression taking advantage of negative permeability of soft magnetic film obtained beyond FMR frequency range.

Idea: It is known that the skin effect is noticeable as the skin depth, δ , becomes thinner than the half thickness, $t/2$, of the conductor.

$$\delta = (\rho / \pi f \mu_0 \mu_r)^{-1/2} \dots (1)$$

where f is the frequency, ρ the resistivity, and μ_r is the relative permeability. Accordingly the ac resistance of a conductor with width w and length L is approximately expressed as;

$$R_{ac} = \rho L / (2w\delta) \dots (2).$$

Some of the authors theoretically claimed in [1] that the skin effect could be avoided in an alternate multilayered structure of metal/magnetic thin films shown in Fig. 1, provided that the magnetic layer has negative permeability and the volume average of relative permeability, μ_{rav} , becomes zero. The μ_{rav} is given by;

$$\mu_{rav} = (t_N + \mu_r t_F) / (t_N + t_F) \dots (3)$$

where t_N and t_F are the thickness of each metallic and ferromagnetic layer, respectively. It is possible to let $\mu = \mu_{rav} = 0$ in eq. (1) if the magnetic material has negative permeability. Then the skin depth becomes infinitely deep. Such a condition should be realized by using a uniaxial magnetic film exhibiting negative permeability beyond the FMR frequency.

Experiments: The 0.3 μm -thick Al film and the 0.1 μm -thick zero-magnetostrictive NiFe film were sputter-deposited in turn to the total thickness of 6 μm on a Glass wafer. A 13 μm -thick Cu metal mask was used for ion milling process to complete the coplanar line as shown in Fig. 2. The signal line is 1000 μm long and 36 μm wide. The signal-to-ground gap is 11 μm . Because of the difficulty of the etching process, the characteristic impedance became 54.8 Ω , deviated a bit from the designed value of 50 Ω . The bends on the ends of the line are to apply wafer probes from the top left and the bottom right directions to measure high frequency properties. For the NiFe layer, $4\pi M_s = 10.0$ kG, $H_k = 10$ Oe (nominally, before microfabrication) and $\rho = 16.7$ $\mu\Omega\text{cm}$. Easy axis direction is along the length direction of the coplanar line. Since the thickness of the metal and the magnetic films are $t_N = 0.3$ μm and $t_F = 0.1$ μm , respectively, the eq. (3) and the required condition of $\mu_{rav} = 0$ need the relative permeability to be $\mu_r = -3$ for the NiFe film, which should be satisfied at (i) closely to the FMR frequency of 0.9 GHz, and (ii) 6.0 GHz, as calculated from the L.L.G. equation using the materials' M_s , H_k , and the supposed damping constant of $\alpha = 0.10$. External large dc magnetic field, $H_{ex} = 0 \sim 5000$ Oe, was applied to the easy axis direction to examine the ferromagnetic nature of the multilayer. This is also useful for the analysis since the effective anisotropy field becomes $10 + H_{ex}$ Oe and accordingly the uncertainties in H_k and α will not matter seriously. Known π -type equivalent circuit analysis was used to extract the series resistance of the line.

Results and Discussion: Fig. 3 shows the frequency dependence of the measured resistance of the multilayer coplanar line. Without the external field, the resistance increases with frequency up to 3 GHz. This means the resistance does not become small at the FMR frequency of 0.9 GHz because of huge FMR losses. At higher frequency range, the resistance turns over to decrease from the top level of 3.2 Ω at 13 GHz to the bottom level of 1.9 Ω at 16.5 GHz. The existence of a frequency range where resistance monotonically decreases is the first experimental verification of the skin effect suppression. This never happens in the case of normal metal. The half-level frequency can be defined as the frequency where the resistance becomes the average of the top and the bottom levels. This parameter is used as a representative of the skin effect suppression hereafter. The half-level frequency is linearly to the applied external field and accordingly the FMR frequency, as summarized in Fig. 4. On the other hand, the half-level frequency can be obtained through eq. (1) and (2), after given the frequency profile of complex permeability from L.L.G equation. The calculated value rather agrees well under the strong external field where the uncertainties in H_k and α would not matter seriously. This is the verification of the skin effect suppression by negative permeability of magnetic material. It is quite interesting that the calculation predicts that the ac resistance can be smaller than that of all-metal conductor of the same thickness.

The high frequency (hf) properties of soft magnetic thin film elements are essential to the operation of a variety of rf devices and magnetic field sensors [1]. The response of the magnetization to hf magnetic fields should normally be fast and homogeneous if optimum device performance is to be achieved. However patterning modifies the effective magnetic field within an element and determines the spectrum of dynamical modes that may be excited. This mode spectrum must therefore be characterized and fully understood if the hf magnetic response is to be controlled. We report on how time-resolved scanning Kerr microscopy has been used to understand the precessional mode spectrum of $\text{Fe}_{70}\text{Co}_8\text{B}_{12}\text{Si}_{10}$ square elements.

The film was magnetron sputtered onto a glass substrate and structured by ion beam etching. The sample consisted of squares of $\text{Fe}_{70}\text{Co}_8\text{B}_{12}\text{Si}_{10}$ of 40 μm width and thickness of 160 nm arranged into a square lattice with 10 μm edge-to-edge separation. Sample deposition was performed in a magnetic field so as to induce a uniaxial magnetic anisotropy parallel to one of the edges of the squares. Measurements of the hf dynamics were performed with a microscope (Fig. 1) that is able to measure all three components of the magnetization vector simultaneously. The magnetization was excited by the hf magnetic fields generated around the 80 μm center conductor of a coplanar waveguide fed with pulsed or sinusoidal current waveforms from a pulse or microwave generator. The pulse and microwave generators were phase locked to the laser so that stroboscopic imaging could be performed. The sample was placed face down on the waveguide with the laser spot focussed on the square element through the glass substrate. A polarizing beamsplitter and quadrant photodiodes were used to detect all three magnetization components simultaneously [2].

With a static magnetic field of 500 Oe applied parallel to the easy axis, pulsed field experiments revealed resonant modes with frequencies of 8.0 and 9.2 GHz. The spatial character of these modes was determined by applying a sinusoidal field with frequency equal to that of the desired mode and scanning the laser spot over the whole square. Images corresponding to different points in the cycle of oscillation are shown in Fig. 2. A time delay of 0 ps was assigned to the image showing maximum contrast at the center of the element. The mode at 8.0 GHz shows a phase difference between the excitation in the central part of the element and the dynamic magnetization closer to the vertical edges. This is reminiscent of the beating of a uniform mode with a backward volume type mode. The image of the 9.2 GHz mode shows a different pattern of contrast with a maximum in the center of the element and two regions closer to the horizontal edges where the dynamic magnetization is shifted in phase with respect to the center. The effective wave vector of this mode therefore lies perpendicular to the static magnetization, which is similar to the Damon Eshbach mode found in continuous films [3].

The finite effective wave vector gives rise to an associated frequency shift. The shift associated with the wave vector perpendicular to the magnetization is much larger than that due to the wave vector component parallel to the magnetization, which is not resolved within the experiment. The field dependence of the peaks was analyzed using the formula for the frequency of the Damon Eshbach mode,

$$2\pi f = \gamma [H(H + M_s) + (2\pi M_s)^2 (1 - e^{-(2kd)})]^{1/2}$$

with applied field H , saturation magnetization M_s , frequency f , gyromagnetic ratio γ , thickness d , and wave vector k depending on the mode number n as $k = n\pi/w$. The 8.0 GHz mode corresponds to the $n=1$ mode while the 9.2 GHz mode corresponds to the case $n=3$.

We will show how the resonant precessional modes of planar magnetic elements may be detected and then characterized. This information is important in understanding the response of the magnetization to magnetic fields of different temporal form.

Electrically detected ferromagnetic resonance in electrodeposited spin valves under AC excitation.

N. Biziere, E. Murè, J. Ansermet

Institut de Physique des nanostructures, Ecole Polytechnique Federale de Lausanne, Lausanne, Switzerland

Abstract: We report on experimental evidence of DC voltage effects induced in a pseudo spin valve by an AC electrical excitation in the microwave range. Two Pseudo spin valve connecting in series were produced by electrodeposition in a polycarbonate membrane. We offer an original set up that allows broadband measurements of nanometric magnetic multilayers without using classical lithography techniques. Results are discussed in terms of AC spin torque and non linear mixing of magnetoresistance and electromagnetic excitations.

It has been demonstrated that a spin polarized current could influence the magnetic properties of magnetic multilayers. This effect known as the Spin Transfer Torque (STT) [1,2] opens new applications in domains of ultrafast switching or microwave generators [3,4] and has been studied mainly in the case of a DC injected current. However, the question of STT in the case of an AC current is to our knowledge rarely discussed, especially from the experimental point of view [5,6].

In this work we show that a pseudo spin valve submitted to a microwave electrical excitation of frequency ω generates a DC and a 2ω signals. The system studied is a nanowire composed of Co(30 nm)/Cu(5 nm)/Co(5 nm)/Cu(1 μ m)/Co(30 nm)/Cu(5 nm)/Co(10 nm) electrodeposited from a single cobalt/copper bath in a 6 μ m thick polycarbonate membrane. On one side of the membrane a gold cap is sputtered on the whole surface allowing electrical contact to a pin placed in a SMA connector. Then the connector is closed by a cap in which a 25 μ m diameter gold wire is weld to a screw. The latter permits to contact the other end of the gold wire to one (or few) magnetic nanowire. This simple technique offers a very attractive alternative to transmission waveguides since it avoids lithography process and many nanowires are accessible in one membrane.

The Giant Magneto Resistance (GMR) curve presented on figure 1 shows the switching of each pseudo spin valve. The geometry insures CPP configuration and the external field is perpendicular to the current. When an AC current is injected in the nanowire we observe at the same time a variation of the DC and of the 2ω voltages (fig. 2) when ω reaches the FMR frequency. The very good sensitivity of electrical transport measurement offers the possibility to follow the evolution of the shape and frequency of the signals as function of the external field (fig. 3) and so the relative orientation of magnetic layers.

We will interpret these results from two different approaches. First we will consider the effect of AC STT predicted theoretically [7]. Second we will discuss the interplay between the magnetoresistance with the electromagnetic field created by the electric excitation [8,9]. Then we will show the similarity between both approaches.

Ferromagnetic resonance modes below the critical thickness of stripe domain formation.

J. McCord¹, A. Gerber², E. Quandt²

1. Institute for Metallic Materials, IFW Dresden, Dresden, Germany; 2. Institute for Inorganic Functional Materials, CAU Kiel, Kiel, Germany

The understanding of high frequency precessional modes in low anisotropy soft magnetic thin films is of vital interest from a fundamental point of view for applications based on magneto-dynamics. In patterned samples low and high frequency modes, which result from magnetic vortices or domains, have been investigated in detail. Another class of soft magnetic materials, exhibiting multiple precessional modes are soft magnetic thin films with perpendicular magnetic anisotropy, possessing stripe domains.

The development of the high frequency precession modes in Permalloy $\text{Ni}_{81}\text{Fe}_{19}$ (NiFe) thin films with uniaxial in-plane and additional out-of-plane magnetic anisotropy component was investigated. As will be shown, signatures of out-of-plane anisotropy can be observed well below the critical thickness of stripe-domain formation.

NiFe films varying in thickness from 100 nm to 400 nm were deposited by rf sputtering in argon atmosphere onto oxidized silicon substrates. A magnetic field was applied to introduce an in-plane magnetic anisotropy. The static and dynamic film properties were investigated by regular quasi-static and pulsed microwave magnetometry.

Two exemplary hysteresis loops of the films are displayed in Fig. 1a. For small thicknesses regular square easy axis loops and above a critical thickness loop shapes typical for stripe domains are observed. From the dependence of the remanence ratio J_r/J_s as well as of the coercivity H_c the onset of occurrence of stripe domains at approx. $t_{\text{NiFe}} = 250$ nm can be deduced (Fig. 1b). The normalized permeability $|\mu|$ spectra is displayed in Fig. 2. A bias field of $H_{\text{ext}} = 10$ Oe is applied to eliminate additional effects from magnetic in-plane domains. For the thick films a bi-modal frequency response is found, which correlates with the films' internal out-of-plane domain structure. Yet, for $t_{\text{NiFe}} < 250$ nm, where no signatures of out-of-plane magnetization could be extracted from the static measurement, secondary precessional modes are excited. The dependence of f_{res} and the relative amplitude of the two dominating modes are displayed in Fig. 3. The dominating low frequency mode, which is related to the uniaxial anisotropy of the NiFe film, displays only a small change at the onset of stripe domain formation. The contribution of the high frequency mode, connected with the out-of-plane magnetization structure, continuously increases with increasing t_{NiFe} . No discontinuity, as for the static magnetic properties, is found in the modal spectra.

In summary, it is shown that different precessional modes of f_{res} can be activated by the existence of an even small magnetic out-of-plane anisotropy. An occurrence of static out-of-plane domains is not necessary for the bi-modal frequency response. Additional results from magnetic domain observations and a discussion of changes of overall high frequency permeability with stripe domain nucleation will be presented.

Funding by the Ministry of Education and Research (BMBF) through the project "MIMAK" is highly acknowledged.

Ferromagnetic resonance study of Fe/FePt coupled films with perpendicular anisotropy.

D. Schmool¹, A. Apolinário¹, F. Casoli², F. Albertini²

1. Physics, Universidade do Porto, Porto, Portugal; 2. IMEM, CNR, Parma, Italy

Exchange spring magnets with perpendicular magnetic anisotropy represent new magnetic properties with respect to their constituent components. These systems typically consist of a hard magnetic layer and a soft magnetic layer which are strongly coupled. The modification of their bulk magnetic properties arises from this strong ferromagnetic exchange coupling, interfacial effects and competing magnetic anisotropies of the two magnetic layers.

We have studied the magnetic bilayer system which consists of an Fe (soft) film exchange coupled to an FePt (hard) layer which has an easy axis aligned along the direction perpendicular to the film plane. The entire structure has the form: MgO/FePt (10 nm)/Fe (2nm or 3.5nm)/ Ag (2nm), where the Ag overlayer acts as protection against oxidation. The epitaxial FePt layers were deposited on MgO (100) substrates using the RF sputtering technique at a substrate temperature of about 390 C. The epitaxy of this layer was studied using x-ray and electron diffraction techniques. Layer morphologies were further studied using atomic force microscopy (AFM), these studies reveal a granular morphology with grain sizes of the order of 40 – 50 nm.

We have made detailed angular measurements using the ferromagnetic resonance (FMR) at room temperature. This angular FMR study, which includes the orientations of in-plane and out-of-plane, was performed in order to study the magnetic anisotropies as well as the exchange coupling between the magnetic layers and interfacial effects. In particular, we have chosen to study two samples with 2 nm and 3.5 nm of Fe, which effectively constitute the rigid magnet (RM) and exchange spring (ES) regimes, respectively. The RM and ES regimes depend implicitly on the magnetic anisotropies and properties of the two coupled layers [1].

In figure 1 (a) we show an example of an FMR spectrum for the RM (2 nm Fe) sample. Of the various resonances observed, only the three low field lines are due to the Fe layer. It will be noted that the FePt does not have any FMR signature in the field range studied due to its very high magnetocrystalline anisotropy. The other resonance features evident in the spectrum arise from the MgO substrate and show no significant angular variations. As such the only FMR signals observed in our samples will arise from the Fe layer. In figure 1 (b) we show the angular variation of the resonance field of the three Fe resonance lines. Of these, two resonances display a uniaxial anisotropy with the easy axes aligned along the direction perpendicular to the film plane and will be directly related to the exchange coupling with the hard (FePt) layer. The third resonance, while also manifesting a uniaxial anisotropy, displays an easy axis direction which is canted by about 50 degrees from the film normal. While the origin of this resonance is not entirely clear, we suspect it may arise from the interfacial region between the FePt and Fe layers. In figure 2 we show the corresponding FMR results for the ES (3.5 nm Fe) sample. It will be noted that in addition to the resonances observed in the RM sample, there are a further two resonances, whose angular dependences are illustrated in figure 2 (b). These also display a uniaxial like behaviour with easy axes close to the film normal. In all spectra lines were fit using a home made programme which allows multiple peak fitting of Lorentzian and Gaussian lines.

We develop a model of FMR based on the magnetic free energy of the coupled layers which is required to interpret the angular dependences of the resonance fields [1]. Existing models fall short of a full explanation of all the resonance lines and we are working to bridge this gap by considering the effects of boundary conditions and spin wave modes.

Nanocomposites exchange-enhanced magnetic materials have a substantial potential for permanent magnets applications [1, 2]. It has been demonstrated [3-5] that the crystallite size of both phases, in particular, the soft one, is important in determining remanence enhancement and coercivity. Mechanical alloying/milling has been extensively applied to synthesize various metastable phases exhibiting exciting magnetic properties including spring magnets [6 -12]. The influence of the milling and annealing conditions on the magnetic inter-phase coupling of mechanically-milled rare-earth hard magnetic phase and $\alpha\text{-Fe}$ soft phase will be presented. Two hard magnetic phases were used: SmCo_5 and SmCo_3Cu_2 . As soft magnetic phase was utilised $\alpha\text{-Fe}$ in 20 or 30 wt%. This study will be based on the hysteresis curves and dM/dH versus H curves.

The hard/soft magnetic nanocomposites were obtained by co-milling of the iron and hard magnetic phase powders in required proportion for different milling times. In order to investigate the influence of the annealing on the composite structure and microstructure, milled powder samples were annealed in evacuated silica tubes. More experimental details are described elsewhere [8-12].

The structure and the microstructure of samples were checked by X-ray diffraction and electron microscopy [8-12]. The as milled samples present very low coercivity and remanence. This behaviour could be connected with the damaged structure obtained after milling, as shown by X-ray diffraction. The coercivity and the remanence highly increase with the heat treatment compared to the as milled samples. The hysteresis curves are given in figure 1 for the samples milled for 8 hours and subsequently annealed. The coercivity and the remanence are increased by more than a factor of 10 and 4 respectively for samples milled up to 8 hours. For the long time milled samples the effect of the annealing is much more important on to structural refinement and magnetic properties. For optimal annealing conditions, the magnetization variation along the hysteresis cycle is smooth testifying for good exchange coupling between hard and soft magnetic phases. Optimum values were obtained for a heat treatment at temperatures between 550 °C and 600 °C for 1.5 h. It results that the annealing temperature is more important than the annealing time in the progressive improvement of the microstructure and optimisation of the inter-phase exchange coupling. Additionally to the hysteresis loops, the evolution of the coupling between the hard and the soft magnetic phases could be very well studied from the dM/dH versus H curves, figure 2. For example in this figure the increasing of the coercivity by appropriate annealing is well illustrated. For higher annealing temperature, as consequence of the recrystallization and increasing of the crystallite sizes, a decoupling between the hard and the soft magnetic phases could be evidenced by the presence of a characteristic peak at low field for uncoupled soft iron phase, figure 2. The drastic reduction of both the coercivity and the remanence of $\text{SmCo}_3\text{Cu}_2/\alpha\text{-Fe}$ composite can be mainly attributed to the deterioration of the microstructure of the SmCo_3Cu_2 hard phase during the milling.

Isotropic $\text{Sm}_x(\text{Co,Fe,Mn})_{100-x}$ Magnets Via High-Energy Ball Milling.

A. Gabay¹, J. Liu², G. C. Hadjipanayis¹

1. University of Delaware, Newark, DE; 2. Electron Energy Corporation, Landisville, PA

Mechanical alloying (or intensive milling) of Sm-Co-(Fe) alloys followed by devitrification annealing forms a uniform nanocrystalline structure leading to excellent isotropic hard magnetic properties [1-3]. The largest values of the maximum energy product $(BH)_{\max}$ are typically observed in the $\text{Sm}_x(\text{Co}_{1-y}\text{Fe}_y)_{100-x}$ alloys with $x = 12 - 13$ and $y = 0.2 - 0.3$ [3-5]. This composition range corresponds to either the equilibrium mixture of 2:17 and 1:5 phases or the metastable “1:7” structure whose actual composition may vary from 1:5 to 2:17. The largest magnetization [and therefore the largest theoretical $(BH)_{\max}$] should be expected, however, for the 2:17 phase and especially for exchange coupled nanocomposites of the hard 2:17 and soft Co-Fe phases. Unfortunately, the coercivity values exhibited even by the stoichiometric $\text{Sm}_2\text{Co}_{17}$ and especially the $\text{Sm}_2(\text{Co,Fe})_{17}$ alloys are relatively low. It has been shown a long time ago that the combined substitution of Fe and Mn for Co may increase considerably both the anisotropy field and saturation magnetization of the $\text{Sm}_2\text{Co}_{17}$ phase [6]. An additional advantage of the Mn substitution, unlike the very popular Zr substitution, is that it does not shift the composition of the alloy towards the 1:5 stoichiometry (the Zr atoms occupy the Sm sites). In this work, we investigate this little explored substitution scheme in high-energy ball-milled (HEBM) alloys with a broad range of Sm concentrations (9 to 16.7 at.%). The combined Fe and Mn substitution for Co in the near-stoichiometric $\text{Sm}_{2.1}\text{Co}_{17}$ alloy markedly increases all the hard magnetic properties in the HEBM alloys annealed for 30 min at 600 - 800 °C (Fig. 1); in particular, the highest $(BH)_{\max}$ increases from 11.6 to 16 MGOe. However, our attempts to introduce a soft magnetic phase by decreasing the Sm content below the 2:17 stoichiometry led to a decline of $(BH)_{\max}$. Poor rectangularity of the hysteresis loops indicates an insufficient magnetic coupling within the composite magnet.

For Sm contents greater than that of the 2:17 phase, the results of the combined Mn and Fe substitution were always within the reach of the different substitution of Fe alone. For instance, very similar hard magnetic properties were obtained in the $\text{Sm}_{13}(\text{Co}_{0.7}\text{Fe}_{0.25}\text{Mn}_{0.05})_{87}$ and $\text{Sm}_{13}(\text{Co}_{0.8}\text{Fe}_{0.2})_{87}$ alloys. Like in the earlier studies [3], the latter composition exhibited the largest $(BH)_{\max}$ of all (17 MGOe with the coercivity of 10.5 kOe). However, the $(BH)_{\max}$ of this alloy rapidly deteriorates when annealed above 650 °C (Fig. 2), apparently because of a transformation of its single 1:7 structure into the equilibrium mixture of the 2:17 and 1:5 phases. This poor temperature stability may complicate fabrication of fully dense magnets via hot pressing. The $\text{Sm}_{11}(\text{Co,Fe,Mn})_{89}$ alloy (open circles in Fig. 2) which is practically a stoichiometric 2:17 does not have this disadvantage: it exhibits a $(BH)_{\max}$ of 15.5 - 16 MGOe when annealed at 700 - 750 °C. Thus, the (Fe,Mn)-substituted 2:17 alloys may present a particular interest for fabrication of isotropic hot-pressed magnets. This work was supported by Air Force through STTR contract FA9550-07-C-0029.

Magnetic nanocomposites [1] consisting of a hard phase in a soft matrix, such as R₂Fe₁₄B/ α -Fe, are promising materials for manufacturing resin bonded magnets. Obtaining the nanostructured magnetic material based on R-Fe-B depends strongly on processing and requires restraining grain growth in the material. Branagan and McCallum [2] found that Ti addition to Nd-Fe-B alloys leads to the suppression of α -Fe dendrites, while Chang et al. [3] have demonstrated that Ti suppresses the formation of the metastable cubic Pr₂Fe₂₃B₃ phase in PrFeB alloys. The addition of C to the composition prevents the formation of detrimental TiB₂ and also favors grain refinement [3, 4]. The hysteresis curves of some Pr_{9.5}Fe_{84.5}B₆ + 3 at% TiC melt spun alloys obtained at different wheel speeds were discussed previously [5]. For material produced at a wheel speed of 25 m/s, and subject to no further annealing treatment, energy products of up to 14.4 MGOe were observed with a coercive field of 8.4 kOe. These values are up to 30% greater than those observed by Kramer et al. [6] for quenched and annealed Nd_{9.5}Fe_{84.5}B₆ + 3 at% TiC. Coercive fields of nanocrystalline PrFeB alloys with Cr additions were also found to be considerably larger than in their Nd counterparts [7]. Recently, Ishii [8] et al. studied nanocrystalline NdFeBTiC materials with transition metal additions and reported very favorable results for Cr additions. For one alloy with composition Nd_{9.3}Fe_{71.8}B_{14.6}C_{0.4}Ti₃Cr₁ these workers reported a coercive field of 20 kOe. This work motivated us to investigate the effect of TiC and Cr additions on nanocrystalline PrFeB materials. Alloys with composition (Pr_{9.5}Fe_{84.5}B₆)_{97-x} + 3%TiC + Cr_x (x = 0, 0.25, 0.5, 0.75, and 1.0) were produced from 99% pure starting materials in an arc furnace and were melt-spun in a He atmosphere at wheel speeds of 20 - 25 m/s. Individual ribbon pieces were measured in a vibrating sample magnetometer at room temperature for each composition. They showed a certain variability in their magnetic properties, however, a hysteresis curve for a quenched but not-annealed ribbon with 1.0% Cr is shown in Figure 1. In this case H_c = 10.2 kOe, larger than the values observed previously in material without Cr addition [5], but far below the values reported in Ref. 8 for nanocrystalline materials of the type NdFeB + TiC + Cr. We found that very short anneals (3 min) were more effective than longer anneals (10 min) and an increase in annealing temperature resulted in a reduction in the coercive field (See Figure 2). All this points to grain growth as responsible for the worsening of the magnetic properties, in agreement with the observation in Ref. 5, that the best magnetic properties were obtained for as-quenched materials.

Although the PrFeB + TiC alloys were improved by Cr addition, our values of H_c are below those reported for NdFeB + TiC + Cr alloys. We are investigating Nd-containing alloys to ascertain whether the H_c values of our alloys can be increased by this means. Our work also indicates that another possibility for increasing H_c might be increasing the quenching rate.

Two Major Effects of Process Temperature on the Characteristic of Bulk Nanostructured Nd-Fe-B / Fe-Co Composite Magnets.

C. H. Chen¹, Y. Shen², M. Huang³, A. K. Higgins¹

1. University of Dayton Research Institute, Dayton, OH; 2. FutureTek Corp, Dayton, OH; 3. UES / Wright Patterson Air Force Base, Dayton, OH

Nanostructured magnets possessing exchange coupled magnetic hard and soft phases are predicted to produce an energy product (BH)max near 90 MGOe. Hot-deformation (HD) after hot-pressing (HP) can produce (BH)max of 48-55 MGOe for nanostructured bulk composites of Nd-Fe-B and coated soft-phase (<4%) [1]; but, it has not resulted in any higher (BH)max. One of the several obstacles to producing high performance magnets is the high process temperature, which significantly affects the characteristics of the magnets, especially those with a large volume of soft-phase.

As new technologies are needed for developing nanostructured magnets, it is necessary to understand the effects of process temperature on the characteristics of the magnets. We must determine if a useful coercivity can be retained when the grain growth can be suppressed for magnets with a large volume of soft-phase.

Two sets of specimens made of nano-grained Nd-Fe-B powder with and without Fe-Co phase were compacted in vacuum at 11 designated temperatures from 25 to 760°C as shown in Fig. 1. The Fe-Co (~4%) was electrically coated on the pre-crystallized Nd_{13.5}Fe₆₁Co_{6.7}Ga_{0.5}B₆ powder. A large particle size (100-150µm) was selected for the hard phase to avoid the oxidation effect, and a small volume of soft-phase was used to avoid a thick coating layer. Each specimen weighed 5g and the pressing time was 2 min. The oxygen content of the magnets was carefully controlled at <0.18 wt%. Characterizations included hysteresigraph, TEM, and SEM.

Fig. 1 shows the H_{ci} vs. process temperature for the specimens. Two major effects that significantly reduce H_{ci} can be observed. One is the grain-growth effect at T > 620°C for the magnets with no soft-phase, and it is clearly seen at T > 660°C where the H_{ci} decreases sharply. The peak H_{ci} at 550~610°C indicates an occurrence of full crystallization. The 2nd major effect is the interdiffusion effect for the magnets with ~4% soft phase, which occurs at T > 300°C. The H_{ci} decreases monotonically from 17 kOe after HP at 300°C down to 3.7 kOe after HP at 760°C, evidencing the interdiffusion of the hard and the soft phases.

Table 1 lists the grain sizes and magnetic properties after processing at various temperatures. For magnets with 0% Fe-Co, HP at 580°C resulted in isotropic grain size of 40-80 nm and H_{ci} of 20 kOe. HD at 760°C resulted in anisotropic grain sizes with 40-110 nm parallel to c-axis and 200-800 nm perpendicular to c-axis, and H_{ci} = 14.1 kOe. For magnets with ~4% Fe-Co, the detrimental temperature effect on H_{ci} is more severe due to the interdiffusion between the hard and soft phases. (BH)max values are also affected significantly by the two major effects.

Discussion:

Using current technologies, including coating, HP and HD, nanostructured magnets with ~1-3% soft-phase did show a small improvement in energy products (~5 to 8%) compared to the magnets without a soft-phase; but, the process has not resulted in (BH)max > 56 MGOe. A larger volume of soft-phase is required for higher magnetization, but the soft-phase has to possess an optimum separation between the hard-phase nano-grains for an effective exchange coupling and to produce a higher (BH)max, which can not be made using current technologies.

The grain-growth and the interdiffusion effects must be avoided in addition to dispersing the hard and the soft phases in nano-scale while controlling the oxygen content. Our experiments in the past

years trying to make nanostructured magnets with coupled Nd-Fe-B and Fe-Co have provided evidence that three major challenges must be overcome before achieving significant progress:

- 1). Dispersing hard and soft phases in nano-scale while controlling oxygen as low as possible;
- 2). Effective compacting at T < 300°C to avoid interdiffusion and at T < 620°C to avoid excessive grain growth (This is the topic of this paper);
- 3). Effective aligning the nanostructured hard phase with the alignment as high as possible.

The US Air Force supported this research effort.

Nd₂Fe₁₄B based Magnetic Nanocomposites Synthesized by Electrodeposition, Microemulsion and Melt Spinning Techniques.

R. Ramanujan, Z. Liu, S. Viswanathan, P. K. Deheri, S. Shukla
School of Mater. Sci. Eng., Nanyang Tech. Univ., Singapore, Singapore

NdFeB based hard magnetic alloys are the most widely used permanent magnets for near room temperature applications. Nanocomposites of Nd₂Fe₁₄B/ α -Fe are estimated to have a much higher maximum energy product (BH)_{max} (up to 1 MJ/m³) compared to single phase Nd₂Fe₁₄B alloys [1]. However, this high energy product has not been experimentally demonstrated so far, apparently due to the difficulty in producing the uniform nanostructures required for efficient exchange coupling [2]. This implies that structures with nanosized grains must be obtained in hard magnetic nanocomposite materials in order to experimentally study the effect of exchange coupling on (BH)_{max} [3,4]. Therefore, we have studied NdFeB nanostructured magnetic materials synthesized by techniques which can yield nanograins: electrodeposition, chemical synthesis and rapid quenching were utilized in these experiments.

NdFeB nanoparticles were galvanostatically deposited on copper substrates by pulse electrodeposition, thin films were prepared by systematically varying processing parameters such as composition, pH value, current density and duty cycle [5]. The as-prepared and vacuum annealed films were found to be aggregates of nanoparticles with size less than 10nm (Fig.1 inset). The XRD pattern of annealed thin films showed good crystallinity of the Nd₂Fe₁₄B phase. The presence of Nd and Fe was confirmed through EDS analysis. The magnetic properties of the NdFeB thin film samples were measured by VSM, samples annealed at 580 °C for 10min exhibited coercivity H_C and magnetization M_S values of ~500 Oe and 0.270 emu/cm², respectively (Fig.1). Work is in progress to increase H_C by adjusting composition and optimizing the annealing process.

The microemulsion method was employed to synthesize nanocomposites of Nd₂Fe₁₄B/ α -Fe with controlled size and size distribution. A microemulsion of salt solution was added to a reducing agent NaBH₄ solution with vigorous stirring. The black precipitate obtained was then washed with ethanol and methanol and capped with oleic acid. TEM studies show that the particles are reasonably monodisperse and the average size is approx. 10 nm (Fig.2a). Annealing in Ar at 650 °C for 30min resulted in Nd₂Fe₁₄B and α -Fe phase formation, as seen in the XRD results (Fig.2b).

The rapid quenching melt spinning technique was utilized to synthesize NdFeB based nanocomposite alloys with Co, Dy, Sm and Ta alloying additions. For example, the effect of Ta doping on the magnetic properties of Nd₉Fe₈₆B₅ nanocomposites was investigated. 2% Ta doping enhanced H_C despite a decrease in the remanence M_r (Fig.3a). The increased H_C is likely to be the result of a fine grain structure and precipitates which can act as pinning centers. The magnetic properties of melt spun RE₂Fe₁₄B/Fe₆₅Co₃₅ alloys were also investigated, since Fe₆₅Co₃₅ alloys have extremely high magnetization value [6]. The VSM results show that high M_S and M_r have been achieved (Fig.3b).

Our work on the synthesis of NdFeB based magnetic nanocomposites will be presented. Synthesis of exchange coupled hard magnetic nanocomposites has been achieved by electrodeposition, microemulsion and rapid quenching techniques, characterization and property evaluation have also been carried out.

Improvement in Morphology and Magnetic Properties of Thick Nanocomposite Film-Magnets with Multi-Layered Structure.

Introduction

Recently, thick film-magnets are needed for applications to micromachines¹⁾. Based on this requirement, we have proposed a pulsed laser deposition (PLD) method of preparing multi-layered nanocomposite film-magnets with the thickness of several tens of microns²⁾.

In this contribution, we evaluated the morphology, magnetic properties, and microstructure of multi-layered Nd-Fe-B/Fe-B and Nd-Fe-B/ α -Fe nanocomposite film-magnets with the thickness of several tens of microns. Furthermore, we found that their magnetic properties and morphology are improved by controlling their composition and by a newly developed PLD system with an auxiliary laser, respectively.

Experimental

The multi-layered films with the thickness of several tens of microns were deposited in vacuum for 1 hour by the PLD method proposed previously, which uses composite targets rotating at 7 rpm²⁾. The targets are composed of magnetically hard ($\text{Nd}_{2.6}\text{Fe}_{14}\text{B}$ or $\text{Nd}_{2.4}\text{Fe}_{14}\text{B-Nb}$) and soft (Fe_3B or α -Fe) segments, and enable us to deposit 14 layers/min. As the deposited films were amorphous, they were crystallized with an infrared furnace.

The roughness of the surface of deposited films was evaluated with a surface roughness meter by the line scan, 24 mm in length.

Results and Discussion

Typical hysteresis loop after crystallization is shown in Fig.1 (a) for a nanocomposite film-magnet deposited from $\text{Nd}_{2.6}\text{Fe}_{14}\text{B}/\text{Fe}_3\text{B}$ target. A $(BH)_{\text{max}}$ value over 60 kJ/m^3 was obtained. The nanostructure of this film was observed with TEM (Fig.1 (b)). It is clearly seen that thin layers with the thickness of several tens of nanometers are stacked periodically.

Improvements in magnetic properties were achieved by adding 0.5 at.% Nb ($H_c=430 \text{ kA/m}$, $M_r=0.83 \text{ T}$, and $(BH)_{\text{max}}=85 \text{ kJ/m}^3$) and by using an α -Fe segment instead of an Fe_3B one ($H_c=430 \text{ kA/m}$, $M_r=1.0 \text{ T}$, and $(BH)_{\text{max}}=90 \text{ kJ/m}^3$).

It was found by SEM observation that there exist many particles ranging from 1 to $20 \mu\text{m}$ on the surface of a deposited film. The analysis of composition with SEM-EDX (Energy Dispersive X-ray Spectrometer) clarified that each particle is composed of small droplets, grows on the surface, and is in the composite state. The smoothness of the films is deteriorated by the existence of particles, and the periodicity of the stacked layers would be disturbed in the particles. Therefore, we developed a new PLD system which has an auxiliary laser in addition to a main laser for ablating a target (Fig.2 (a)). The laser beam from the auxiliary laser hits droplets flying between the target and the substrate and ablates them. In addition, we found that the number of particles is decreased by inserting intervals during depositions.

Subsequently, we deposited multi-layered films by the newly developed method from a $\text{Nd}_{2.6}\text{Fe}_{14}\text{B}/\text{Fe}_3\text{B}$ target, and the height of particles on film surface was measured by the line scan, and is plotted in Fig.2 (b), together with the result for the multi-layered film deposited by the PLD systems reported previously. As seen clearly, the newly developed PLD method reduced the num-

ber of particles on the surface significantly, which suggests that the developed method is a promising one for improving the morphology of a thick multi-layered film.

Fig.2 Schematic representation of the developed PLD system with auxiliary laser (a), and height of particles on the film surface deposited by the developed system, together with the result for the film deposited by the PLD method reported previously (b). In the developed method, the deposition for 15 min. was repeated 4 times (totally 1 hour) with intervals between depositions, although the deposition was carried out for 1 hour continuously in the previous method (the inset of Fig.(b)).

Magnetic properties of Nd-Fe-B thin films with island structure prepared on Mo buffer layer.

T. Shima¹, H. Kato¹, T. Sato²

1. Faculty of Engineering, Tohoku Gakuin University, Tagajo, Japan; 2. Toyota Central R&D Labs., Nagakute, Japan

Nd₂Fe₁₄B phase has a large magnetocrystalline anisotropy [1] and has been widely used as a permanent magnet with energy products ten times greater than ferrites. Recently, with increasing an awareness of environmental and energy issues, the market of hybrid vehicles has been explosively growing. In consequence, the interest in the development of a high performance permanent magnet is being attracted again. It is well known that coercivity H_c of commercial Nd-Fe-B magnets is much smaller than that of the theoretical value [2]. Heavy rare earth elements such as Dy and Tb are inevitably added to enhance the H_c of Nd-Fe-B sintered magnet. However, an urgent problem of scarce resources is forcing us to reduce the use of these elements. Furthermore, the mechanism of the magnetization process has not fully understood yet. In this study, in order to elucidate the coercivity mechanism, Nd-Fe-B thin films with island structure [3] were fabricated and their magnetization processes were investigated.

The (Cr/Mo/Nd-Fe-B/Cr) films were prepared on MgO (100) single crystal substrates using an UHV-compatible dc-sputtering apparatus. The base pressure is below 1×10^{-8} Pa. The nominal thickness t of the Nd-Fe-B layer was varied between 5 and 30 nm. The films were heated at 500 - 675 °C during the deposition of the Nd-Fe-B layer. The magnetic properties were measured by a superconducting quantum interference device (SQUID) magnetometer. The structure characterization was performed by an X-ray diffraction with $K\alpha$ radiation. The film composition was determined by an electron probe micro-analysis (EPMA).

The Nd₂Fe₁₄B phase was grown with the epitaxial relationship as $(001)_{\text{MgO}} // (001)_{\text{Mo}} // (001)_{\text{Nd}_2\text{Fe}_{14}\text{B}}$ for the films deposited in the temperature range from 540 to 625 °C. The island structure was formed for a sample with $t = 5$ nm, and its typical lateral size was 80 nm. The initial magnetization curves of the Nd-Fe-B films with different t are shown in Fig. 1. t was changed from 5, 8, 10 and 30 nm. The substrate temperature during deposition was fixed at 625 °C. It is clearly seen from this figure, the magnetization behavior was changed from single-domain (SD) particles to multiple-domain (MD) particles. The initial magnetization curve increases steeply for the MD particles ($t = 30$ nm), indicating that the magnetization process is dominated by domain wall displacement. On the other hand, the initial magnetization curve increases slowly with applied magnetic field for the SD particles ($t = 5$ nm). A mixture of different initial magnetization behaviors is observed in the films with $t = 8$ and 10 nm, indicating the co-existence of SD and MD particles. The maximum value of H_c for a Nd₂Fe₁₄B film was 18 kOe.

This work was partly supported by Toyota Motor Corporation. The magnetization measurement was performed at Magnetic Material Laboratory at IMR, Tohoku University. The structural characterization was performed at the Hi-tech Research Center of Tohoku Gakuin University.

Highly Coercive Nanocrystalline Electro-Deposited CoPt Thin Films.

K. Zuzek Rozman¹, J. Kovac², P. J. McGuinness¹, S. Kobe¹

1. Department for Nanostructured Materials, Jozef Stefan Institute, Ljubljana, Slovenia; 2. Department of Surface Engineering and Optoelectronics, Jozef Stefan Institute, Ljubljana, Slovenia

CoPt systems are very promising as magnetic storage media and for MEMS devices. They have a strong perpendicular magnetocrystalline anisotropy and they also exhibit excellent resistance to oxidation and corrosion.

Near-stoichiometric CoPt 50:50 thin films were prepared by electrodeposition from a single electrolyte. The electrolyte consisted of 2 mmol/l of Pt “p”-salt, 4 mmol/l of Co-sulphamate, 20 mmol/l of ammonium citrate and 0.2 mmol/l of glycine. The films of thickness up to 300 nm were deposited on glass/Cr/Au potentiostatically with the potential referenced to the potential of the Ag/AgCl electrode. The as-deposited films were annealed at temperatures up to 700°C for 60 min in forming gas (Ar+7% H₂) and examined with AFM, XRD, SQUID, SEM/EDXS and AES.

The surface of the as-deposited Co₄₅Pt₅₅ film was investigated with an AFM. The film shows a nanocrystalline structure with grain sizes ranging between 10 and 80 nm and a RMS roughness of 2.766 nm.

The XRD diagrams of the as-deposited and annealed Co₄₅Pt₅₅ presented in Figure 1 show the FCC CoPt phase with a predominant (111) texture, all additional peaks can be attributed to the substrate. After annealing at 500°C for 60 min no ordering into the L1₀ phase was observed. The ordering begins when the sample is annealed at 600°C for 60 min, with the appearance of the (001) and (110) reflections, which grow even larger when increasing the temperature to 700°C, where the (200) peak-splitting characteristic for the L1₀ ordering was also observed. In the XRD pattern of the sample annealed at 700°C an additional peak was observed at 2 θ =45.4°, which can be attributed to the Co₂Si phase. This implies interdiffusion between the CoPt film and the substrate. The magnetic properties of the annealed samples are displayed in Figure 2. A significant increase in the coercivity is observed with increasing annealing temperature, which is connected to the development of the L1₀ structure, reaching a value of $\mu_0 H_C = 1.2$ T, which is to the best of our knowledge the highest coercivity observed in electrodeposited CoPt films. On the other hand, the remanence decreases with the increasing annealing temperature because of the transformation of the highly symmetrical FCC phase into the L1₀ phase.

The in-depth composition across the film thickness and its dependence upon annealing according to the AES depth profiles is shown in Figure 3. The as-deposited film (Figure 3a) is Pt rich with a composition of Co₄₆Pt₅₄, which is not constant across the film thickness; there is an excess of Pt present at the surface in the middle and at the substrate-film boundary. Beneath the Co-Pt film the well-defined structure of the Au and Cr layers on the SiO₂ substrate is observed. After annealing at 700°C for 1 h in Ar+H₂ (Figure 3b), the film shows a more homogeneous composition. On the other hand, an interdiffusion of Co into the substrate was observed, which is in agreement with the XRD investigations that showed the formation of Co₂Si when annealed at 700°C. In the Co-Pt-Si system the interdiffusion of Co and Si is hard to avoid (Ref. 1). However, even though high coercivities can be achieved when choosing glass-based substrates, adding an appropriate diffusion barrier on the glass substrate would result in even better magnetic properties.

Magnetism and magnetocaloric effect in multiferroic LuFe_2O_4

J. Gass¹, N. Frey¹, M. Phan¹, H. Srikanth¹, M. Angst², B. Sales², D. Mandrus²

1. Department of Physics, University of South Florida, Tampa, FL; 2. Materials Science and Technology Division, Oak Ridge National Laboratory, Oak Ridge, TN

A systematic study of the DC, AC, RF susceptibility as well as the magnetocaloric effect (MCE) in LuFe_2O_4 single crystals is presented. The family of RFe_2O_4 ($\text{R} = \text{Y, Er, Yb, Tm, and Lu}$) compounds, which exhibit charge and magnetic order on a geometrically frustrated lattice, have received growing attention from the scientific community, owing to their extraordinarily interesting physical properties [1,2]. In particular in LuFe_2O_4 , the observation of an electric polarization possibly originating from charge order [3] and the subsequent discovery of a giant room-temperature magneto-capacitance [4] has created a lot of attention [5]. Multiferroic properties along with the intrinsic geometric spin frustration in LuFe_2O_4 make it a very promising candidate material for magnetic refrigeration and other technologies. While recent magnetization and neutron results suggest a three-dimensional magnetic structure with additional transitions, understanding the unusual magnetic properties of LuFe_2O_4 still remains incomplete, partially due to the complex phase diagram [6,7]. The very complexity makes it attractive for magnetocaloric applications and we propose LuFe_2O_4 to be a good candidate material as it can show large magnetic field-induced magnetic entropy change over a wide temperature range due to the occurrence of multiple successive metamagnetic transitions.

Here, we present a systematic study of the magnetic properties and the first report of the magnetocaloric effect (MCE) in LuFe_2O_4 . Correlation between the magnetism and MCE is established and the influence of the magnetic field on the metamagnetic transitions and MCE are analyzed and discussed. Our study underscores the important point that magnetic cooling power can be greatly enhanced in materials showing multiple successive magnetic phase transitions.

LuFe_2O_4 crystals were grown in an image furnace as described elsewhere [6,7]. DC and AC magnetization measurements were performed using a Physical Property Measurement System from Quantum Design in the temperature range of 5 – 300 K at applied fields up to 70 kOe. The magnetic entropy change (ΔS_M) was numerically extracted using the Maxwell relation from a large family of M-H curves collected at different fixed temperatures.

Our magnetization reveal unusual magnetic behavior only in fields applied parallel to the c-axis of the crystal, in agreement with previous studies [1,6,7]. Zero-field-cooled (ZFC) magnetization curves at applied field ~ 100 Oe show the two transitions around 240 K and 170 K also indicated by neutron scattering [6]. Field-cooled (FC) magnetization curves at the same field exhibit three broad cusps, two of which coincide with the above transitions. The magnetic entropy changes $\Delta S_M(T)$ at these features were calculated from a family of M-H curves at fixed temperatures using the Maxwell relation: $\Delta S_M(T) = \int (\partial M / \partial T)_H dH$.

$\Delta S_M(T)$ curves show three peaks at temperatures which correspond to the cusps in the FC magnetization. As the magnetic field is increased, the positions of MCE peaks at ~ 170 and 240 K tend to remain unchanged, whereas the one at ~ 65 K significantly shifts to a lower value. Noticeably, the MCE peak temperature of ~ 65 K for $\Delta H = 3$ kOe decreases to ~ 55 K which remains almost unchanged for $\Delta H \geq 42$ kOe. This is consistent with the observation that this low temperature metamagnetic transition in LuFe_2O_4 is kinetically arrested below ~ 55 K [7]. The magnitude of $\Delta S_M(T)$ at the peak temperatures varies differently as the applied magnetic field is increased. For $\Delta H \leq 21$ kOe, the magnitude of $\Delta S_M(T)$ is obviously larger for the case at ~ 55 K than for those at ~ 170 and 240 K, while the opposite trend is observed for $\Delta H > 21$ kOe. This suggests different mechanisms

for AF-FM couplings/correlations for the metamagnetic transitions. An important conclusion is that enhanced spin entropy (at the kinetically arrested transition) yields large MCE at lower applied fields which is desirable for applications. From the practical magnetic cooling perspective, the application of magnetic field leads to a broadening of the metamagnetic transitions and hence a broadened $\Delta S_M(T)$ curve over very wide temperature range. As a result, the magnetic cooling power – which is proportional to the width of the $\Delta S_M(T)$ curve – is greatly enhanced. This opens up new opportunities for the developments of a new class of material with multiple successive metamagnetic transitions for magnetic refrigeration.

Design and processing of new ferrite materials from an atomistic perspective.

A. Yang¹, A. Geiler¹, X. Zuo², C. Vittoria¹, V. G. Harris¹

1. Center for Microwave Magnetic Materials and Integrated Circuits, Electrical and Computer Engineering, Northeastern University, Boston, MA; 2. College of Information Technical Science, Nankai University, Tianjin, China

Ferrites of spinel and hexagonal crystal structure have been widely utilized in the design of various microwave and millimeter-wave components. These material structures consist of a closed packed oxygen framework in which magnetic and nonmagnetic cations reside at the interstitial sites. The electrical and magnetic properties of ferrite materials are largely determined by the distribution and valence of these cations. The ability to fine tune the cation distribution allows the material properties to be adjusted towards specific applications. The alternating target laser ablation deposition (ATLAD) technique was developed for just such a purpose. This technique allows the spinel^{1,2,3} and hexagonal ferrite structures⁴ to be deposited with control over the atomic scale distribution of cations by the controlled and sequential ablation of two or more targets. The ablation of the targets at carefully chosen intervals allows for the construction of unique ferrite structures. Previously, Zuo et al.² employed this technique to grow Mn-ferrite films having magnetic anisotropy fields as many as 100 times larger than conventionally grown films and, in some cases, aligned perpendicular to the film plane. The unique properties of these films correlated with a distinct inversion parameter (percentage of the divalent cations residing at octahedral sites in spinel ferrite) compared to the equilibrium value. Yang et al.³ further demonstrated control of the distribution of Cu cations in spinel Cu-ferrite films and obtained a 65% enhancement in the saturation magnetization of the Cu ferrite films over the equilibrium value. Most recently, the application of the ALTAD technique was applied for the first time to the growth of hexagonal M-type barium ferrite ($\text{BaFe}_{12}\text{O}_{19}$).⁴ In an extension of this work, Geiler et al. guided Mn substitutional cations to specific sublattices in the unit cell. By specific design the Mn resided preferentially on the octahedral sublattices in the spinel block within the hexagonal structure. Extended x-ray absorption fine structure analysis was utilized in all experiments to study the short range order of the atoms and the cation distribution. The ATLAD technique has been successfully employed to engineer the cation distribution in ferrite unit cells resulting in unique and useful microwave properties. First principle calculations were carried out and found to agree with the experimental results.

Texture analysis of ferrite materials by means of electron backscatter diffraction (EBSD).

A. D. Koblishka-Veneva¹, M. R. Koblishka², F. Muecklich¹

1. Institute for Functional Materials, University of the Saarland, Saarbruecken, Germany; 2. Institute of Experimental Physics, Saarland University, Saarbruecken, Germany

The analysis of the achieved texture is of great importance for ferrite materials, either bulk or thin films. The commonly employed techniques like X-ray pole figures do, however, not reach the required resolution to resolve fine details within the grain structure. Therefore, a technique with a relatively high spatial resolution would be required. The recently developed electron backscatter diffraction (EBSD) technique, which works within a scanning electron microscope, enables a spatially resolved study of the crystallographic orientations by means of recording of Kikuchi patterns. To our knowledge, such an EBSD analysis was not yet performed in any oxidic magnetic material, and only very recently on magnetite thin films by us [1,2]. A good surface polishing/cleaning is essential for this analysis, as the method requires an undisturbed surface area for a high image quality (IQ). This information is recorded to each measured Kikuchi pattern, together with a parameter describing the quality of indexation. To each pattern, the three Eulerian angles determine the crystallographic orientation [3]. From this information, orientation maps and local pole figures can be constructed.

In this contribution, we present the results of EBSD scans on various ferrite materials, including bulk M-type hexaferrite $\text{BaFe}_{12}\text{O}_{19}$ (Ba-ferrite) and thin films of a spinel-type $(\text{Ni,Zn})\text{Fe}_2\text{O}_4$ [(Ni,Zn)-ferrite] and thin films of $\text{Ba}_3\text{Co}_3\text{Fe}_{24}\text{O}_{41}$ (BCFO), which is a Z-type hexaferrite. Both types of thin films were grown by RF sputtering on Si substrates without an additional buffer layer.

The surface preparation process of the bulk ferrites is a delicate task, as for a high spatial resolution a mechanical polishing down to 40 nm colloidal silica is required, which is then followed by a thermal etching. For the thin films, no special polishing procedure is required.

Figure 2 presents a typical result obtained on a bulk ferrite sample. An IQ map and an inverse pole figure map in (0 0 1) direction is presented. Additionally, the detected grain boundaries are marked in black. The sample is polycrystalline and consists of several large grains. Two main growth directions of these large grains can be found. Here, it is remarkable that the growth of large ferrite grains is accompanied by several small, randomly oriented grains filling the gaps between the large ones. Furthermore, several misoriented small subgrains are located within the large grains. Here, the spatially highly resolved EBSD mappings provide additional information as compared to the standard analysis techniques, which can contribute to an optimization of the growth process.

The EBSD-analyzed ferrite thin films are both also polycrystalline, and do not exhibit a preferred texture. The as-grown films only exhibit small grains with sizes ranging between 30 and 50 nm. An extended annealing time leads to a considerable grain growth, so that grains with sizes ranging between 100 nm and 1 μm could be obtained. Using EBSD with optimized parameter settings, step sizes within the scan grid down to 20 nm can be applied, so that grains of around 60 nm size (corresponding to three data points) can be properly identified.

This work is financially supported by DFG-project no. Mu959/19, which is gratefully acknowledged. We would like to thank D. Makovec (Ljubljana) for providing the Ba-ferrite samples.

Oxide electrode on LAO (110) substrate for studying low-symmetry perovskite oxides.

J. Kim¹, J. Kim¹, H. Na¹, B. Lee¹, I. Choi¹, C. Jung¹, S. Chae²

1. Dept. of Physics, Hankuk University of Foreign Studies, Yongin, South Korea; 2. School of Physics and Astronomy, Seoul National University, Seoul, South Korea

Perovskite oxides distorted from cubic structures have shown interesting properties. These include ferromagnetic insulator of YTiO₃, Multiferroicity in BiMnO₃ and BiFeO₃. [1-3] The in-plane asymmetric atomic arrangements at the substrate surface of LAO(110) substrate allowed us to grow epitaxial thin films of YTiO₃, which have an orthorhombic crystal structure with quite different a- and b-axes lattice constants. [1,4]

This time we tried to develop an oxide electrode on LAO (110) substrate for studying low-symmetry perovskite oxides. This oxide bottom electrode should have a metallic properties down to low temperature where interesting magnetic transition occurs and should be grown coherently on top of LAO (110) substrate. While SrRuO₃ is too big to be grown coherently and metallically on top of LAO(110) due to rather large mismatch, CaRuO₃ (CRO) is a highly distorted perovskite oxide with smaller lattice constant. [4,5]

The CaRuO₃ thin films were grown on the LaAlO₃ (110) substrate using a pulsed laser deposition technique. A ceramic CaRuO₃ target was ablated by using a KrF laser with a fluence of 2-3 J/cm² at 3-4 Hz. The base pressure of the vacuum chamber was 1×10^{-9} Torr. The oxygen partial pressure, P_{O₂} was maintained at 60 mTorr. The temperature of substrate was varied from 640 °C to 800 °C and were cooled slowly to room temperature under a constant PO₂. The high resolution x-ray diffractor meter (D8 discovery, Bruker) was used to characterize the crystallinity of CaRuO₃ thin films. Figure 1 shows the x-ray diffraction θ -2 θ scan pattern of CaRuO₃ thin films grown at different growth temperature from 640 °C to 800 °C. The x-ray diffraction pattern shows only clear CaRuO₃ single phase peaks with LaAlO₃ substrate peaks. As the growth temperature increased, the intensity of CaRuO₃ peaks was increased. The peak of CaRuO₃ was also shifted which indicates that the volume of CaRuO₃ is increased. [In this paper, we choose the pseudo-cubic unit cell notation for LAO and CRO]

Figure 2 shows the reciprocal space mapping of CaRuO₃ thin films grown at different temperature, i. e., 740 °C and 800 °C. At 740 °C, the CaRuO₃ thin films was grown coherently according to the LaAlO₃ (110) substrate as shown in Figs. 2 (c) and (d). However, as the growth temperature increased up to 800 °C, the relaxation of peak was enhanced as shown in Figs 2(a) and (b). This indicates that the higher temperature for film growth might resulted in the volume expansion and lattice relaxation of inplane lattice constant of CaRuO₃ thin film.

Figure 3 shows the temperature dependence of resistance of CaRuO₃ thin films. As the temperature decreased, the resistance of CaRuO₃ thin films was decreased which indicates the clear metallic properties of CaRuO₃ thin films. [6] However, the resistance of CaRuO₃ thin films shows different low temperature dependence and high temperature dependence. The linear $T^{0.5}$ dependence was observed above 50 K, whereas the linear $T^{1.5}$ dependence of resistance to below 50 K.

Mössbauer studies of the $\text{Co}_{1-x}\text{Zn}_x\text{Fe}_2\text{O}_4$ Ferrite.

Y. Zhang¹, X. Yuan¹, Z. Ren¹, Z. Kou¹, X. Bai², Y. Zhai^{1,2}, Y. Xu³, J. Du², H. Zhai²

1. Department of Physics, Southeast University, Nanjing, China; 2. National Laboratory of Solid Microstructures, Nanjing University, Nanjing, China; 3. Department of Electronics, University of York, York, United Kingdom

Many methods have been developed to prepare nanosized ferrite, the structure and physical properties of ferrite nanoparticles are related to the preparation method and synthesis conditions, such as pH value, temperature and concentration, etc. [1, 2, 3]. This paper reports a series of nanoparticles of $\text{Co}_{1-x}\text{Zn}_x\text{Fe}_2\text{O}_4$ ($x = 0, 0.20, 0.40, 0.50, 0.60, 0.7$ and 0.80) ferrites prepared by chemical coprecipitation method under the temperature of 100 centigrade and pH of 11-12. The structure and magnetic properties of the powders were characterized by XRD, VSM, SQUID and Mössbauer measurements. The precipitated particles showed single-phase fcc spinel structure for all samples with different compositions of zinc. The average grain sizes and the lattice parameters of samples increase from 8.359 Å to 8.399 Å and 9 nm to 6 nm respectively as increasing the Zn content, estimated from X-ray diffractions.

The Mössbauer spectra were taken at room temperature with a $^{57}\text{Co(Pd)}$. They are composed of two sets of sextets and one set of doublet as Zn content $x < 0.7$, corresponding to the part of the particles which is in ferrimagnetic ordered state with two components due to Fe^{3+} ions at octahedral/tetrahedral sublattice sites and part of particles with non magnetic order phase as shown in Fig.1. By fitting, various Mössbauer parameters were obtained. The hyperfine magnetic fields of the octahedral and tetrahedral sites are reduced from 460 kOe to 168 kOe and 411 kOe to 0 with increasing the doped Zn contents from 0 to 0.6, suggesting a parallel changing tendency of magnetization measured by VSM. This indicates that Zn cation enters into the tetrahedral sites. The relative area of the subspectra of each Fe site changes strongly with the content of Zn. The areas covered by doublet increase as ranging from 10% to 58.5% with increasing the Zn concentration, and the spectra change to a single doublet as the Zn content $x \geq 0.7$. The doublet component may be originated from the part in superparamagnetic state.

Magnetization measurements were performed for each obtained sample with a VSM and a SQUID at the temperature of 300 K and 5 K respectively, which may give some evidence to support Mössbauer measurements. The value of the saturation magnetization and the coercivity are all decreasing with the doping Zn content increasing at 300 K, and the relationship between saturation magnetization and the Zn concentration at 5 K is similar to that at 300 K. The Magnetic parameters of $\text{Co}_{1-x}\text{Zn}_x\text{Fe}_2\text{O}_4$ nanoparticles exhibited a strong dependence on composition and temperature. Hysteresis loops of two representative samples of $\text{Co}_{0.6}\text{Zn}_{0.4}\text{Fe}_2\text{O}_4$ and $\text{Co}_{0.3}\text{Zn}_{0.7}\text{Fe}_2\text{O}_4$ are shown in Fig. 2. For the sample of $\text{Co}_{0.6}\text{Zn}_{0.4}\text{Fe}_2\text{O}_4$, a well defined hysteresis loop with $H_c = 25$ Oe was obtained at room temperature, while for sample of $\text{Co}_{0.3}\text{Zn}_{0.7}\text{Fe}_2\text{O}_4$, the coercivity H_c is nearly zero, which is nearly 3000 Oe at 5 K. The magnetization also shows a large change at 300 K and 5 K. For two representative samples of $\text{Co}_{0.6}\text{Zn}_{0.4}\text{Fe}_2\text{O}_4$ and $\text{Co}_{0.3}\text{Zn}_{0.7}\text{Fe}_2\text{O}_4$, the magnetization increases from 52 emu/g to 92 emu/g and 32 emu/g to 87 emu/g with decreasing temperature from 300 K to 5 K. The temperature dependence of magnetization for various Zn content, measured by SQUID for both field-cooled (FC) and zero-field-cooled (ZFC) samples under a 100 Oe field, was also found the meeting point T_b of the FC and ZFC curves, to decrease as the doped Zn contents increasing. The details of data, analysis, and discussion will be given in full manuscript.

Synthesis of iron oxide nanoparticles of controlled size, shape and magnetic properties.

P. Guardia, A. Labarta, X. Batlle
Fundamental Physics, UB, Barcelona, Spain

Magnetic nanoparticles (MNP) are an ideal system to study finite-size and surface effects, all these yielding new interesting phenomena and enhanced properties with respect to their bulk counterpart [1]. Besides, the potential application of MNP for biomedical purposes relies on the synthesis of high quality materials, from both the crystalline and magnetic points of view. In this work, we report on the influence of a variety of parameters in the synthesis of iron oxide nanoparticles (magnetite/maghemite $\text{Fe}_3\text{O}_4/\text{Fe}_2\text{O}_3$) by the thermal decomposition of an organic iron precursor in an organic media [2]. It is well known that this method allows the preparation of highly crystalline MNP with excellent magnetic parameters [3,4]. We study the role of both the reductor and surfactant on the shape, size distribution and the magnetic properties. We aim at the synthesis of MNP with an average size of a few nanometers. A narrow size distribution of spherical particles with a high saturation magnetization of 80 emu/g at low temperature, is observed when using oleic acid as a surfactant. In contrast, decanoic acid yields a wider size distribution of cubic particles with a large saturation magnetization within 90-110 emu/g at low temperature. The use of a variety of reductors also monitors the magnetic behaviour. In the case of hexadecanediol, nanoparticles have a uniform oxidation and a saturation magnetization similar to the bulk counterpart. In contrast, hydrazine seems to promote a non-uniform oxidation that results in the appearance of exchange bias and in a smaller saturation magnetization of about 70 emu/g. The funding from the Spanish MEC (NAN2004-08805-CO4-02, NAN2004-08805-CO4-01, CONSOLIDER CSD2006-12 and MAT2006-03999), and from the Catalan DURSI (2005SGR00969) is acknowledged.

The dispersion of BaFe₁₂O₁₉ particles in a liquid.

D. Lisjak¹, M. Drofenik^{1,2}

1. Jozef Stefan Institute, Ljubljana, Slovenia; 2. Faculty of Chemistry and Chemical Engineering, University of Maribor, Maribor, Slovenia

BaFe₁₂O₁₉ (BaM) is a well-known material suitable for various applications, like hard magnets, magnetic recording, microwave and mm-wave devices and absorbers. Depending on the application BaM is used in the form of bulk, powder, films or composites. Composites are of special interest. The repeatability of the synthesis and the ultimate control of the composite's behaviour can only be achieved by a homogeneous incorporation of fully dispersed (= non-agglomerated) particles in the matrix. All particles tend to agglomerate due to Van der Waals attractive forces when they approach at distances of a few nanometres. However, attractive magnetic forces are much stronger and act at longer distances than Van der Waals forces. So the main problem in the synthesis of magnetic composites is to overcome the magnetic attraction between the particles and consequently, to prevent their agglomeration.

The existing solutions to the agglomeration problem have been addressed for soft magnetic particles, which can be synthesized directly in a carrier liquid or in a polymer matrix at low temperatures. The particles' surfaces are coated with a thin non-magnetic layer, which prevents any magnetic attraction between the particles. Such surface-modified particles can then be subsequently incorporated into various matrices. Most often superparamagnetic particles are used for the preparation of ferrofluids. In this case any magnetic attraction is absent in the absence of an external magnetic field and only the Van der Waals attraction has to be considered. Minimum temperatures of 500°C are required for the crystallization of BaM, and these temperatures are too high for any synthesis in liquids. On the other hand, hard magnetic particles of BaM become superparamagnetic at a diameter of around 3 nm, due to their large magnetocrystalline anisotropy. However, the synthesis of such small BaM particles is not trivial. The aim of this work was to study another possibility: the de-agglomeration of single-domain BaM particles in liquids.

Commercial BaM particles (Aldrich) with an approximate mean diameter of 100 nm and with an approximate mean thickness of 50 nm were chosen for this study. The particles exhibited a remanent magnetization of 17 A/m²kg, a coercivity of 306 kA/m and a magnetization of 31 A/m²kg at 1 T. The field of 1 T was not enough to saturate the particles. The contribution of the magnetic attraction between the BaM particles with respect to the Van der Waals attraction was estimated on the basis of known equations (refs. 1,2), and was several orders of magnitude larger than the Van der Waals attraction energy (Fig. 1). The magnetic attraction energy between such particles is lower than the thermal energy at separation distances larger than 10 nm. This means that such particles would be stable if they were covered with a nonmagnetic layer with a minimum thickness of 5 nm. The BaM dispersions were prepared using ultrasound or milling. Two surfactants, dodecylbenzenesulfonic acid (DBSa) and Sarkosyl "O" (SO), were examined for the electrosteric stabilization of the particles. The stability of the BaM particles in water was determined with sedimentation tests and with zeta-potential measurements. The zeta-potential measurements indicated that the surfaces of the particles were modified regardless of the conditions used. The sedimentation of particles treated with the DBSa started after 5 min, while the sedimentation of particles treated with SO started after just 1 min. The dispersions prepared with milling and with DBSa were significantly more stable than the others prepared with the ultrasound. The particles only settled under an external magnetic field.

The dispersed particles were further analyzed with thermogravimetry coupled with mass spectroscopy. The thickness of the DBSa layer was estimated to be thick enough (>5 nm) to prevent the particles' agglomeration. Nevertheless, only dispersions prepared with milling were really stable. This can be explained by the fact that the milling was more efficient in breaking the pre-existing agglomerates in the raw powder than was the ultrasound. As was observed with a transmission electron microscope, in the latter case, the DBSa did not only coat the dispersed particles, it also completely covered the smaller agglomerates in their entirety. Measurements of the magnetic and magnetorehological properties of the stable dispersion were also performed and will be presented.

FREEZE Granulation: A novel technique for low-loss MnZn ferrites.

V. Tsakaloudi, G. Kogias, V. T. Zaspalis

Laboratory of Inorganic Materials, Centre for Research and Technology Hellas, Thessaloniki, Greece

It is widely accepted that the magnetic quality of MnZn ferrites in terms of high initial permeability and low power losses lies on an optimized combination of chemical and morphological homogeneity of the sintered ferrite[1]. This study focuses on the evaluation of freeze granulation and subsequent freeze-drying, a novel technique applied on ferrite processing, on the quality of the compacted specimen and, consequently, on the magnetic quality of the final sintered MnZn ferrite.

The conventional spray-drying method, used in production-scale processing of MnZn ferrites, shows significant drawbacks, such as inflation defects visible as large voids in the interior of the granule. Moreover, the rapid water evaporation gives rise to the development of capillary stresses that may initiate undesirable diffusion phenomena that reduce the compositional and morphological homogeneity of the granule. Those imperfections may resist compaction and also be present in the compacted specimens[2]. Freeze granulation on the other hand, is based on the spraying of the slurry droplets into liquid N₂ followed by subsequent freeze-drying. It is advantageous in terms of homogeneous granule density, absence of cavities in the granules, since due to elimination of the evaporation step it doesn't involve any capillary action and shrinkage of the droplet. The achieved homogeneity and density of the granule are retained after sublimation[3].

In this study, MnZn ferrite powders have been prepared by the conventional ceramic route as reported elsewhere[4]. After mixing, pre-firing and milling, binder is added to the slurry of the milled powder that is separated in two fractions. The first fraction is spray-dried, while the other is freeze-granulated and subsequently freeze-dried. The quality of granulates is compared through compaction testing, electron microscopy observation of granulates and compacted cylinders after BBO, pore surface area determination and power loss measurement of sintered toroids under equilibrium partial pressures of oxygen[5].

The observation of the microstructure of pre-sintered pressed cylinders so that the binder is burnt out, has shown that in the case of spray drying there is a strong "memory effect" that follows the compacted specimen during the sintering process. The granule structure can be recognized in the structure of the compacted specimen. This morphological inhomogeneity is now found to accompany the specimen during the sintering process, as the granule area can be clearly seen and even the intragranular void can be detected. It is, therefore, most possible that the temperature increase during sintering will lead to the entrapment of the voids and, finally, to the formation of isolated intragranular pores which will affect the sintered density and, consequently, deteriorate the magnetic quality of the final MnZn ferrite. On the contrary, the cylinder prepared from granules after freeze-granulation is characterized by a totally homogeneous microstructure, where any voids or cavities of potential isolated pore formation are absent.

The Pore Size Distribution presented in Figure 1 of pre-sintered specimens compacted from the spray-dried and freeze-granulation processes confirms the above characteristics. In the case of the spray-drying process the total pore surface area remaining is much larger than in the case of freeze-granulation. The increased pore surface area will most probably lead to a decreased sintered density and lower magnetic quality of the final MnZn ferrite. The magnetic characterization of the sintered toroids at 100 kHz-200 mT indicated that freeze granulation leads to sintered toroids with lower power losses at lower densities, in comparison to the spray-dried granules, as presented in Figure 2.

The above results indicate that the novel technique of freeze granulation offers advantages in the MnZn ferrite manufacturing since it leads to better green compact microstructures and finally to better magnetic quality products. A draw-back of the process is the low bulk density of the granulated matter. This will have as an unavoidable consequence a re-design of the pressing tools.

Bit patterned media (BPM) is one option to extend areal density growth in magnetic recording to and beyond Terabit per square inch (Tbpsi) [1]. This technology relies on recording single bits on single magnetic islands (dots), which are pre-patterned on a rotating storage disk. There are many system challenges related to servo and bit formatting, in particular, avoiding write errors due to mis-synchronization of the write field relative to the bits. Entering into this problem are sigmas of size and placement and magnetic anisotropy of the dots. These need to be kept extremely tight to about 5% (1 sigma) as a percentage of size, spacing and Hk. Recording physics modeling indicates that densities approaching 10 Tbpsi are possible if this condition is met by combining BPM and domain wall assisted (exchange spring) media with trailing/side shield writers [2].

Electron Beam Writing (EBW), resist materials and developing strategies are in place to generate appropriate resolution with tight sigmas up to at least 2 Tbpsi [3]. More relevant rotating stage e-beam recordings for disks have been achieved up to about 450 Gbps. The developed resist pattern is transferred via reactive ion etching into a thin quartz substrate to form a template suitable for subsequent UV cure nano-imprint lithography (NIL). This intermediate NIL process is necessary to contain cost in a future manufacturing scenario. Different options exist to convert the imprinted resist pattern into magnetic islands: (1) etch pattern into disk substrate and coat over with magnetic film, (2) etch nanoholes in a dielectric down to a seed layer, e.g. Ru, and plate up magnetic material, e.g. Co3Pt or (3) carboxyl reactive ion etch or ion beam etch pattern into a full perpendicular film stack recording disk, based on CoX alloys or multilayers. Planarization of the surface to minimize any residual topography (roughness) is critical to achieve good flyability, especially when crossing from servo to data zones.

Fig 1 shows representative MOKE hysteresis curves of a continuous, non-granular CoX film before and after patterning at 250 Gdpsi. Dot size and placement sigmas of the patterned film is <5% (1 sigma). Analysis of the hysteresis curves using the Berger method [4] indicate switching field distributions (SFD) <5%. Complementary transverse susceptibility (TS) data indicate an intrinsic sigma_Hk of 4.5% [5] (Fig 2). Table 1 summarizes typical magnetic data from such patterned films and Fig 3 shows MFM images of an ac-demagnetized sample, indicating well resolved dots.

The main conclusion of the paper is that tight intrinsic magnetic sigmas of less than 5% are achievable in BPM at 250 Gdpsi. Maintaining these sigmas at Tbpsi and beyond and synchronizing the write timing to the patterned dots remain critical challenges going forward.

Film	Thickness (nm)	H _c (Oe)	H _{int} (Oe)	H _{is} (Oe)	KuV/KT	SFD(%)	Sigma_Hk (%)
CoX	16	6340	5260	10280	320	4.9	4.5

Modeling and Simulation of the Writing Process on Bit-Patterned Perpendicular Media.

H. Muraoka¹, S. J. Greaves¹, Y. Kanai²

1. RIEC, Tohoku University, Sendai, Japan; 2. Niigata Institute of Technology, Kashiwazaki, Japan

Bit-patterned perpendicular magnetic media are strong candidates for extending the thermal stability limit of current granular media [1]. However, since all of the bits are pre-fabricated, the physical structure is fundamentally different from conventional media and the write/read scheme must be totally re-established. Extraction of the necessary control parameters to maximize the recording density and to optimize performance is indispensable. The recording performance is known to be governed by various patterning fluctuations, such that the major media noise source is the dispersion of patterned dots [2]. The statistical characteristics of these fluctuations are therefore important. In this work, the influence of pattern fluctuations in experimental samples is discussed to determine the appropriate writing process, based on a recording model of bit-patterned media. Computer simulations were used to demonstrate the effectiveness of the model by maximizing the areal recording density through optimization of the media fabrication and recording conditions.

Unlike conventional, granular recording media, in which the micro-magnetic structure of the recording layer determines media noise, the noise in patterned media is dominated by fluctuations in the size and position of the patterned dots [3]. Measurements of these fluctuations were made for dot patterns fabricated by electron beam lithography. The statistical characteristics did not perfectly obey Gaussian distributions. The fluctuation of line edge roughness had dominant low frequency components for random distributions [4]. The measured line edge roughness was compared with several simulated random patterns created from Voronoi cells, and is shown in Fig 1. Auto-correlation of the location of neighboring patterns, indicated a positive, finite correlation. A random distribution was not observed in this sense.

Bit errors during writing (written-in errors) are fatal and dominant in bit-patterned media. The necessary condition to avoid these errors is that the difference in the write head field between any pair of neighboring dots exceeds the overall switching field distribution (SFD) of the dots. The difference in the write field is the product of the dot pitch and the head field gradient. The SFD has to take account of the magneto-static field from surrounding dots. This slope model requires that the entire SFD should be less than the product of the head field gradient and the dot pitch. For example, in the case of a dot pitch of 12.7 nm (2 Tbit/in² with an aspect ratio of 2), a head field gradient of 300 Oe/nm requires an overall SFD of 3810 Oe, which corresponds to a small standard deviation of 420 Oe to satisfy an error rate of 10⁻⁶ (4.5 σ).

Computer simulations of bit-patterned media were carried out. A shielded, single-pole writer with a tapered main pole was assumed and the head field distribution was calculated using a FEM model. Fig. 2 shows an example of successfully written bits at 2 Tbit/in². There are seven tracks shown, of which the center track was written with a ...010101... pattern. The background dots were randomly pre-programmed to include magneto-static interference. The magnetic dot size was optimized before this writing test. Accurate write synchronization within approximately 2 nm was required in this case. Adjacent Track Erasure is another critical issue for error-free writing.

Nanoscale perpendicular magnetic island arrays fabricated by extreme ultraviolet interference lithography.

F. Luo, L. J. Heyderman, H. H. Solak

Laboratory for Micro- and Nanotechnology, Paul Scherrer Institut, Villigen, Switzerland

The increase of the recording density in hard disk drives has been achieved mainly by decreasing the size of the magnetic grains which record bits in the storage layer. However, the recorded data can be erased by thermal fluctuations of the magnetization when the grain volume is reduced so much that the magnetic energy per grain becomes comparable with the thermal energy. By patterning the magnetic recording media into isolated small elements, referred to as bit patterned media (BPM), the onset of this superparamagnetic effect can be delayed. In order to determine the viability of BPM for future magnetic recording, it is important to determine which factors (e.g. lithographic irregularities, distribution of intrinsic magnetic anisotropy, and magnetostatic interaction of the neighbouring islands) give the most important contributions to the switching field distribution (SFD).

In the current work, 50 nm-period arrays of magnetic islands with perpendicular anisotropy were fabricated by depositing Co/Pd multilayer films on substrates pre-patterned with SiO_x pillars fabricated with extreme ultraviolet interference lithography (EUV-IL). This fabrication technique has the advantage that it not only provides high resolution, with periods down to a theoretical limit of 6.5 nm (half the EUV wavelength) and precise positioning of nanostructures, but also provides a high throughput (with parallel processing and exposure times in the 5-30 second range) and can expose large areas up to several mm², depending on the structure size. The array of magnetic islands created on top of the SiO_x pillars is magnetically decoupled from the magnetic material in the trenches between the pillars. This is facilitated by the negative sidewall profile of the pillars which prevents deposition of magnetic material on the pillar sidewalls.

The effect of the size distribution on the SFD was investigated on a 50 nm-period array. In order to unambiguously identify individual islands we chose three inhomogeneously exposed areas (comprising a total of 289 magnetic islands) at the edge of a SiO_x pillar array. This allowed easy identification of each island so that it was possible to match each island switching field measured with magnetic force microscopy (MFM) with the island size measured with high resolution SEM. A map of switching fields for each individual island is shown in Fig. (a): the color corresponds to the switching field and the size is proportional to the magnetic island size measured from the SEM images. Fig. (b) and (c) show the distribution of switching fields and island diameter for all of the 289 islands measured together with Gaussian fits. The Gaussian fit of the size distribution yields $\sigma = 1.2$ nm ($\sigma/\langle\text{mean}\rangle = 5\%$), demonstrating the narrow size distribution obtained from EUV interference lithography. The mean switching field is 7200 Oe with $\sigma = 830$ Oe ($\sigma/\langle\text{mean}\rangle = 11.5\%$) which is comparable with previous results on samples produced by e-beam lithography [1]. Simulations of an SFD due solely to magnetostatic interactions show that these interactions are not responsible for the majority of the SFD. In addition, we do not observe a strong dependence of the switching field distribution on the island size. These results imply that it is rather a distribution of material properties, such as anisotropy, which is responsible for the SFD, in agreement with previous work [2].

In conclusion, we have fabricated perpendicular nanoscale magnetic island arrays on pre-patterned substrates with periods of 50 nm by EUV-IL. SEM and MFM measurements on the same islands allowed a direct comparison of the island sizes and switching fields. The results indicate that the SFD is dominated by a distribution of the material properties. Therefore it should be possible to

decrease the SFD by improving the material homogeneity. Recent advances in EUV-IL have demonstrated that periods of 25 nm are achievable providing a competitive technology for fabrication of future data storage devices at 1 Tbit/in².

Department of Engineering Materials, University of Sheffield, Sheffield, United Kingdom

In modern magnetic recording materials the ‘superparamagnetic effect’ has become increasingly important as new magnetic hard disk drive products are designed for higher storage densities. In this regard, patterned media [1], where two-dimensional arrays of nanostructures with high magnetic anisotropy are used, is one of the concepts that might provide the required areal density in future magnetic recording devices.

In this presentation, I will introduce a novel magnetic gradient nanomaterial, which has been created by depositing Co/Pd multilayers onto two-dimensional arrays of self-assembled nanoparticles [2] as depicted in figure 1A. The so-formed nanostructures are monodisperse, magnetically exchange decoupled, single-domain, and exhibit a uniform magnetic anisotropy with an unexpected switching behavior induced by their spherical shape [3]. The Co layer thickness dependence and the bilayer dependence was studied for various particle sizes. Equivalent nanostructures can also be fabricated by Co/Pd film deposition into spherical indentations formed by spherical particle arrays [4] as shown in figure 2.

Recently, this approach was also extended to further thin film systems providing perpendicular magnetic anisotropy, i.e. FePt and CoPtCr-SiO₂ alloys. For the latter, it is well known that the intergranular exchange can be controlled by the SiO₂ content and by the sputter pressure during film deposition. It turned out that by tuning the growth conditions single domain nanocaps with enhanced magnetic coercivity fields can be achieved even for particle sizes down to 10 nm.

Patterned media for storage applications at densities beyond 1Tb/in² requires fabrication of periodic patterns at 27nm full pitch and smaller. Templating patterns at these dimensions is particularly challenging when considering the stringent quality restrictions imposed by storage applications in terms of feature size distribution, line edge roughness, placement and long-range ordering. We present here a guided self-assembly approach that combines e-beam lithography with block copolymer self-assembly. E-beam lithography is used to pre-pattern a guiding substrate defining features with registration and long-range orientational and translational order. A block copolymer film is applied on top of the guiding pattern. The uniformity of the self-assembled features effectively corrects noise and non-uniformities introduced by the e-beam and the e-beam resist. We use image processing to quantify the pattern quality rectification achieved by the block copolymer.

We also use this guided self-assembly approach as a pattern density multiplier. The self-assembled pattern can be used to multiply the density of e-beam features by at least a factor of four. This density multiplication approach enables the possibility to pattern features at resolutions not accessible by state-of-the-art e-beam lithography but still taking full advantage of its registration and long-range ordering properties.

Fabrication and Characterization of High-density Patterned Media.

An anodic alumina template, as being known to have perpendicular holes and highly ordered hole array, is particularly excellent for patterned media application.

We have adopted AlHf alloy for suppressing the surface roughness. Therefore, the anodic alumina film with high-density ordered holes of 1.86Tdots/in² (honeycomb) and 1.61Tdots/in² (square) corresponding with 20nm period was obtained as shown in Fig. 1.

We have developed a new anodizing process in order to fabricate pillar structure.^[1] The media fabrication process is as follows: 1) The AlHf(35nm) / Nb(32.5nm) / Ti(2.5nm) / CoZrNb(150nm) / Ti(5nm) layered film was deposited on Si disk substrate (1 inch size) by a conventional sputtering technique. The film with shallow dimples of a square array was formed by FIB as shown in Fig. 2(a); 2) When AlHf(35nm) layer was anodized at 10.8V and 20 degree C in sulfuric acid solution of 1mol/L, the anodic alumina film was obtained as shown in a cross-sectional schematic drawing of Fig. 2(b) and a plane-view SEM image of Fig. 2(b'); 3) Then second anodizing process on the condition of 18V and 20 degree C in ammonium borate solution of 0.15mol/L was applied for the anodized film. As shown in a cross-sectional schematic drawing of Fig. 2(c) and a plane-view SEM image of Fig. 2(c'), Niobium-oxide growth was promoted from the bottom area of the holes, which was caused from anodization of the Nb(32.5nm) layer. The top surface of the pillars was polished for flatness; 4) Figure 3(d) and 3(d'), which are a cross-sectional schematic drawing and a plane-view SEM image, show the standing Niobium-oxide pillars formed by etching the alumina part of the film for 5 hours in 5weight% phosphoric acid solution at room temperature. We successfully obtained the pillar structure from the porous structure by a new anodizing process; 5) Magnetic recording layer, which consists of the hcp-Co₇₀Pt₃₀ / Ru / Pt / Ti layered structure, was deposited on the pillar structure. Finally, the magnetic patterned media, as shown in Fig. 3(A), were fabricated by coating of lubricant and DLC layers. Every niobium oxide pillars had same height with 25nm period. Coating process was effectively done without obvious sidewall coating as shown in a cross-sectional TEM image of Fig. 3(B).

Figure 4(a) and 4(b) show the read-back signal waveforms from the media with 65nm period (153Gdots/in²) and 25nm period (1.03Tdots/in²) measured by a spin-stand respectively.^[2] Figure 4(c) shows the read-back signal waveforms from the media with 25nm period measured by a static-tester. These read-back signals were measured from different position. The signals from the media with 65nm period in the flying condition were resolved into a bit length of 1dot, 2dots and 3dots. Next, the read-back signals from the media with 25nm period in the flying condition were not resolved into a bit length of 1dot, but resolved into a bit length of 2dots and 3dots. Furthermore, the read-back signals from the media with 25nm period in the contact condition were resolved into a bit length of 1dot, 2dots and 3dots. Thus we proved that the media with 25nm period (1.03Tdots/in²) had a potential of 1Tb/in² in the contact condition.

An investigation of noise increased in TMR readers during drive operation
Pak Kin Wong, Yi Mei Tam, Vincent M. F. Chiah and Tad Shimizu
SAE Magnetics (HK) Ltd.

Tunneling MR (TMR) reader head has been widely adopted in the production of hard disk drives with > 100 Gb/in² recording density. With AlO_x tunneling barrier, failure in drive reliability test due to barrier breakdown and pinhole development is rarely reported. Instead, the major failure mode in drive reliability test, with occurrence of 0~150dppm, is increase in noise after a few to hundreds of hours of drive operation. In this article, we report our investigations on the mechanism and possible triggers of such reader noise.

Figure 1 shows the typical instability observed after noise increased in drives. Firstly, we analyzed the failed readers for any distortion from the pre-set alignment of the magnetizations of the constituent layers of reader. High field QST technique is used, in which the reader response during field sweeping is captured. After each field sweeping, the reader noise is checked. We have observed that a small portion of the failure population have reader noise eliminated by sweeping field along the pre-set magnetization of the hard magnets (HM). The HFQST curves suggest a distortion of HM magnetization (Figure 2). The possible causes of HM distortion in drives will be discussed.

The noise in most of the failed readers cannot be eliminated by a sweeping field. We have applied field in HM direction of increasing magnitude to check at what magnitude the noise can be suppressed (Figure 3). We have found that the field required to suppress the noise falls between the field of reader shield saturation and HM saturation. After removing the field, the noise comes back. We conclude that the noise comes from the degradation of HM property, but in this case, it is not a non-permanent distortion in HM. To search for the reason of HM degradation, we put the failed heads at elevated temperature (140C) and observed a reduction in noise level, and in many cases, the noise is eliminated. Firstly, this indicates that the noise is not resulted from a degradation of HM remanence with thermal energy. Secondly, the recovery from noise hints a link between the noise and the mechanical stress which can possibly be relaxed or changed at elevated temperature. We have further investigated the effect of stress on the noisy heads. Mechanical deformations on the heads surface covering the whole reader is made by nano-indentation technique which a round-topped tip of 5 μ m diameter. The deformation depth ranges from 3~6 nm, about 5% of the reader strip height (Figure 4). After such deformation, the noise level is significantly lowered and in most cases, the noise level comes down to be same as normal readers. Finally we conclude that the noise occurred in drive reliability test is likely caused by a modification of surface stress and morphology of the readers, instead of the intrinsic degradation of the HM. Further investigations imply that the stress related to noise occurrence is not intrinsic with the wafer geometries, but slider process related. Detailed results of the studies and a discussion on the possible mechanism of surface stress and morphology change in drive will be made in the article.

Figure 1. Unstable waveform after 339hours of drive operation.

Figure 2. An example of HM distortion captured by high field QST. The field was swept along the direction of HM magnetization pre-set in production. The opening at zero field is closed with a field of 1300 Oe, which is the typical saturation field of HM in our shielded devices.

Figure 3. Noise is suppressed by applying a field along HM magnetization, with magnitude close to saturation field of HM.

Improvement of TMR effect of magnetic tunneling junctions with very thin MgO barrier sputtered by noble gas mixture at low RA product below $1.0 \Omega\mu\text{m}^2$

K. Noma¹, K. Komagaki², K. Sunaga², H. Kanai², Y. Uehara², T. Umehara¹

1. Introduction

A Magnetic tunneling junction (MTJ) film with (001)-oriented MgO barrier layer is a hopeful material for a high-density read head because of its huge magnetoresistive ratio (MR-ratio) above 200%[1][2]. It is necessary to decrease RA product of the MTJ film to $1.0 \Omega\mu\text{m}^2$ for a development of the read heads of hard-disk drives with the areal recording density of 500 Gbits/in² because a junction size of $0.05 \mu\text{m}$ -square and a resistivity of the element below 400Ω are required. However, MR-ratio of sputter-deposited MgO-based MTJ films rapidly dropped at RA below $1.5 \Omega\mu\text{m}^2$. The huge MR-ratio is caused by a coherent tunneling of electrons along [100] axis of the MgO crystallites[3] and imperfect crystallites at an initial layer of the MgO barrier seemed to increase an incoherent scattering and the decrease of MR-ratio at low RA. In this study, mixture of noble gases was used as a sputtering gas of the MgO barrier layer in the MTJ film for decreasing a density of vacancies caused by an impact with energetic particles on the surface or by a re-sputtering of oxygen atoms and their magnetoresistive characteristics were investigated.

2. Experiments

MTJ films were deposited on a silicon substrate at room temperature in an UHV sputtering apparatus. The structure of the MTJ films was underlayer/Ru/IrMn/CoFe/Ru/CoFeB/MgO/CoFeB/Ta/Ru. The MgO layer was sputtered with pure Ar, pure Ne or Ar-Ne mixed gas from a sintered MgO target and the other layers were sputtered with pure Ar gas. The deposited films were post-annealed with applying a DC magnetic field for ordering a uni-axial magnetic anisotropy in the pinned CoFe layer. MR characteristics were evaluated by a current-in-plane-tunneling (CIPT) measurement at room temperature[4].

3. Results and Discussion

At first, an MgO layer in MTJ films was sputtered with pure Ar or Ne gas at various pressure. Fig. 1 shows dependences of RA and MR-ratio on the pressure of Ar or Ne gas (p_{Ar} or p_{Ne}). The target value of RA was set at $1.8 \Omega\mu\text{m}^2$ by controlling the MgO layer thickness. The deposition rate of the MgO layer sputtered with Ne gas was three times larger than that with Ar gas at a same sputtering power. MR-ratio was the maximum at 0.06 Pa for the MTJ films sputtered with either Ar or Ne gas and that of the films sputtered with Ne gas was very lower than that with Ar gas. An excess incorporation of neon atoms into the MgO layer seemed to cause the lower MR-ratio.

At second, gas mixture of Ar and Ne gases was applied for sputtering of an MgO layer. The total pressure was fixed at 0.06 Pa and the partial Ne gas pressure, p_{Ne} , was varied from 0 to 0.06 Pa. The deposition rate of the MgO layer was increasing with an increase of p_{Ne} at same sputtering power. Fig. 2 shows dependences of RA on the thickness of MgO layer (t_{MgO}) sputtered at various p_{Ne} . RA at each t_{MgO} were mostly maximum at p_{Ne} of 0.01 Pa compared with those at p_{Ne} below 0.005 Pa, and those at p_{Ne} above 0.02 Pa. It suggests that the density of oxygen vacancies in the MgO layer was the minimum at p_{Ne} of 0.01 Pa and it increased at low p_{Ne} below 0.01 Pa. The decrease of RA at p_{Ne} above 0.02 Pa seemed due to the increase of the incorporation of neon atoms into the MgO layer. Fig. 3 shows dependences of RA and MR-ratio on p_{Ne} with the target value of RA of $1.0 \Omega\mu\text{m}^2$. MR-ratio of the films was higher at p_{Ne} of 0.01 to 0.03 Pa, compared with the films sputtered with pure Ar or Ne gas. These results suggest that the imperfection in the MgO crystallites

due to the lack of oxygen or the incorporation of neon atoms are minimized at an optimum p_{Ne} of 0.01 Pa.

4. Conclusion

An improved MR-ratio of 90% is achieved at very low RA of $1.0 \Omega\mu\text{m}^2$ by applying Ar-Ne mixed gas as a sputtering gas of the MgO barrier layer. These films seem to be suitable for applying for a read head of a hard-disk drive with the areal density above 600 Gbits/in².

Atomic layer deposition Al₂O₃ films for permanent magnet isolation in TMR read heads.

M. Kautzky, A. Demtchouk, Y. Chen, S. McKinlay, K. Brown, J. Xue
Advanced Transducer Development, Seagate Technology, Bloomington, MN

Conventional tunneling magnetoresistive (TMR) readers use bottom-type reader stacks stabilized with abutted permanent magnets isolated by thin dielectric layers. As recording areal densities push above 300 Gb/in², physical reader widths of sub-100nm are required, driving demand for several design features: steep junctions to enable accurate read width targeting; controlled magnet vertical placement; and precise free layer-magnet separation. This places a large set of materials and process requirements on the dielectric isolation layer. Electrically, it must provide low leakage, high breakdown, and low stack edge damage. Geometrically, it must have high conformality on etched junctions, high within-wafer uniformity, and compatibility with self-aligned patterning schemes. Chemically, properties such as repeatable nucleation of high-coercivity, high M_rt permanent magnets, and long-term chemical and thermal stability are needed. In this paper we report the use of Al₂O₃ dielectric isolation layers fabricated using atomic layer deposition (ALD) to satisfy these requirements.

Thermal ALD processing consisting of alternate pulse/purge cycles of trimethylaluminum (TMA) and H₂O was used for Al₂O₃ film deposition. Use of a self-aligned patterning scheme having resist on the wafer during deposition has led to development of a low-temperature deposition process. Resulting films show excellent thickness uniformity (<2% within-wafer), leakage current density ($J_{\text{leak}} < 1 \times 10^{-8} \text{ A/cm}^2$) and breakdown properties ($F_{\text{bd}} > 9 \text{ MV/cm}$) (Fig 1.) TEMs of sub-100nm TMR readers fabricated using these processes show >95% conformality on junction sidewalls, indicating nonselective growth of ALD Al₂O₃ on the various stack and bottom shield surfaces (Fig 2). Permanent magnets with well-controlled junction grain structure and coercivities in excess of 2500 Oe have been deposited with existing processes. FEM modeling shows the effective stabilizing field from the magnets at the junction edge scales inversely with ALD layer thickness, in agreement with device-level free layer stability metrics showing improvements at lower ALD thicknesses (Fig 3). As the conformal ALD layer thickness is easily tuned, this technology provides flexibility in trading off reader amplitude and stability that should support scaling of the abutted TMR design out to 500 Gb/in² and beyond.

Analysis of the current-confined-paths in the film plane for CPP-GMR films.

H. Fukuzawa, M. Hara, H. Yuasa, Y. Fuji
Corporate R&D Center, Toshiba Corporation, Kawasaki, Japan

Introduction

Current-perpendicular-to-plane giant magnetoresistance (CPP-GMR) is attracting great attention for future high-density recording, because the lower resistance-area product(RA) is advantageous for high data transfer rate. We have previously proposed current-confined-path (CCP) structures, using a nano-oxide layer (NOL) with small metal paths, in order to increase the MR ratio while maintaining small RA [1], and confirmed the MR enhancement [2]. However, CCP-NOL is a source of concern in terms of the variation of RA at an extremely small device size for higher density recording, because the CCPs are distributed in the film plane. Therefore, it is important to understand the status of distribuon of the CCPs in the film plane. Although there have been a few reports on the CCP nanostructure analysis by high-resolution transmission electron microscope (HRTEM) [3] or by three-dimensional atom probe (3DAP) [4, 5], the main factor to determine the variation of RA for future higher density recording is still unknown. In order to clarify this point, we have analyzed the distribution of the CCPs in the film plane by 3DAP.

Experiment and Result

The film structure of the CPP-GMR films with a CCP-NOL was substrate/Ta 5/Ru 2/PtMn 15 or IrMn 7/CoFe 3.4/Ru 0.9/(FeCo 1/Cu 0.25)*2/FeCo 1/CCP-NOL spacer 1.5/CoFe 1/NiFe 30 (unit: nm), where CCP-NOL of AlCu-NOL was formed by ion-assisted oxidation (IAO)[1]. The films were deposited onto high conductivity Sn-doped Si substrates necessary for obtaining the pulsed voltage required for field evaporation in the 3DAP. Figure 1 shows isoconcentration surface image at a level of 30 at. % Cu of the CCP-NOL from the top view. The CCP structure made by metallic Cu in the Al₂O₃ matrix is clearly detected in the 3DAP image; only Cu is shown in this image. The distances between Cu paths are about 10nm, coinciding with the grain size of underlayers of the CCP-NOL confirmed by HRTEM. In fact, the HRTEM result showed that the CCPs were not formed randomly on the grain of the underlayers, but in the center of the grain. It indicates that the decrease of the grain size of the underlayers can result in the increase of the number of the CCPs per unit area in the film plane, which improves the variation of RA even for a higher density recording head with smaller device size.

Figure 2 shows the the areal density of the CCP in the film plane extracted from the isoconcentration surface image by 3DAP as a function of RA, where RA was controlled by changing the formation process of the CCP-NOL. It should be noted that it is very difficult to derive the areal density of the CCP in the film plane because very thin CCP-NOL is formed in the middle of multilayer stack and it cannot be analyzed by conventional analysis methods such as HRTEM. As can be seen in the figure, the data shows the areal density of the CCP has very clear dependence on RA, and it increases with decreasing RA. Although this is intended to control RA, it is firstly confirmed by experimental data. It means that the RA was determined by the change of the areal density of the CCPs. A larger number of areal density of the CCP is naturally preferred for better distribution at a smaller device size. Therefore, the use of lower RA is very useful for a stable RA for higher-density recording, where the realization of lower RA for CPP-GMR films with a CCP-NOL is design matters.

In summary, nanostructure analysis showed that the grain size of the CCP-NOL underlayers and the design of an RA determin the distribution of the CCPs. The decrease of the grain size of the CCP-

NOL underlayers and the use of small RA can extend the availability of the CCP-NOL for a high-density recording head.

Development of CPP-GMR Heads for High-Density Magnetic Recording.

J. R. Childress, M. J. Carey, S. Maat, N. Smith, X. Liu, H. Balamane, S. Chandrashekariah, T. D. Boone, R. E. Fontana, P. Vanderheijden, Y. Hong, K. Carey, J. Tabib, J. Li, B. York, T. Lin, J. A. Katine, W. Jayasekara, N. Robertson, M. Alex, J. Moore, C. Tsang
Hitachi Global Storage Technologies, San Jose, CA

As commercial recording densities increase above 100 Gb/in², current-perpendicular-to-the plane (CPP) sensors have replaced conventional current-in-plane GMR sensors due to advantages in term of fabrication, scaling, and sensor performance.[1] At today's lateral dimensions of ~100nm, tunneling magnetoresistance (TMR) CPP sensors are ideal due to their large MR(~20-100%). The resistance-area (RA) product of practical TMR sensors has been demonstrated as low as ~1 Ω - μ m² [2], so that reasonable impedances (a few hundred Ω) are achievable for sensors down to ~50 nm. Consequently, CPP-TMR sensors are the main sensor candidates for areal densities to 300 Gb/in² and beyond.[3,4]

All-metal CPP-GMR sensors are an attractive alternative as the sensor dimensions are reduced below 50nm. With RA products in the range 0.03-0.10 Ω - μ m², CPP-GMR sensors deliver low impedance at the smallest conceivable dimensions, and therefore lower noise and higher bandwidth performance.[5] Remaining challenges are low signal levels and current-induced noise and instability due to the spin-torque effect. Dual-spin-valve (dual-SV) sensors provide a significant increase in $\Delta R/R$ and cancellation of spin-torque due to the symmetric arrangement of the dual fixed reference layers. Their ultimate performance is however limited by a larger shield-to-shield spacing and a complex stack structure. On the other hand, alternative ferromagnetic alloys such as CoFeAl[6] and Heusler alloys[7] can result in sizeable $\Delta R/R$ even with less complex single-SV's. In this context we discuss progress achieved in developing CPP-GMR sensor for ultra-narrow magnetic recording head sensors with dimensions < 50nm.

Single- and dual-SV multilayers were deposited by sputtering. Antiparallel (AP)-coupled pinned layer structures consisted of a 7 nm-thick IrMn antiferromagnet, CoFe-based pinned layer (2-3 nm) and various reference magnetic layers (3-4 nm) based on either CoFe or magnetic Heusler alloys with higher electron spin scattering. Generally, the free layer had a magnetic thickness equivalent to 4-6 nm of Ni₈₀Fe₂₀ and was separated from the pinned layer structure by a Cu spacer layer. Compared to standard GMR and TMR sensors, the $\Delta R/R$ of CPP-GMR sensors benefits from thicker magnetic layers due to spin-diffusion length effects, but total thickness is limited by the desired shield-to-shield spacing (which determines the maximum linear density). Optimized film-level $\Delta R/R$ of ~ 10% have been obtained, even for relatively thin sensors with shield-to-shield spacings < 45nm. Read head sensors were defined by a combination of optical lithography and e-beam lithography to achieve physical widths between 30nm and 60nm, as shown in Fig.1. The final sensor height after mechanical lapping at the air-bearing surface was typically around 50 nm, resulting in sensor resistances of 30-60 Ω .

During magnetic recording readback tests, transfer curves of suspended read heads had a total $\Delta R/R$ similar to the wafer-level film values. Well-behaved microtrack profiles (Fig.2) were obtained for all sensor sizes. For the best performing heads, substantial operating bias voltages up to 50-100mV could be applied (corresponding to current densities ~ 1.5×10^8 A/cm²) before the onset of spin-torque induced instabilities, yielding signal amplitudes over 1mV (peak-to-peak) as well as head & electronics SNR around 30db. We demonstrate performance suitable for 400 Gb/in² recording. The onset of spin-torque instabilities result in a sudden and dramatic increase in read error rate, fully reversible upon reducing the bias voltage below the threshold. We also observe the

expected dependence of spin-torque on the sensor excitation level as the head-media spacing is reduced. Thus the reduction of spin-torque excitations, along with further increases in $\Delta R/R$, are key to the application of CPP-GMR to recording heads at ever-increasing densities.

Current Confined Path (CCP) Giant Magneto Resistive (GMR) Sensors.

X. Peng, P. Kolbo, K. Nikolaev, S. Chen, Z. Wang, T. Boonstra, P. Anderson, S. Kalderon, P. Czoschke, A. Morrone, D. Dimtrov, S. Xue, Y. Chen
RHO, Seagate Technology, Bloomington, MN

Current-perpendicular-to-the plane (CPP) giant magneto resistive (GMR) sensors with current-confined-path (CCP) layer inserted within the Cu spacer has been manufactured using ultrahigh vacuum PVD sputtering, photolithography, and ion milling processes. Compared with pure metallic CPP system, CCP insertion layer enables substantial increase of the sensor resistance and equivalent or better GMR ratio, and thus, a significant improvement of the Delta (RA). Such CPP-GMR sensors/heads with CCP layer have been tested under various biasing currents and it was found that the resistance of the sensors increases with increasing of biasing current and voltage, following typical metallic ohmic behavior. Also, CCP insertion enables higher bias voltage compared with the pure metallic sensors (without CCP insertion layer) and thus higher output voltage. This could be largely due to the vortex status cancels each other around the current confined paths (with $i_s < 6$ nm) and enables better magnetic stability. Finally, the CPP-GMR heads with CCP layer were tested under high-density recording conditions using perpendicular magnetic recording heads media. The Delta(RA) product of ~ 30 m $\Omega\mu\text{m}^2$ has been achieved for these CCP devices. Spin stand testing demonstrated that these CCP heads recovered data with a BER of -4.3 at 1420 kbp, indicating the potential capability for an areal density of > 500 Gb/in 2 . In the future, more focus will be on controlling of conducting channel size and distribution for even smaller sensors.

GMR as a function of RA for CCP sensors

Bit error rate (BER) vs. linear density rolling off for CCP heads

Current Density Limitation by Spin Transfer Torque for CPP-GMR Heads.

K. Yamada, M. Takagishi, M. Takashita, H. Iwasaki
Corporate R&D Center, Toshiba Corporation, Kawasaki, Japan

Introduction

It is well known that read heads using CPP-GMR with low RA and high dR/R are required for future tera-bits high-density recording [1]. However, spin transfer torque (STT) is one of important issues for low RA heads [2][3]. It is excess STT by high current density needed for high output that induces magnetic instability in the free layer [3][4]. Some papers suggest that non-uniform precession mode by magnon is suppressed on small element and that relaxation time is longer [5]. This would reduce critical current density limited by STT. In this paper, we study influence of element size on critical current density (J_c) of CPP-GMR with Current-Confining-Path (CCP) nano-oxide-layer spacer (NOL).

Experiment and Calculation model

We fabricated test chips with 66nm by 100nm in size, non-shield and longitudinal hard magnets. CCP-CPP-GMR films with dR/R \approx 6% and RA \approx 0.3 $\Omega\mu\text{m}^2$ were used [6]. The Onset of STT, critical current density J_c , was defined by measuring the one-side-field transfer curve saturation, resulting in 10% dR degradation, in the same way as we have reported for all-metal CPP-GMR [4]. We also confirmed 1/f-like noise above J_c . Magnetization is simulated by micromagnetic model using modified Landau-Lifshitz-Gilbert equation with STT and thermal fluctuation effect with a damping parameter α of 0.02 [3]. Each magnetic layer is divided into 16x16 cells and no division in thickness. For example, cell size is 6nm by 6nm for 90nm square element. Longitudinal bias fields is applied to fit experiment. STT is transferred on boundary of cells in magnetic layers which are attached to metal path in spacer. Thermal fluctuation is considered by adding random field into the effective field. We used random distribution of 22 metal paths with a density of 2.8% in NOL.

Result and discussion

First, we estimated the spin polarity P_0 of CCP-CPP-GMR from measured transfer curves. Electron flows into the free layer on positive current. Fig. 1 shows experiment and calculation of dR vs current density. The measurement is well explained when P_0 is assumed to be 0.57 and 0.3 for positive and negative current. These P_0 values are reasonable to other report [2]. It is found that CCP-CPP-GMR shows almost the same J_c as that of metal-based CPP-GMR [4].

Second, we made calculation for critical current density vs element size. Exchange bias from anti-ferromagnet is changed inverse proportionally to element size to keep a stable pinned layer. The same map of metal path is used by shrinking metal paths for smaller element. Aspect ratio of element is 1. Figure 2 shows J_c vs element size. J_c decreases linearly to size below 60nm, while it is the same above 60nm. This result requires higher MR than what we have reported [1]. Achieving higher J_c against STT, as well as developing higher MR, is needed especially for metal-based CPP-GMR with lower RA. Also J_c on T=4K of 35nm size is calculated. J_c is the same as that on 300K, and thermal fluctuation is not serious. To understand this dependency, power spectrum density (PSD) of GMR output is calculated for 90nm and 35nm element as shown on Figure 3. PSD of 35nm has sharper peaks, which indicates that effective damping is smaller than that of 90nm, and such a smaller damping corresponds to smaller J_c . Magnon scattering may play a role for this dependency [5].

Suppression of spin-torque in current perpendicular to the plane spin-valves by addition of Dy caps.

S. Maat, M. J. Carey, N. Smith, J. R. Childress
Hitachi Global Storage Technologies, San Jose, CA

The magneto-transport and spin-torque of current-perpendicular to the plane giant magneto-resistive spin valves with and without Dy caps have been analyzed. Spin-valve giant-magnetoresistive sensors with current perpendicular to the plane (CPP-GMR) are of interest for future high-density magnetic recording applications due to their low resistance which is suitable for narrow trackwidth dimensions ($<50\text{nm}$). In the CPP geometry, the spin-torque effect¹⁻⁴ and the use of spin-polarized current to switch the magnetization of a magnetic layer is useful to realize novel devices such as spin-torque memory. However, for sensor applications, the spin-torque effect is a source of noise and undesirable excitations which limit the maximum output voltage and degrade the signal-to-noise ratio. Consequently it is desirable to find methods to cancel or damp spin-torque excitations in order to improve sensor performance.

Recently it has been reported how alloying of transition metal free layer with rare-earth elements increases the magnetic damping and reduces its susceptibility to spin-torque.⁵ However alloying typically dilutes the magnetic moment. Here we show that the addition of a Dy cap on top of the free layer can also enhance the spin-torque critical current density threshold. The spin-valves under investigation were standard antiparallel-pinned spin-valves with structure $\text{IrMn}(70\text{\AA})/\text{CoFe}(25\text{\AA})/\text{Ru}(7\text{\AA})/\text{CoFe}(25\text{\AA})/\text{Cu}(40\text{\AA})/\text{CoFe}(7\text{\AA})/\text{NiFe}(25\text{\AA})/\text{Dy}(t)/\text{Ru}$. Films were patterned by e-beam lithography and ion milling to produce CPP test devices with diameters down to 50nm . The Dy cap addition ($10\text{-}15\text{\AA}$ thick) does not degrade the magnetic properties of the sensor free layer, although the magneto-resistance ratio is slightly reduced due to the additional series resistance from the Dy layer itself. Figure 1 (a) and (b) show the resistance vs field loops for a 50 nm circular devices without and with a 15 \AA Dy cap, respectively. While spin-torque induced instability was observed at $4 \times 10^7\text{ A/cm}^2$ in spin-valves without Dy, this instability was successfully suppressed by addition of a 15 \AA Dy cap. Figure 2 shows the roll-off of the ΔRA upon applying a bias voltage. Positive polarity refers to current flowing from the free to the reference layer, negative current refers to current flowing from the reference to the free layer. The critical current density at which spin-torque is observed is increased at least twofold.

Introduction

CPP-GMR sensor is expected as a candidate for future generation read head because of its good scalability to small sensor size [1]. CPP-GMR sensor consisting of metallic materials such as CoFe, NiFe and Cu shows low resistance than MTJ's with TMR barrier, so this character will bring extendibility to super narrow track structures while keeping its high frequency response. However, its output voltage is still too small for application to hard disk head devices. The efficient injection of spin currents into spacer layer is needed for higher MR ratio. One candidate of high spin polarization materials is Heusler alloy and the recent progress of Co-based Heusler alloy has made it possible to obtain higher MR ratio than that of typical transition metals and alloys [2]. The objective of the present paper is to explore the possibility of CoMnSi (CMS) for enhancement of CPP-GMR ratio. Basic film level study was carried out and test junctions were made to investigate CPP-GMR ratio. We found that CMS was more effective to enhance CPP-GMR ratio than usual CoFe and NiFe alloys.

Experiment

CMS films were grown by magnetron sputtering on SiO₂ substrate to evaluate its crystallization. After deposition, the CMS films were annealed up to 773K in vacuum. The annealing effect on the structural and magnetic properties were also investigated. The structure of CMS films was identified by x-ray diffraction (XRD). In order to investigate the effect of CMS on MR ratio, test junctions with an area of 0.2μm-φ pillar were patterned for magneto-transport measurements in the current-perpendicular-to-plane (CPP) geometry by standard optical lithography. Spin-valve films with Cu spacer-layer which Pinned-layer and/or Free-layer were consisted of CMS alloy were made on the bottom electrode. Four-point probe R, DR/R measurements were taken by applying a constant current. The measurements were taken at room temperature using a 5mA sense current and a field range of 0.1[T].

Structural characterization

The composition of deposited CMS film was measured as Co:Mn:Si = 48:21:31 from X-ray fluorescence analysis. Figure.1 shows a θ -2 θ XRD profile for a 70nm thick CMS film grown directly on a SiO₂ substrate. The post annealing process was made for crystallization of CMS at 673K and 773K. Despite the absence of any seed layer, clear diffraction peaks were identified in the diffraction pattern. One can distinguish in the XRD pattern from (200) B2 ordered peak for 673K and 773K annealed sample. The sample annealed at 773K shows magnetization of 1.1[T] at room temperature while the samples of as-deposited and annealed at 673K did not show any magnetization.

Evaluation of CPP GMR ratio

Figure.2 shows CPP GMR ratio among these three types of CPP-GMR films.

Type-A: Both Pinned and Free-layer consists of CoFe alloys.

Type-B: Pinned-layer (CMS and CoFe alloy), Free-layer (CoFe and NiFe alloy).

Type-C: Both Pinned and Free-layer consists of CMS and CoFe alloys.

We have also checked the effect of composition of CMS on CPP GMR ratio for Type-C. Two samples which have different compositions were prepared as CMS-I (Co:Mn:Si = 48:21:31) and CMS-II (Co:Mn:Si = 46:25:29). As shown in figure.2 Type-C (CMS-I) shows relatively high CPP GMR ratio about 9.0% while the value of Type-A (CMS-I) was 3.6%. It suggests that Type-C (CMS-I) shows 2.5 times larger CPP GMR ratio than the value of Type-A which is same structure as tradi-

tional CPP-GMR film. Here we should notice that the MR ratio of Type-C (CMS-II) shows only 7.2%. This smaller MR ratio is maybe due to the Co-poor or Si-rich composition of CMS-II.

Next the difference of free-layer between Type-B (CMS-I) and Type-C (CMS-I) was compared. The CPP GMR ratio of Type-B (CMS-I) shows half of Type-C (CMS-I). This suggests that Free-layer with CMS has great advantage of enhancement of CPP GMR ratio. However, there is still concern of CMS used in Free-layer from the point of magnetostriction. It was found that the magnetostriction of CMS is three to five times larger than that of CoFe alloys, and this will prevent CMS from practical use for sensor applications. In order to overcome this issue, we propose new Heusler-base material, which has almost the same magnetostriction as CoFe alloys while keeping its high MR ratio.

Mesoscopic Extraordinary Magnetoresistance and the Effects of Impact Ionization and Velocity Saturation.

T. D. Boone, L. Folks, J. A. Katine, E. E. Marinero, N. Smith, B. A. Gurney
San Jose Research Center, Hitachi Global Storage Technologies, San Jose, CA

Magnetic field sensors utilizing the Extraordinary Magnetoresistance effect (EMR) have been proposed for implementation in future magnetic recording applications [1, 2]. These devices are hybrid distributed resistors comprised of a high mobility semiconductor in parallel and in contact with a low resistance metallic shunt. EMR devices are attractive possible future recording sensors because they contain no ferromagnetic materials and therefore have no magnetic noise, an increasingly significant source of noise in devices that use a ferromagnetic sense layer as they are made smaller. Here we present characterization results from EMR devices with dimensions approaching that needed for magnetic recording head applications in the I-V-I-V configuration. This report includes results from a new device geometry that removes the semiconductor tabs below the mesa that form contacts to the EMR structure. Minimum feature sizes have been reduced to 50 nm and the magnetically sensitive surface area is designed to be 150 nm wide. The 2-DEGs used for these devices consisted of AlSb(2 nm)/InAs(12.5 nm)/AlSb(2 nm) quantum wells with room temperature mobility above $10,000 \text{ cm}^2/\text{Vs}$. To achieve the signal levels required for magnetic recording, EMR devices must operate at relatively large current densities beyond $1 \times 10^7 \text{ A/cm}^2$. Previously, Brar et al. reported that high electron mobility transistors (HEMTs) with 10 micron channel widths made from type II heterostructures of AlSb/InAs/AlSb suffered from poor performance due to impact ionization within the channel at modest drain source voltages [3]. Therefore, we have investigated applied bias effects on the sensitivity of EMR devices and Hall crosses.

In previous investigations, mesoscopic EMR devices were created with abutted junctions formed by high angle deposition of metal directly on exposed edges of quantum wells. Those devices were characterized by sensing the voltage in an I-V-V-I four wire resistance measurement, and required unconventional fabrication techniques, such as edge cleaving and metal depositions through a shadow mask [1, 2]. In contrast, here we have demonstrated EMR devices with minimum feature sizes less than 100 nm using standard planar processing techniques. Rather than the I-V-V-I configuration, these devices were characterized in an I-V-I-V non-local resistance measurement [4]. It has been predicted numerically that the I-V-I-V configuration produces superior sensitivity to the I-V-V-I configuration [5,6].

Our devices have been characterized at room temperature in magnetic fields of $\pm 5 \text{ kOe}$ and applied currents up to 1 mA. We find that the sensitivity is linear with both applied magnetic field and applied bias up to current densities beyond $1 \times 10^7 \text{ A/cm}^2$. Sensitivities of $6 \text{ } \mu\text{V/Oe}$ were observed, which are comparable to GMR sensors of equivalent size excited by typical media fields of 200 Oe. To further understand transport in our EMR devices we fabricated Hall crosses with similar lateral dimensions, ranging from 100 nm to 1 μm . Bias voltages up to 1V were applied resulting in current densities beyond $1 \times 10^7 \text{ A/cm}^2$. Average electron drift velocity and carrier concentrations were determined directly from the geometry, current and Hall voltage measurements. Consistent with impact ionization, carrier concentration within the channel increases monotonically as the applied voltage exceeds the band gap of 0.38 V. Additionally, the carrier velocity is observed to saturate between $3\text{--}7 \times 10^7 \text{ cm/sec}$, approaching the limit derived theoretically.[7]. Analysis of the scaling of transport with size, effects of $1/f$ noise and the implications for further miniaturization of Hall sensors and EMR devices will be discussed.

The magnetization \mathbf{M} may be switched to the opposite direction with a circularly polarized optical laser pulse [1]. We show that \mathbf{M} can also be switched even multiple times with one half cycle pulse of terahertz (THZ) radiation. As THZ lasers become generally available [2], switching with THZ radiation is of general interest to observe and induce ultrafast changes of \mathbf{M} . As a source of THZ radiation we use highly relativistic electron bunches containing 1.6×10^{10} electrons compressed to a temporal length of 0.140 ps ($1 \text{ ps} = 10^{-12} \text{ s}$). The electromagnetic fields of the bunch are best described by a cloud of virtual photons [3] flying in vacuo with the electrons at the speed of light. Fig. 1 shows an example of a virtual photon spectrum, consisting of coherent THZ-photons and incoherent x-ray photons of low intensity. When the bunch enters a solid, it continues to fly with the speed of light while the virtual photons are slowed down and thus separate from the bunch leading to bremsstrahlung emitted in the forward direction and to coherent “transition radiation” emitted into the backward direction. However, the THZ photons penetrate into the solid up to the skin depth $\geq 50 \text{ nm}$. The sample is 10 nm thick and thus exposed to the THZ-fields. According to Fig. 2 the coherent fields are gigantic with the compressed electron bunch. As the incoherent fields can be neglected with a thin sample the electron bunch interacts with the solid solely via the coherent THZ radiation. The switching pattern generated by one single compressed electron bunch is shown in Fig. 3. The figure 8 shape of the pattern resembles the patterns seen before with uncompressed electron bunches of several ps duration [4]. Yet there are striking new features like the deviation from the circular shaped switching boundaries expected if the B-field acted alone. This distortion of the switching boundaries is due to a new type of magnetic anisotropy induced by the electric field \mathbf{E} in the valence states. For symmetry reasons, any magnetic anisotropy induced by \mathbf{E} must be $\propto E^2$, and therefore appears with compressed bunches only. The absence of beam damage with a bunch intensity of $4 \times 10^{19} \text{ W/cm}^2$, evident in Fig. 3 is a phantastic feat. It means that the metallic sample behaves like a ferromagnetic dielectric during the field pulse.

Fig.1: The virtual photon spectrum carried by a bunch of highly relativistic electrons. The bunch has a Gaussian shape in all 3 coordinates, the variance of the temporal bunch duration τ corresponds to a bunch length of $c\tau = 0.3 \text{ mm}$ in the laboratory frame.

Fig.3 Magnetic pattern written by one bunch of electrons into a uniaxial CoFe-sample of 10 nm thickness. The magnetic pattern was recorded with spin-SEM. In the light grey regions, \mathbf{M} points into the preset direction, while in the dark regions, \mathbf{M} has switched into the opposite direction. The fitted circles are lines of constant torque assuming that only the B-field of the terahertz pulse is active. The deficit of torque in the upper part of the pattern reveals the opposing torque generated by the presence of the extreme electric field.

Fig. 2: Basic data of the present experiment. The electron bunch of energy 28 GeV per electron traverses a thin uniaxial ferromagnetic metal perpendicular to the surface, the magnetization \mathbf{M} is uniform and initially set along the horizontal as shown. Bunch diameter σ and temporal length τ of the bunch are also given. The maximum value of the electric field \mathbf{E} and the magnetic field \mathbf{B} generated by the half cycle pulse of the coherent virtual photons is given as a function of distance from the bunch center.

Terahertz Emission Spectroscopy as a Probe of Laser-Induced Ultrafast Demagnetization Dynamics.

E. Beaurepaire¹, J. Arabski¹, M. Vomir¹, J. Bigot¹, S. M. Harrel², J. M. Schleicher², C. A. Schmuttenmaer²

1. IPCMS-GEMME, CNRS, Strasbourg, France; 2. Dept. of Chemistry, Yale University, New Haven, CT

Laser-induced ultrafast magnetization dynamics have been the subject of a large amount of experimental studies since originally reported [1]. A recent time-resolved X-ray magnetic circular dichroism experiment confirmed the previous observation by magneto-optical measurements of a magnetization drop within a few hundreds of femtoseconds following the absorption of a femtosecond optical pulse, thus directly quantifying this effect [2]. The microscopic mechanisms of the ultrafast magnetization are still unclear and the dissipation of angular momentum is still debated. We have recently shown that the interaction of a thin ferromagnetic nickel film with femtosecond optical pulses leads to the emission of a short terahertz electromagnetic pulse that can be associated to the demagnetization [3]. However similar experiments by other workers lead to a different interpretation invoking surface magneto-optical non-linear response[4]. The aim of the present work is to present a detailed study of this phenomenon for Ni and Fe films varying the thickness and experimental geometry. From these results we show how surface and volume contributions to the demagnetization can be distinguished.

The experimental setup has been described elsewhere [3]. In brief, a regeneratively amplified Ti:Sapphire laser produces ~ 100 fs laser pulses centered at a wavelength of 800 nm with a repetition rate of 1 kHz. The beam is split into two parts, pump and readout, where the pump photoexcites the sample and the readout beam detects the emitted THz radiation in the far-field via free space electro-optic sampling in a 0.5 mm thick ZnTe(110) crystal. The detection system used is optimized to detect horizontally polarized THz radiation.

The ferromagnetic samples used are: (i) Al₂O₃ / Ni (x Å) thin films with a thickness x $50 \text{ Å} < x < 500 \text{ Å}$ deposited on glass substrates, obtained by sputter deposition on Ar etched glass substrates. In-plane uniaxial anisotropy in Ni films was achieved by deposition with an oblique incidence of $\sim 45^\circ$. (ii) MgO (200 Å) / Fe (x Å) single crystal films deposited on MgO(001) under UHV in a MBE chamber. THz measurements are then performed after saturating the samples along the easy axis, providing 90% or higher remanence. The magnetization of the sample is modified via heating of the spins following the absorption of a 0.2 mJ pulse with spot size of ~ 5 mm (leading to ~ 1 mJ/cm² fluence). The sample is placed between 5 and 15 mm away from the ZnTe detector, and thus the emission cannot be considered as emanating from a point dipole. Therefore, the THz waveforms $E(t)$ might be distorted, but this can be accounted for when necessary.

Typical results representing the electric field emitted upon ultrafast demagnetization of Ni thin films are displayed in Figures 1-2. Four configurations have been used, depending on whether visible excitation and THz detection are on the same side (reflection geometry) or on opposite sides of the sample (transmission geometry), and whether the excitation comes from the glass side or the film side. The inset of Figure 1 displays the coordinate system used. As the sample is rotated around the z-axis, the amplitude of the y-polarized emission varies as the cosine of the angle between the magnetization axis and the x-axis. Thus, one concludes that the signals discussed here have a purely magnetic origin. There are two salient features in the waveforms of the electric field in the thicker Ni films ($>200 \text{ Å}$). First, the waveform is nearly insensitive to whether the glass side or metal side of the sample has been excited, whereas the signal changes polarity when the sample is excit-

ed in transmission vs. reflection. We relate this feature to an interface non-linear effect, since the dissymmetry of the stack induces a change of the sign of the emitted electric field, assuming that Ni/glass and Ni/Al₂O₃ interfaces are characterized by different non-linear susceptibilities. A different behavior is found for thick Ni films and Fe films (disregarding thickness), where the shape of the emitted waveform is relatively independent of the excitation side (figures 1, 3). We interpret this effect as a signature of the demagnetization. We shall discuss the physical mechanism responsible of the waveform (magnetic dipole antenna [3] and current generation due to Lentz's law), and its connection with the time dependent demagnetization and re-magnetization of the sample.

Since it was shown experimentally [1] that the magnetic state of a material can be changed on a picosecond timescale using pulsed lasers there has been an increasing experimental and theoretical interest in the phenomenon. Theoretically there is a need to go beyond the formalism of micromagnetics, especially since complete demagnetization is possible following a laser pulse and it is known that the standard formulation of micromagnetics is not capable of dealing with phase transitions. From a technological point of view an understanding of fast laser processes is made more pressing by the fact that ultra-high density information storage may require Heat Assisted Magnetic Recording (HAMR), which involves heating up to or beyond the Curie temperature. Micromagnetics is a continuum formalism using an approximation to the exchange which limits it to long wavelength magnetization fluctuations and consequently to temperatures well below the Curie temperature. To surmount this problem, atomistic models are currently under development and have already given important insight, for example into the properties of FePt [2]; an important candidate for ultra-high density recording media. The basis of atomistic models will be outlined. Essentially this consists of the use of a classical spin model based on the Heisenberg interaction. Dynamic properties are calculated using the Langevin dynamic approach (essentially the LLG equation augmented by a random field term representing thermal fluctuations) to describe the time evolution of the ensemble of coupled spins at non-zero temperature. The model enables representation of the temperature dependent static and dynamic magnetic properties and complete magnetic excitation spectrum. This is important because it allows the magnetic phase transition to occur at a realistic Curie temperature. We have recently developed [3] an atomistic model of the response of a material to a sub-picosecond laser pulse. The model assumes that the laser power gives rise to an elevated conduction electron temperature which couples to the spin system. In agreement with experiment the atomistic model is shown to exhibit a rapid reduction of the magnetisation, on the picosecond timescale, to an extent dependent on the strength of the coupling between the spins and the conduction electrons. The recovery of the magnetisation is a more complex phenomenon, taking place on a timescale determined by the extent to which the system is demagnetised. In the case of complete demagnetisation, recovery takes place randomly at many nucleation sites leading to severe frustration effects resulting in timescales on the order of nanoseconds for complete magnetisation recovery. The model has been used to simulate magnetisation reversal during the HAMR process, and simulations of the magnetisation reversal process will be presented. It is shown that a non-precessional reversal mechanism termed ‘linear reversal’ in which the magnetisation vanishes and recovers in the field direction is important for the HAMR process. We also consider the phenomenon of ‘Opto-magnetism’ which has recently been demonstrated experimentally [4,5]. Here the magnetic state is shown to be affected by the use of circularly polarised light in the absence of an externally applied field. Indeed in [5] complete reversal of the magnetisation is demonstrated on a sub-picosecond timescale. It is shown that in order to achieve reversal on this timescale the reversal process must be linear, since precessional timescales are too long. We discuss a recent model [6] of the physical interaction channel between the laser and spin system which requires the presence of RE spins. Calculations of the timescale for linear reversal as a function of the applied field and temperature will be presented. We also discuss the implications of the assumption of white noise in the Langevin Dynamic approach, which might be expected to break down at very short

timescales. We present an approach introducing coloured noise in which the usual delta function correlations are replaced by correlated fluctuations with a characteristic correlation time. The effect of correlations on the ultrafast demagnetisation process will be presented. Finally we consider the options for extending the atomistic calculations using a macrospin model based on the Landau-Lifshitz-Bloch equation, which has been shown [7] to encapsulate much of the important physics of the atomistic model.

Femtosecond transfer of angular momentum in ferromagnets probed by X-ray spectroscopy.

H. A. Dürr
BESSY, Berlin, Germany

When energy is pumped into electronic excitations of a metal via absorbing a fs optical laser pulse it takes time to re-establish thermal equilibrium. This timescale is ultimately determined by energy transfer from the electronic system to the lattice. If for ferromagnetic metals laser excitation should also lead to an ultrafast quenching of the ferromagnetic order [1,2] angular momentum conservation dictates that an exchange of spin angular momentum with a reservoir such as the lattice has to occur [3-5]

There is considerable disagreement about the timescale for such spin-lattice relaxation. It was established early that spin-lattice relaxation should proceed on timescales 100 ps [1,3]. Such values are also obtained from the damping of magnetization precession [3]. There is growing evidence, although no direct observation, that on the fs timescale the magnetic moment is affected by laser heating [2,3,5,6]. Even on the fs timescale total energy and angular momentum are conserved. It is debated whether the reduction of the magnetic moment, which corresponds mainly to spin angular momentum, occurs via spin-orbit coupling during coherent laser excitation [8] with an angular momentum transfer from the spins to the electron orbits or via a fs spin-lattice relaxation mechanism [7]. The latter mechanism can be viewed as an Einstein-de-Haas effect occurring on an ultrafast time scale and is schematically depicted in Fig. 1 (top).

Here we present the first time-resolved x-ray magnetic circular dichroism measurements using femtosecond pulses from a synchrotron-based slicing source [9]. An ultrafast laser pulse excited a Nickel film, and a succeeding x-ray pulse from the BESSY femtoslicing facility probed the Ni L_3 -edge. By choosing either linear or circular x-ray polarization, the spectra represent snapshots of the magnetic state with an exposure time of about 100 fs [10,11]. Fig. 1 displays time resolved optical pump - x-ray probe measurements with the x-ray photon energy fixed at the Ni L_3 absorption maximum. At this photon energy and with an x-ray bandwidth of 3 eV the XMCD signal essentially corresponds to the integral over the L_3 absorption edge. It takes 120 ± 70 fs to quench the ferromagnetic order as determined from fitting the data to a three-temperature model of energy transfer between electron, spin and lattice reservoirs (line in Fig. 1) [9]. XMCD measures a linear combination of spin, S , and orbital, L , angular momentum components along the magnetization direction as $2S+3L$ [9]. The temporal evolution of $2S+3L$ in Fig. 1 represents the first direct demonstration that spin angular momentum, S , is quenched and is transferred to the lattice on a 120 fs timescale and not to the orbital angular momentum, L . This shows that electron orbits do not act as a reservoir for angular momentum and demonstrates the existence of a novel fs spin-lattice relaxation channel.

The demand for the ever-increasing speed of information storage and manipulation has triggered an intense search for ways to control the magnetization of a medium by means other than magnetic fields. The control of magnetism by light is one of the promising approaches to this problem, because such methods may access timescales of a picosecond (10⁻¹² sec) or less. In particular, it has been demonstrated recently that laser-excitation of a bulk antiferromagnet may result in sub-picosecond modification of magnetic anisotropy followed by 90-degree reorientation of antiferromagnetic spins within few picosecond [1].

Here we present experimental results on the laser control of spins in ferromagnet-antiferromagnet heterostructure Co/SmFeO₃. For our study we have used bulk SmFeO₃ (010) crystals that possess 90-degree in-plane spin reorientation, when heated from 445 K to 455 K. Co-layer (4 nm) has been deposited on the surface of the AFM and capped by 2 nm Pt-layer.

We have investigated laser-induced and heat-induced magnetic changes in the Co/SmFeO₃ heterostructure using a Photoemission Electron Microscope (PEEM) as well as employing X-ray Magnetic Circular (XMCD) and Linear Dichroism (XMLD). Strong temperature dependencies of the XMCD and XMLD signals at Co and Fe edges are observed and discussed. On figure 1 we observe a strong change with the temperature in the contrast of the Co XMCD at the L₃ edge, indicating a 90° in-plane rotation of the Co magnetization.

We also induced a change of the SmFeO antiferromagnetic orientation by the means of a laser by thermal activation. On figure 2.a is represented the Co XMCD image for a temperature of 425K and without laser. So we observed strong black and white domains. Figure 2.b shows the same image but with the laser hitting the sample. In the region where the laser heated the sample, we observed a change of both black and white domains which become gray. That means we changed the orientation of the Co magnetization by 90 degrees and then the AFM direction of the SFO.

As proposed in [1,2] the ultrafast demagnetization process is caused by an Elliot-Yafet type like spin flip scattering. In that case the lattice acts as an active sink to allow the conservation of the systems total angular momentum. This model was recently supported by an experimental analysis of a thin cobalt film on copper combining the complementary techniques of TR-MOKE with spin and time resolved two-photon photoemission (2PPE) [3]. There are other experiments that strongly favour an ultrafast electron lattice channel over an orbital to spin momentum transfer. Stamm *et al.* exploited the potential of an XMCD experiment with respect to its time resolved separation of spin S and orbital L momentum. Measurements on a thin nickel film showed that the process of demagnetization could only be explained to at maximum ten percent by a pure transfer of angular momentum within electronic system [4]. Therefore the main contribution should be carried by an electron lattice mediated spin flip.

In this contribution we report on the effect of the electronic band structure on spin dynamics. In a comparative study the 3d-ferromagnets Ni, Co and the Heusler alloy $\text{Co}_2\text{Cr}_{0.6}\text{Fe}_{0.4}\text{Al}$ (CCFA), both with strongly deviating bandstructures, were investigated by means of time resolved MOKE. In conjunction with the search for materials with high spin polarization, so called Heusler alloys form a class with intriguing physical properties. Heusler compounds possess a characteristic band structure exhibiting metallic behaviour for one spin direction and a band gap for the other. From the fs-magnetization point of view Heuslers serve therefore as a well suited test material in order to study the effects of a band gap on spin dynamics. A complete understanding of such processes would be extremely helpful for technical applications such as ultrafast magnetization-switching schemes for read-write processes.

In our study focus was put on the ultrafast magnetization dynamics following an optical excitation with a high intensive femtosecond laser pulse. A slightly pronounced difference in the first ultrafast demagnetization step is found for the CCFA. Additionally, the picosecond thermalization between the participating subsystems is drastically delayed in the case of the Heusler alloy. We ascribe this behavior to a blocked Elliot-Yafet like scattering due to the half metallicity of CCFA. To investigate the magnetic response we use the MOKE in a pump probe set up. The pump pulse at a central wavelength of 800 nm and the weaker frequency doubled probe pulse both with a FWHM of 50 fs were generated by a Ti:Sapphire amplifier system with 1 kHz repetition rate.

The incident ultrashort optical pulse couples with its electric field component effectively to the electronic system. As a consequence the electronic system is driven far away from its equilibrium; a description by the Fermi-Dirac distribution is no longer valid. The induced imbalance in the electronic subsystem is essential to trigger spin dynamics. The relaxation of the created hot electron gas is the driving force in this case, leading to the observed ultrafast demagnetization. Subsequently, electron lattice or electron impurity scattering events set in. They are, with a certain probability, accompanied by a spin flip; the flip probability is assumed to be independent of the spin state. When increasing the pump fluence the total number of spin flip events and the rate of demagnetization will alter since the number of excited spin up and spin down electrons is not equal. In Fig. 1 the time resolved magneto optical Kerr rotation is recorded from the CCFA sample for a series of different pump fluences. Similar fluence dependent measurements were performed for nickel and cobalt (not shown here). To analyse the demagnetization step the data were fitted assuming an

exponential decay of the following form: $\Delta M/M = A_0(\exp(-t/\tau_M) - 1) + 1$. From the fit the two parameters A_0 and τ_M were extracted. A_0 represents the maximal drop depth which increases with increasing pump fluence whereby τ_M denotes the decay time. The ratio A_0/τ_M is a measure of the number of flipped spins per time unit which is plotted against A_0 in Fig. 2. For the 3d-transition metals the number of flipped spins increases with the parameter A_0 which is attributed to the more established imbalance between majority and minority spins after excitation. In contrast, the CCFA exhibits a rather constant behaviour meaning that the number of flipped spins is independent on the laser density, a signature of the band gap. The experimental data (squares in Fig. 2) is compared to a theoretical calculation (solid lines) connecting the Brillouin-function with the $F(T/T_C)$ function from Ref. [1]. Solely the macroscopic Gilbert damping α was optimized to attain best coincidence between theoretical model and experimental data. The apparent discrepancy will be discussed in terms of the high perturbation scheme.

Dynamics of the coercivity in (ultrafast) pump-probe experiments.

D. Steil, T. Roth, M. Cinchetti, M. Aeschlimann

FB Physik, AG Aeschlimann, TU Kaiserslautern, Kaiserslautern, Germany

In the last decade the field of ultrafast magnetization dynamic studies have attracted huge attention. It addresses fundamental open questions as well as possible applications including ultrafast magnetization switching [1]. Under irradiation of fs laser pulses ferromagnetic films show an ultrafast decrease of the magnetization signal within hundreds of femtoseconds. Time resolved experiments utilising the magnetooptical Kerr effect (TR-MOKE) have shown that the magnitude of demagnetization is dependent on the incident pump-pulse energy [2]. Demagnetization can be interpreted as a nonadiabatic energy, momentum and angular transfer process. Due to the different temperature dependencies of several anisotropy contributions the incident pump pulse triggers an ultrafast change in the overall anisotropy followed by a sudden alteration of the magnetization direction [4]. As a consequence the magnetization vector \mathbf{M} performs an ultrafast reorientational motion. Knowledge about the behavior of the fs anisotropy is essential. Observing the evolution of the coercivity would surely help to clarify the phenomena of ultrafast demagnetization.

In this contribution we want to stress the fact that an optical pump-probe technique in the stroboscopic mode using many repeating cycles requires reversible processes and is, hence, in general not suitable to gain access to the time dependent behavior of the coercivity. Observed reductions of the coercivity with increasing pump power are due to laser induced static heating effect.

Hysteresis loops were recorded from an exipaxially grown 10 nm thick Co/Cu(001) thin film at the time delay of maximal demagnetization (approx. 500 fs). To judge the effect of different pump pulse powers on the width of the loops a plot of three different pump fluences is shown (Fig. 1a). The feature of interest is the decrease of coercivity with higher pump fluences. At a first glance one is surprised not to recognize any time dependent variation of the coercivity. There is no recovery of the coercivity to be found - even for time delays when the pump lags behind the probe.

By optically exciting a sample with an intense pump pulse a hierarchy of different heating phenomena take place: 1. Initial laser-heating. The incident laser pulse creates a hot electron system. Back relaxation is established by e-e scattering and interactions with the lattice (including E-Y spin flip processes). 2. After some picoseconds heat-diffusion becomes the dominant contribution. 3. Dependent on the thermal conductivity the substrate can act as a heat barrier and heat-accumulation occurs.

Let's now assume that there exists a time dependent coercivity $H_C = H_C(t)$. If we further assume that the change in H_C is caused by simple heating effects $H_C = H_C(t) = H_C(T)$, then the response should map the different temperature dependent steps.

The absence of any signature in the response of the coercivity (Fig. 1a) indicates that there is either no temperature dependence or technical restrictions inhibit such a measurement in a TR-MOKE experiment.

Fig. 1b shows the situation just before changing the orientation of magnetization of the sample in an external field. The first of N ($N \geq 100$) pump pulses for a fixed position on the hysteresis loop lowers the coercivity in such a way that the magnetization at (1b) 1.) $H = H_C - \Delta H_C$ ($\Delta H_C < H_C$) changes its orientation. In the time to the arrival of the second pump-pulse the coercivity will recover. However the recovery is not accompanied with a reorientation of the magnetization to its initial direction (1b) 2.) as the switching is an irreversible process.

The second pump pulse therefore meets the new magnetic state having no influence on the *measured* coercivity. Consequently, an effect triggered by the first pump-pulse will be detected as a time

dependent signature merely by the neighboring probe pulse, because of the irreversibility of the process.

The measured change in coercivity is just the optical equivalent of adiabatically heating the sample using a heat source.

To detect the evolution of the coercivity one must perform single-shot experiments. The condition to be fulfilled is that a single pump pulse significantly affects the coercivity. Surely this approach will suffer from a bad signal-to-noise ratio. Another way is to fast magnetic field sweeping (ms-time scale) to reset the whole system to its initial magnetic state. The application of short field pulses could present an experimental tool.

In conclusion we have shown that with present pump-probe setups it is not possible to measure time-dependent coercivity changes. Measured effects are mainly heating effects on long time scales.

LLB-Micromagnetic modelling of ultra-fast optical magnetisation dynamics.

U. Atxitia¹, O. Chubykalo-Fesenko¹, N. Kazantseva², D. Hinzke², U. Nowak², R. W. Chantrell²
 1. POMT, ICMC-CSIC, Madrid, Spain; 2. Department of Physics, University of York, York, United Kingdom

Recent advances in ultra-fast pulsed laser experiments in magnetic media have opened new possibilities of controlling magnetisation dynamics at the femtosecond regime [1,2]. An essential part of these experiments is a heat pulse, produced by the laser, acting on the magnetic material. Although the underlying processes are complicated, magnetisation dynamics at high temperatures can reasonably be understood taking into account that during ultra-fast laser-induced processes, the electron temperature rapidly increases up to and above the Curie temperature T_c . Standard micromagnetic models, based on the Landau-Lifshitz-Gilbert (LLG) equation cannot account for effects taking place at high temperature. This is because of the assumption of a constant magnetisation length and the fact that high-frequency spin waves are not included into simulations.

In this work we present a new micromagnetic approach, based on the Landau-Lifshitz-Bloch (LLB) equation [3] and its Langevin dynamics [4]. This equation was derived by D. Garanin [3] for classical and quantum average spin polarisation. Its main features are the following (i) The magnetisation magnitude is not conserved. (ii) Two relaxation mechanisms: longitudinal and transverse are present. (iv) The damping parameters are temperature dependent. (v) It is based on the free energy rather than on the internal energy. (vi) At low temperatures it coincides with the standard LLG equation but it is valid up to and beyond the Curie temperature T_c . Previously, we have shown that this equation gives an excellent agreement with the atomistic models [5].

As an example of new LLB-based micromagnetics, we show its suitability to model high temperature dynamics below and above the Curie temperature. We assume laser pulses with Gaussian shape of 50 fs duration and different fluences. During the laser-induced demagnetisation we assume that the photon energy is transferred to electrons and phonons and the magnetisation is coupled to the electron temperature within the two-temperature model. For temperature dependence of the equilibrium magnetisation $m_e(T)$ we suppose the Curie-Weiss law and for anisotropy and exchange parameters - the scaling relations: $K(T) \propto m_e^3$ and $A(T) \propto m_e^2$.

First we model a demagnetisation process produced by a laser pulse with high fluence. Our model reproduces all essential features of the heat-assisted demagnetisation, Fig.1. We observe a very fast demagnetisation, occurring at femto-second scale, followed by a more slow (ps) recovery. The rate of the recovery is different depending on the minimum magnetisation value achieved during the demagnetisation. The observed slow recovery rate at high laser pulse fluence is due to the loss of correlations at high temperature since the micromagnetic exchange vanishes. These results are consistent with recent atomistic simulations [6].

In our second calculation, we reproduce the optical FMR experiments reported in Ref.[1]. We assume a thin film with in-plane anisotropy and a laser pulse which produces a maximum electron temperature $T_e = 900$ K. An external field of 0.35 T was applied perpendicular to the plane. During the laser pulse, the magnetisation value rapidly decreases. Consequently, the anisotropy value decreases, the system is no longer in equilibrium and a laser-induced precession appears as the magnetisation recovers. The results of our LLB simulation, Fig.2, are similar to the ones reported experimentally in Ref.[1].

Switching Characteristics and Bias Voltage Dependence of Spin Torque Switching in MgO based Magnetic Tunnel Junctions.

S. Oh¹, K. T. Nam¹, J. E. Lee¹, W. J. Kim¹, J. H. Jeoung¹, D. K. Kim¹, S. Y. Lee¹, K. Kim², U. Chung¹, J. T. Moon¹

1. Memory Division, Semiconductor Business, Samsung Electronics Co., LTD., Yongin-City, Gyeonggi-Do, South Korea; 2. Semiconductor Device Lab, Samsung Advanced Institute of Technology, Yongin-City, South Korea

Spin-transfer torque MRAM (STT-MRAM) based on the current induced magnetization switching effect has been recently proposed and demonstrated by several research groups. The STT-MRAM has an advantage in scalability compared with conventional MRAM, because of its low operating current and the simple cell structure such as DRAM. However, there still exist some issues to achieve high density STT-MRAM: thermal instability, reliability of tunnel oxide, switching current, and switching current distribution. The switching current distribution of STT-MRAM can be triggered by the interlayer coupling, cell size dispersion and thermal excitation due to the joule heating effect. Fail bits are arising from the case the shift field (Hsh) by interlayer coupling is larger than the coercivity (Hc). Thus, minimization of the interlayer coupling is indispensable to achieve MTJ switching with stable memory states and the balanced switching current. The Hc distribution is very large, because of the local change of CoFeB composition during annealing process and shape dispersion by the MTJ fabrication. Thus, it is important to investigate the STT switching distribution due to this Hc distribution.

In the present work, we report the STT switching distribution of the MgO based MTJs where the interlayer coupling is minimized by optimizing patterning processes. The bias dependency of the STT switching measured at room temperature is also shown.

The stacking structure of MTJ for this work was PtMn/CoFe/Ru/CoFeB/MgO/CoFeB/Ta. All samples were annealed in vacuum for 30 min at 360°C under the magnetic field of 1 Tesla. In order to investigate STT, nano-sized MTJs were patterned by conventional lithography and etching process. Cell width and aspect ratio (AR) of MTJs were 70nm and 2, respectively. Especially, the thickness of MgO was carefully controlled below 1 nm to keep resistance area product (RA) about 25 ohm-um². In this work, a positive bias voltage denotes that electron passes from the pinned layer to the free layer and the MTJ is switched from anti-parallel state (AP) to parallel state (P) in the positive magnetic field.

For MTJ switching with stable memory states, the interlayer coupling should be small compared with the Hc of MTJs. Generally, both CoFeB layers can be interacted by the direct magnetic coupling due to pinholes in the thin MgO layer. In addition, Neel coupling and stray field can arise from interface roughness and the dipoles of the pinned layer, respectively. Figure 1(a) exhibits the change of the Hsh by the interlayer coupling in various MgO thicknesses. In this case, the width of MTJ was 1um and the aspect ratio was 30 to estimate the pure Neel coupling. The continuous MgO film was formed by 5.8Å, where the Hsh was around -140Oe. When the MgO thickness was reduced below 5.8Å, the Hsh was abruptly increased by the direct magnetic coupling due to pinholes. Thus, the pure Neel coupling strength at MgO thickness for a stable STT switching is below -140Oe

To minimize the stray field, the MTJs were etched up to the free layer. As shown in figure 1(b), the bias voltage dependency of Hsh was scrutinized. The average Hsh at zero bias voltage was about -100Oe and this indicated that the etching process was stopped onto the MgO tunnel barrier. In this figure 2, it is shown that bias voltage dependency on the Hsh is due to the STT switching effect.

Namely, when a positive magnetic field is applied, the positive bias voltage helps the AP to P switching and thus the negative Hsh increases.

Figure 2(a) shows the dependence of bias voltage on the Hc and Hsh at the samples with different Hc values. The Hc values were 120Oe and 40Oe, respectively. Figure 2(b) shows the R-V curves of these MTJs at 50ns pulse width. The switching voltages were almost the same as shown in this figure. Here, the Jc was about 4.5MA/cm². This result shows the STT switching voltage is not sensitive about the Hc of MTJs. The Hc distribution is very large due to the local change of magnetic composition during annealing process and shape dispersion by the MTJ fabrication. In spite of this large Hc distribution, this shows that it is possible for STT switching to obtain low switching voltage distribution.

In addition to these results, the switching characteristics and a bias voltage dependence of STT switching in various annealing temperature will be presented in detail.

(a) The change of Hsh by interlayer coupling in various MgO thicknesses. In this case, the width of MTJ was 1um and the aspect ratio was 30. (b) Bias voltage dependence of Hsh with various MTJs.

Impact of antiferromagnet-induced magnetization fluctuation control on switching current distribution reduction in MRAM.

Y. Katoh, H. Hada, N. Kasai

Device Platforms Research Laboratories, NEC Corporation, Kanagawa, Japan

Introduction

Magnetoresistive random access memory (MRAM) with magnetic tunnel junctions (MTJs) has attracted a great deal of attention due to its non-volatility and potential for high-speed operations. The write current for memory cell is designed based on both the average and distribution of MTJ switching current. We already clarified that the MTJ deformation causes 50% of the distribution, and have been analyzing the factor of other 50%. The importance of improving the distribution to reduce power consumption is high for all writing methods: a spin torque transfer[1], a 1-axis magnetic field[2], and a toggle operation[3]. In these MRAMs, an antiferromagnetic layer is commonly used to fix the magnetization direction of a pinned layer in an MTJ. In this work, we reveal that the antiferromagnetic layer is one of significant factors of switching current distribution. And we also show some efficient methods for distribution reduction about 20%.

Experiments and Results

To know all the factors of switching current distribution, we introduced the new assumption, “the magnetic domain structure of the pinned layer induces stray field.” A Landau-Lifshitz-Gilbert (LLG) simulation was performed in several cases with different domain structures and magnetization conditions. Fig. 1 shows the simulation results of the switching magnetic field (H_{sw}) distribution dependence on the MTJ size. It clarified that the domain structure exists and that its magnetic fluctuation causes the distribution in both cases of the single free layer and the toggle layer [4].

To determine the effect of pinned condition, we investigated H_{sw} distribution using some magnetic annealing treatment to control the magnetization condition of the pinned layer. The MTJ consisted of a free layer (NiFe), a tunneling layer (AlO), and a pinned layer (CoFe/Ru/CoFe/PtMn). The magnetic anneal temperature, time, and magnetic field were 275 degrees, 30 minutes, and 1.2 teslas toward the easy axis of the free layer, respectively. Fig. 2 shows the normalized variances of the switching magnetic field depending on the number of the annealing treatment. It improved at the second treatment more than it did at the first treatment. At the third time, the value did not improve any more. It is clarified that the magnetization condition of the pinned layer has much effect on the H_{sw} distribution, and it was considered to become stable after the second treatment.

To determine that the main factor is the CoFe pinned layer or the antiferromagnetic layer, we investigated the distributions with different pinned structures. They were (a) CoFe (1.2 nm)/Ru/CoFe (1.4 nm)/PtMn and (b) CoFe (1.2 nm)/Ru/CoFe (2.6 nm)/Ru/CoFe (1.4 nm)/PtMn as shown in Fig. 3. The free layer was a toggle type, and the MTJ shape was a $0.32 \times 0.64 \mu\text{m}$ ellipse. Fig. 4 shows the normalized variances of the switching currents of these samples. It does not increase drastically with insertion of a thick CoFe layer. It indicates that the antiferromagnetic layer is the significant factor of distribution and that the effect of the material anisotropy is small.

To improve the H_{sw} distribution, we proposed two methods. Method1 is a pinned layer without an antiferromagnetic layer. It is (c) CoFe(1.2nm)/Ru/CoFe(2.6nm)/Ru/CoFe(1.4nm)/Ru as shown in Fig. 3. The magnetization is fixed with sufficient exchange coupling of magnetic layers. To control the magnetization direction by applying large magnetic field, it includes one thick magnetic layer. And it can compensate stray field from the edge among three magnetic layers. It was determined that 22% of the variance improves with structure (c) as shown in Fig. 4.

Method2 is a new magnetic annealing procedure called swing anneal. It consists of an annealing treatment toward several degrees off from the easy axis and an additional treatment toward the easy axis. Because the torque depends on the direction difference between applied magnetic field and the magnetization in each domain, only the magnetization in the direction far from the easy axis could be modified in the swing anneal. Therefore, it was expected that antiferromagnet-induced fluctuation of magnetization in pinned layer decreased. It was determined that 17% of the variance improves in the sample in Fig. 2 by the swing anneal.

The fabrication process was developed by the Toshiba-NEC MRAM development project.

Spin Torque Random Access Memory down to 22nm Technology.

X. Wang, Y. Chen, H. Li, D. Dimitrov, H. Liu
Seagate Technology, Bloomington, MN, MN

Magnetic Random Access Memory (MRAM) is one promising candidate for future nonvolatile and universal memory. MRAM writing based upon spin-polarized current induced magnetic tunneling junction (MTJ) switching has been proposed as SPRAM. In this paper, a combined magnetic dynamics and electric circuit model is developed to study physics and scalability of SPRAM. We use this model to explore one-transistor-one-MTJ SPRAM (Fig.1) design down to 22nm CMOS technology node. Constrains limiting SPRAM achievable capacities are analyzed; possible approaches to improve achievable capacities are discussed.

MTJ and CMOS are dynamically coupled in SPRAM writing operation. SPRAM switching behavior is highly dependent on the dynamics and histories of write current applied to MTJ, which shows as a time varying resistance in electric circuit and greatly affects the driving current provided by CMOS. We developed a dynamic MTJ switching model by combining micro-magnetic simulation of MTJ and SPICE simulation of CMOS circuit. Fig. 2 shows an example of the time varying MTJ resistance and CMOS driving current during MTJ switching. The fluctuations in resistance and current are signatures of MTJ magnetization oscillation during switching. The abrupt driving current changes correspond to MTJ resistance switched from one resistance state to the other resistance state. The asymmetry in low-to-high resistance switching behavior and high-to-low resistance switching behavior is due to CMOS forward and backward driving current strength difference. As discussed in [1], our dynamic MTJ-CMOS approach leads to much improved predictions at the required write current compared to the conventional static model without explicitly considering dynamic coupling between MTJ and CMOS.

Scaling down SPRAM requires shrinking both CMOS and MTJ dimensions. Although source-drain leakage from electron thermal diffusion and gate current leakage from quantum-mechanic tunneling put fundamental physics limit on CMOS size, it is believed that CMOS technology can achieve 22nm channel length with power-supply voltage around 1.0V [2]. Fig. 3 shows the current provided by CMOS as a function of MTJ resistance for 22nm channel length with different channel width. As CMOS scales down, decreased driving current requires decreasing MTJ writing current threshold. However the competition between the short time dynamic writability and the long time thermal stability is a well-known physics factor limiting magnetic device scaling down. In this paper, SPRAM design spaces at CMOS 22nm technology node are explored using our dynamic MTJ-CMOS model. Fig. 2 is one example of MTJ design achieving 34F2 capacity at CMOS 22nm technology node with channel width 100nm. However this design is far from achieving maximum potential capacity supported by CMOS 22nm technology node. In this paper, we will analyze trade-offs between MTJ current threshold, MTJ thermal stability and CMOS driving strength. The analysis provides information on physics requirements and technology bottlenecks for MTJ to achieve maximum capacity supported by CMOS 22nm technology. Magnetic solutions for MTJ to fully achieve CMOS 22nm potential capacities are suggested.

Multilevel Magnetic Random Access Memory Based on Spin Transfer Torque Switching.

Y. Zhang, X. Yao, J. Wang

MINT Center & Electrical and Computer Engineering Department, University of Minnesota, Minneapolis, MN

Experimental demonstration of spin transfer torque (STT) switching [1], has attracted much attention due to its rich basic physics and potential industry applications, especially providing a promising writing scheme for ultra high density magnetic random access memory (MRAM). In recent years, studies focusing on lowering the critical switching current density and promoting the magnetoresistance (MR) signal have been reported intensively based on the STT induced magnetization switching. To further increase the storage density, the size of the cells needs be scaled down, for which perpendicular magnetized STT was demonstrated to maintain the thermal stability [2]. On the other hand, improving the storage capability of each memory cell can increase the recording density in theory. A multilevel MRAM, based on GMR spin-valve structure and external field induced magnetic switching, has been investigated by Jeong, et al [3], which faces the same challenges as the recent field-driven MRAM. In our work, novel design of multilevel STT MRAM based on MgO MTJ with perpendicular anisotropy is reported, which is also applicable to CPP-GMR or MTJ with in-plane anisotropy.

Fig.1(a) shows the proposed 2-bit 4-state STT MRAM cell. The full structure can be treated as two STT MTJs. The MTJ-1 consists of the fixed layer and freelayr1 with the resistance R_{1L} and R_{1H} when the two magnetic layers are parallel and antiparallel to each other and the critical switching current density is J_{c1} . With the higher critical switching current density, the freelayr1 will act as “fixed layer” for the freelayr2, and the J_{c2} is the critical current density between the R_{2L} and R_{2H} for the MTJ-2. Here for both MTJs the current from top free layer to bottom pinned layer (electrons flow from bottom to top) is defined as the positive current. Based on the STT effect, the free layer can be written as “0” and “1” representing low resistance parallel state and high resistance antiparallel state respectively by a positive or negative current pulse. For an experimental demonstration in this two-level structure, the fixed layer consist a high perpendicular anisotropy FePt layer and a high spin polarization CoFeB layer which are also included in two composite magnetic free-layer, freelayr1 (CoFeB/FePt/CoFeB) and freelayr2 (CoFeB/FePt/FeSiO). In the composite freelayr, the CoFeB layer is also used as a soft layer to lower the switching current density and to enhance MR ratio due to CoFeB/MgO/CoFeB structure providing high TMR signal. In order to write two free-layers separately and make the free-layer1 work as the “fixed layer” of the MTJ2, the J_{c1} should be larger than the J_{c2} just as discussed above. In this case, a nano current channel (NCC) layer will be deposited in the freelayr2 to decrease the J_{c2} distinctly [4].

A typical resistance vs current loop is shown in Fig1(b) to describe the writing and reading process of this multilevel MTJ-based memory cell. When a positive large pulse(J_{c1}) applied, both two free-layers will be parallel to the fixed layer. The resistance will be the sum of two lower states $R_{1L}+R_{2L}$ labeled as “00”. If a negative small pulse(J_{c2}) is followed, the MTJ1 won’t be affected while the freelayr2 will be switched antiparallel to the freelayr1 and the resistance will be $R_{1L}+R_{2H}$ labeled as “01”. On the other hand, a negative large pulse will make the three magnetic layer antiparallel to each other with the highest resistance $R_{1H}+R_{2H}$ (state “11”) and a followed positive small pulse can reduce the resistance to $R_{1H}+R_{2L}$ (state “10”). The four states can be sensed by a small current. For the high MR ratio of MTJ, the resistance change between “00” and “01” or between “11” and “10” will be clear. Thus the requirement of reading goes to $R_{1H}+R_{2L} > R_{1L}+R_{2H}$ which means $\Delta R_1 > \Delta R_2$ or $MR_1\% \cdot R_{1L} > MR_2\% \cdot R_{2L}$. The writing pulse sequence, the

sensed resistance state and the logic state are listed as a form in Fig1(c). A reasonable experimental tolerance of the resistance level and switching current density can be expected because 1) the experiment data shows that the MgO MTJ has provided a large range of barrier resistance and MR ratio [5]; 2) we recently reported that the switching current density could be adjusted by a factor of 2 – 4 by using the composite free layer with perpendicular anisotropy [6].

Heat-assisted magnetization reversal using pulsed laser irradiation in patterned magnetic thin film with perpendicular anisotropy.

K. Waseda, R. Doi, B. Purnama, S. Yoshimura, Y. Nozaki, K. Matsuyama
Dept. of Electronics, Kyushu University, Fukuoka, Japan

Heat-assisted magnetization reversal is one of the promising candidates for the method to decrease the switching field efficiently without sacrificing the thermal stability of the bit information in magnetic random access memories (MRAMs). For the application to heat-assisted MRAMs, it is essential to establish the device configuration ensuring not only a high-speed heating and cooling of the memory cell but also the heating efficiency. In this paper, we have experimentally investigated both the heating efficiency and the cooling speed of the micron-scale TbFe thin film laterally connected with electrical lead patterns. Figures 1(a) and 1(b) shows the optical photograph and the schematic cross-section of the prepared device. The device consists of 100 nm-thick TbFe film with a lateral size of $50 \times 50 \mu\text{m}^2$ connected with electrical leads, 300 nm-thick Cu loop conductor to produce the magnetic field perpendicular to the film plane, and 50 nm-thick Cr aperture. The patterned TbFe film was heated up using pulsed YAG laser irradiations through the Cr aperture. The pulse width and the wavelength of YAG are 1 ns and 532 nm, respectively. The amplitude of the laser irradiation was attenuated using optical filters with transmission coefficients T_{filter} in the range from 3 to 10 %. As shown in Fig. 1(c), a pulsed perpendicular magnetic field of 80 Oe ($t_w = 30, 50$ and 100 ns) was applied with a delay of t_{delay} from the laser irradiation. The magnetization reversal of the TbFe film caused by the simultaneous applications of both the heating and the magnetic field was measured using the anomalous Hall effect. Figure 2 shows the temperature dependence of the normalized Hall voltage V_{AHE} . The V_{AHE} , which is proportional to the perpendicular component of magnetization in patterned TbFe film, is gradually decreased with increasing temperature and becomes zero at 383 K corresponding to the Curie temperature T_c . Figure 3(a) shows the ratio of magnetization reversal caused by applying both external magnetic fields and pulsed laser irradiations with various amplitudes. The increase of magnetization reversal is saturated as the T_{filter} becomes larger than 5 %. It is, therefore, expected that the patterned TbFe film is heated above the T_c as $T_{\text{filter}} > 5$ %. Assuming an adiabatic process, the energy required for heating the patterned TbFe film with the volumetric heat capacity of $2.6 \times 10^6 \text{ J m}^{-3} \text{ K}^{-1}$ from room temperature to the T_c is estimated as 7.2 nJ, which is 19 % of the measured irradiation energy of the pulsed laser with $T_{\text{filter}} = 5$ %. Figure 3(b) shows the ratio of magnetization reversal caused by applying both pulsed magnetic field of 80 Oe and pulsed laser irradiations as a function of t_{delay} ranging from -100 to 100 ns. The data for $t_{\text{delay}} > 0$ indicates the magnetization reversal in the cooling process after the laser irradiation. The time to cool the patterned TbFe film from the T_c to the critical temperature required for the magnetization reversal at 80 Oe is 17 ns. It is also found that the cooling time is almost independent of the width of the electrical leads connected to the patterned TbFe film. This suggests that the thermal diffusion is predominantly occurred through the top and bottom surface of the TbFe film. Therefore, faster cooling can be expected for a memory cell with a magnetic tunneling junction because metallic leads are connected to the top and bottom surface of the cell.

Estimation of Thermal Stability Factor in Current-Induced Magnetization Switching.

H. Suh, K. Lee

Korea University, Seoul, South Korea

I. Introduction

The current-induced magnetization switching (CIMS) has been demonstrated in spin valve structures [1]. The CIMS provides various merits for the use in the magnetic random access memory (MRAM) such as better scalability and selectivity in comparison with the field-induced magnetization switching. For the application of CIMS in MRAM, the thermal stability factor, $\Delta = (H_k M_s V) / (2k_B T)$ should be larger than 60 where H_k is the in-plane anisotropy field, M_s is the saturation magnetization, k_B is the Boltzmann constant, T is the temperature, and V is the magnetic volume of cell. Because of its importance, experimental studies to estimate the thermal stability factor have been performed [2]. There are several methods to estimate the Δ in experiments of CIMS, but a reliable method has not been confirmed yet. In this work, we have tested three different methods to estimate the Δ and confirmed which one is the most efficient and reliable.

II. Three methods to estimate the thermal stability factor

Any method to estimate the Δ should adopt the Arrhenius-Néel equation, $\tau = \tau_0 \exp(E_b^* / k_B T)$ where is the relaxation time, τ_0 is the reciprocal of the attempt frequency, E_b^* is the effective energy barrier [3]. In the presence of the spin-transfer torque, the energy barrier E_b^* can be described by $E_b^* = \Delta(1 - J/J_{C0})$ where J is the current density, and J_{C0} is the threshold current density for the current-induced magnetic excitation [4]. In experiments, two unknown variables Δ and J_{C0} should be determined by fitting through a use of the modified Arrhenius-Néel equation. Three methods for fitting are as follows;

[Method 1] In method 1, the probability of not switching (P_{ns}) is measured as a function of the switching time (t) at a fixed current density. The eq. (1) is used to fit Δ and J_{C0} .

$$\ln(P_{ns}) = -t/\tau = -t/\tau_0 \exp[-\Delta(1 - J/J_{C0})]. \quad (1)$$

[Method 2] In method 2, the probability of not switching (P_{ns}) is measured as a function of the current density (J) at a fixed current pulse (t). The eq. (1) is also used to fit Δ and J_{C0} .

[Method 3] In method 3, the average switching current density is measured as a function of the pulse-width τ_p . The eq. (2) is used to fit Δ and J_{C0} .

$$J = J_{C0} [1 - \{\ln(\tau_p/\tau_0)\} / \Delta]. \quad (2)$$

III. Model

We performed the macrospin simulation to test the three methods for estimating the thermal stability factor. The modified Landau-Lifshitz-Gilbert equation with including the spin torque term is used. The spin transfer torque is described by $\Gamma = (\gamma a_f / M_s) \mathbf{M} \times (\mathbf{M} \times \mathbf{M}_p)$ where γ is the gyromagnetic ratio, \mathbf{M} is the magnetization vector of free layer, \mathbf{M}_p is the unit vector of magnetization of pinned layer, $a_f = (\hbar \bar{e} / 2e(PJ/M_s d))$, P is the spin-torque efficiency factor, d is the thickness of free layer. We assumed $M_s = 600 \text{ emu/cm}^3$, $P = 0.7$, and $T = 300 \text{ K}$. The geometry of magnetic cell is $150 \times 70 \times 3$ (length \times width \times thickness) nm^3 of which thermal stability factor is 54.4. For each case, more than 100 switching events were calculated.

IV. Results and Discussions

Figure 1(a) shows results obtained by the method 1 at $J = 4.2 \times 10^6 \text{ A/cm}^2$ and $\tau_0 = 1 \text{ ns}$. In this method, we could not obtain the correct Δ and J_{C0} . It is because the variable, t is outside the exponential function whereas both unknown parameters are in the exponential function. Therefore any combination of Δ and J_{C0} can fit the simulation results.

In method 2 and 3, however, we could obtain a reasonable fitted value of Δ which nearly coincides with the correct one ($=54.4$) since the two unknown parameters, Δ and J_{C0} can be independently determined. Figure 1 (b) and (c) show results of method 2 and method 3 assuming $\tau_0 = 1 \text{ ns}$, respectively. In method 2, the thermal stability factor (Δ) is determined by the slope of plot and is 50.5. We could also determine the J_{C0} ($=5.76 \times 10^6 \text{ A/cm}^2$) by extrapolating J to the point of $-\ln\{-\ln(P_{ns})/(-\tau_0^{-1}t)\} = 0$. In method 3, the thermal stability factor (Δ) is also determined by the slope of plot and is 51.8. We obtained J_{C0} of $5.72 \times 10^6 \text{ A/cm}^2$ by extrapolating J to the point of $-\ln(\tau_p/\tau_0) = 0$. Since the τ_0 is in principle another unknown parameter although it is conventionally assumed to be 1 ns , a fitted value of Δ should be insensitive to the τ_0 . Assuming $\tau_0 = 0.1 \text{ ns}$, we obtained $\Delta = 52.8$ by method 2 and $\Delta = 54.1$ by method 3. It indicates both methods are reliable to estimate the thermal stability factor.

In conclusion, we have tested three different methods to estimate Δ and J_{C0} based on the modified Arrhenius-Néel equation. It was found that both of the method 2 and 3 are reliable.

Nano-ring MTJ and nano-ring MRAM.

X. Han, Z. Wen, H. Wei

State Key Lab of Magnetism, Institute of Physics, CAS, Beijing, China

Nano-ring-shaped magnetic tunnel junctions (NR-MTJ) were fabricated. The tunneling magnetoresistance (TMR) versus current (I) loops of the NR-MTJs for a spin-polarized current switching were measured and the TMR ratio of around 20%~50% with a Al-O barrier at room temperature were observed. The critical value of switching current for the free Co₆₀Fe₂₀B₂₀ layer between parallel and anti-parallel magnetization states is smaller than 500 μ A. The NR-MTJs arrays were also integrated above the transistors in CMOS circuit for 4x4 bit MRAM demo devices. After each positive and negative pulse writing current the high and low resistance of a NR-MTJ as a MRAM bit were read out using a low read current of between 10 and 20 μ A which does not affect the magnetic state of the NR-MTJ. Such design could distinctly reduce MRAM energy consumption and memory cell size and increase the cell density compared with existing designs. It is suggested that the MRAM fabrication with the density and capacity higher than 6 Gb/ite/inch² are possible based on 1 NR-MTJ + 1 transistor structure and current switching.

Magnetic characterization of embedded MgO ferromagnetic contacts for spin injection in silicon.

T. Uhrmann¹, T. Dimopoulos¹, D. Schwarz¹, V. Lazarov², D. Kirk², A. Kohn², S. Weyers³, U. Paschen³, H. Brückl¹

1. Nano-Systemtechnologies, Austrian Research Centers GmbH - ARC, Vienna, Austria; 2. Department of Materials, University of Oxford, Oxford, United Kingdom; 3. Fraunhofer Institute of Microelectronic Circuits and Systems, Duisburg, Germany

The control of the magnetic switching is a prerequisite for the successful implementation of a new data storage technology like magnetic random access memory (MRAM). An alternative MRAM design is based on the front-end implementation of the magnetic modules, employing spin-polarized current injection and detection through properly doped silicon. Each magnetic module consists of a tunneling barrier, a thin ferromagnet (FM) and a capping layer, embedded into a SiO₂ dielectric layer. The aim of this work is to study the magnetic properties of such magnetic modules.

The samples were fabricated on Si wafers with 42 nm thermally grown oxide. The oxide layer has been structured by deep-UV lithography in combination with CHF₃ reactive ion etching and buffered HF wet-chemical etching, in order to form eight different arrays of rectangular holes down to the silicon surface. The rectangular elements have widths of $d=300, 400, 450$ and 500 nm and two different lengths $l=1500, 3000$ nm. Directly after the HF wet etching, multilayers with the following compositions have been deposited, using RF (for the MgO film) and DC magnetron sputtering: MgO ($x=0, 0.5, 1.0, 1.5, 2.5$ nm)/ Co₇₀Fe₃₀(1nm)/ Ni₈₁Fe₁₉(4nm)/ Ta. The CoFe/NiFe bilayer has been chosen in order to combine the soft magnetic properties of NiFe with the high tunneling spin polarization of CoFe. The fabrication was completed by lift off processing to remove the resist and the multilayer from outside the holes. A RMS-roughness of 0.25 nm has been measured by atomic force microscopy (AFM). Additional structural investigations by transmission electron microscopy (TEM) for a MgO thickness of 2.5 nm have shown smooth interfaces with a low roughness. The FM bilayer is polycrystalline, while the MgO barrier appears to be amorphous. Due to processing, the rectangular edges are rounded, which should lead to a decreased switching field, compared to the ideal rectangular case.

The magnetic properties of the arrays were studied using Magneto-optical Kerr effect (MOKE) measurements. In Fig. 1 we present easy-axis MOKE loops (with the magnetic field aligned along the long axis of the elements), measured for the as-deposited multilayer with $l=3000$ nm and $x=2.5$ nm. Such measurements have been done for every MgO barrier thickness and all fabricated array sizes. From the easy axis loops we extracted the switching field, H_S , and the switching field distribution, ΔH_S .

The magnetization switching is characterized by a high remanent moment that is desirable for a magnetic memory device. The hard axis loops (not shown here), on the contrary, show the typical rotation-like switching with very small hysteresis and remanence.

The dependence of H_S on the elements' width, d , is depicted in Fig. 2(a), where the switching field is decreasing over the width. Particularly important is the observed large magnetic selectivity, which in some cases surpasses 20 or 25 Oe.

As it can be seen in Fig. 2(b), $\Delta H_S/H_S$ is increasing with the width of the elements, and is generally larger for the length of 1500 nm, than for 3000 nm long elements.

The plot of the switching field as a function of the MgO thickness in Fig. 3 shows, that H_S has similar values for $x=0, 1.5$ and 2.5 nm and reaches a maximum between $x=0.5$ nm and 1.0 nm. This

behaviour is most probably related to the early stages of the MgO layer growth. The barrier should be at the limit of film continuity at 1 nm, which induces interfacial roughness that may raise H_S . In conclusion, the magnetic switching characteristics of embedded magnetic cells, for an alternative front-end MRAM design, have been evaluated by localized magneto-optical Kerr effect measurements. It is shown that the switching field and distribution depend strongly on the MgO tunneling barrier thickness and the element's width.

Easy axis magnetization loops for arrays of rectangular elements with varying width and 3000 nm length for a MgO thickness of $x=2.5$ nm.

Dependence of the switching field H_S on the MgO thickness for $l=3000$ nm.

High thermal stability and low switching current in a perpendicular-CPP-GMR with an ultrathin epitaxial FePt free layer.

K. Yakushiji, S. Yuasa, A. Fukushima, H. Kubota, T. Nagahama, T. Katayama, K. Ando
National Institute of Advanced Industrial Science and Technology (AIST), Tsukuba, Japan

We have focused our study on spin-torque switching in a magnetoresistive memory cell with perpendicular magnetic anisotropy predicting high-density spin-torque switching type MRAM (so-called Spin-RAM). Large perpendicular anisotropy (K_u) and collinear demagnetizing field to the perpendicular anisotropy field are expected to realize large thermal stability ($\Delta = K_u V / k_B T$) and small switching current density (J_{c0}). Although basic properties in nanopillars with perpendicular anisotropy have been studied in recent years[1-3], there have been few systematic studies intensively on Spin-RAM application. In this study, we employed monatomic alternate layer deposition method to prepare high-quality ultrathin FePt switching layers. The deposition method is effective in preparing an ultrathin film ($< 2\text{ nm}$) without deteriorating the film quality[4-6]. We investigated spin-transfer switching and thermal stability in epitaxial $[\text{Fe}(1\text{ monolayer(ML)})/\text{Pt}(1\text{ ML})]_{12} / \text{Au} / [\text{Fe}(1\text{ ML})/\text{Pt}(1\text{ ML})]_n$ CPP-GMR nanopillars.

A Film was prepared on an MgO(001) substrate by MBE method. Fe of 1 ML, a $[\text{Fe}(1\text{ ML})/\text{Pt}(1\text{ ML})]_n$ pinned layer with $n = 12$ (4.0 nm- thick), Fe of 2 ML, a 2.7 nm- thick Au spacer layer, Fe of 1ML, and a $[\text{Fe}(1\text{ ML})/\text{Pt}(1\text{ ML})]_n$ free layer were successively deposited on a Cr/Au buffer at 200 °C. The number of alternation period n for the free layer was varied at 3 (1.02nm), 4, 5 and 6 (2.04nm). Pillars were prepared in a circle shape with various diameters (d) from 100 nm to 170 nm.

Figure 1 (a) shows typical minor R - H loop at room temperature for a cell with the free layer thickness (t_{free}) of 1.02 nm ($n = 3$) and $d = 130$ nm. We obtain MR of 1.6 % and RA of $0.06\ \Omega\mu\text{m}^2$. The loop shifts about 1200 Oe because of the dipole interaction between the free and pinned layers. Fig. 1 (b) shows spin-torque switching property (R - I loop) measured at $H = 1200$ Oe with the current pulse duration of 100 ms. Sharp transitions of both AP to P and P to AP state were clearly observed. It was suggested that domain wall motion governed the magneto-switching because the coherent rotation should only take place for a pillar diameter below 50 nm. Average critical current density (J_{c0}) and Δ were estimated from current pulse duration (t) dependence of switching current (I_c), to be $1.2 \times 10^7\ \text{A/cm}^2$ and 66, respectively. We consider that the high perpendicular anisotropy of FePt gave rise to practical Δ even in an ultrathin layer, and use of such an ultrathin free layer leads to small J_{c0} in spite of small MR and large damping property of FePt. Fig. 2 plots average critical current density (J_{c0_av}) versus average thermal stability (Δ_{av}) for cells with $t_{\text{free}} = 1.02$ nm ($n = 3$). Although a cell with in-plane anisotropy usually shows trade-off relationship between J_{c0_av} and Δ_{av} , J_{c0_av} shows little change against Δ_{av} in these perpendicular cells. Therefore, better performance was realized in cells with large pillar size: J_{c0_av} of $1.8 \times 10^7\ \text{A/cm}^2$ and Δ_{av} of 97 were obtained in the cell with $d = 165$ nm.

Stress assisted reversal of perpendicular magnetization of thin films with giant magnetostriction constant.

N. Saito, S. Nakagawa

Dept. of Physical Electronics, Tokyo Institute of Technology, Tokyo, Japan

I. INTRODUCTION

Perpendicular MRAM has been regarded as a next generation memory. However, high power consumption arising from writing process is one of the demerits for practical application. So we have proposed stress assisted magnetization reversal (SAMR) method^[1]. The principle of SAMR is as follows. By applying a stress to magnetic thin films, magnetization turns from perpendicular to in-plane caused by an inverse magnetostrictive effect. Sequential application of a magnetic field and a release of the stress causes magnetization reversal at lower field than the original coercivity. For example, by the use of SAMR, magnetization of DyFeCo thin films that have 4500 Oe of an original coercivity is reversed at 100 Oe with applying 495 MPa stress^[2]. However, 495 MPa is too high to induce such high internal stress to the film by piezoelectric effect for practical application. So we focused the Terfenol-D ($\text{Tb}_{0.27}\text{Dy}_{0.73}\text{Fe}_{1.9}$) that has giant magnetostrictive effect and aim to attain magnetization reversal at lower stress.

II. EXPERIMENTS

50 nm-thick Terfenol-D films were deposited at room temperature on disk-type cover glass substrates at Ar gas pressures of 0.08 Pa by facing targets sputtering system. Composite plates, consisted of $\text{Tb}_{0.27}\text{Dy}_{0.73}\text{Fe}_{1.9}$ alloy plate and Fe chips, were used as targets. Perpendicular magnetization was observed by using extraordinary Hall effect. A mechanical tensile stress was applied by distorting the center of the cover glass. Magnetostriction constant was measured by optical deflection technique. Atomic composition of the films was evaluated by inductively coupled plasma (ICP) spectroscopy analysis.

III. RESULTS AND DISCUSSIONS

Since the perpendicular M-H loop of Terfenol-D thin film revealed low squareness ratio and low coercivity of 50 Oe as shown in Fig.1(a), Fe composition in the film was slightly modified with keeping composition ratio between Tb and Dy. As a result, high squareness ratio and appropriate coercivity in perpendicular direction were attained as shown in Fig.1(b). Since the saturation magnetization gradually disappeared at zero field about the film of Fe: 69.1 at.%, Fe 70.2 and 71.6 at.% films were chosen and studied about magnetization reversal characteristic. Fig.2 shows change of magnetostriction constant as a function of Fe compositions. Magnetostriction constant keeps high enough at a region of the composition ratio even away from Terfenol-D (Fe: 67.2 at.%).

Solid line and dashed line in Fig.3 indicate perpendicular M-H loops under various mechanical stresses. In addition, dots in Fig.3 (a) and (b) show results of SAMR of the films for Fe:70.2 and 71.6 at.%, respectively, by applying stresses of 165 and 330 MPa. Transverse and vertical axes of the dots show the applied fields during SAMR and residual magnetization after reversal, respectively. In the case of (a), magnetization turned to in-plane at 165 MPa stress. Inverse magnetostriction effect was confirmed at lower stress compared to that of DyFeCo thin films. SAMR measurement clarified that magnetization began to reverse at lower field. But magnetization was reversed completely at 700 Oe, that is, same field as no stress. In the case of (b), by contrast, magnetization turned to in-plane at 330 MPa. SAMR measurement told that magnetization was reversed at 300 Oe while the original coercivity of this film is 600 Oe.

A Novel Macro-Model for Spin-Transfer-Torque based Magnetic-Tunnel-Junction Elements.

S. Lee, H. Lee, S. Lee, H. Shin

Information Electronics Engineering, Ewha W. Univ., Seoul, South Korea

1. Introduction

Spin transfer torque (STT) switching in magnetic tunnel junction (MTJ) has important merits over the conventional field induced magnetic switching (FIMS) MRAM in avoiding half-select problem, and improving the scalability and selectivity [1]. Design of effective MRAM circuitry using STT-based MTJ elements requires an accurate circuit model which can exactly emulate the characteristics of MTJ in a circuit simulator such as HSPICE. In recently published works, there were attempts to model some characteristics of FIMS MTJs [2]. In this paper, we present a novel macro-model that fully emulates the important characteristics of STT-based MTJ.

2. A Novel Macro-Model for STT-based MTJ

In STT switching method, self-read disturbance becomes an issue because an STT MTJ uses the same current path for both reading and writing. Therefore, an accurate simulation model which can reproduce the characteristics of tunneling magneto resistance (TMR) is required [3]. The bias-dependent TMR effect has more influence on high resistance (RH) state and it also shows an asymmetric resistance versus current (R-I) characteristics [3]-[4]. Besides, TMR ratio and switching threshold of hysteresis shrink as the operating temperature increases [5].

Now we introduce a macro-model which can emulate all of the aforementioned characteristics shown in the R-I loop measured by Miura's group [6]. The equation for Miura's R-I loop fitted by Lorentz function is given as

$$y = y_0 + 2 \cdot A \cdot w / \pi \cdot (4 \cdot (x - x_c)^2 + w^2) \quad (1)$$

In equation (1), y_0 , A , w , and x_c are incorporated as parameterized variables, and x is the amount of tunneling current across the MTJ. Two separate Lorentzian fittings for RH are achieved for positive current region (RH_P) and negative current region (RH_N) to reproduce the asymmetric characteristics.

As shown in Fig. 1, the macro-model includes nodes of BL1, BL0, and SL. RBIT is the bit-line metal resistance per cell and RL is the TMR value of STT MTJ at low resistance state. Gdelta is a voltage-controlled resistor and it represents the difference of resistance between RH and RL. Iwr or Isense flows through BL1~SL by writing (WR) or reading (RD) command signal, respectively. These currents are supplied externally. In writing operation, bi-directional current flows between BL1 and SL. Ewb detects both the direction and the amount of current flowing through RL. Ecomp1 realizes the hysteresis by comparing value of ne1 with temperature-dependent switching threshold. Ecomp2 and Esum realize asymmetric characteristic. Using (1), GHIGH_N and GHIGH_P emulate R-I loop for RH_N and RH_P regions, respectively. It also models the temperature dependence of TMR ratio. Gdelta gets a value among 0, function of ng1, and function of ng2 according to RL, RH_N, and RH_P states of MTJ, respectively

R-I loop for STT-based MTJ is simulated with HSPICE as shown in Fig. 2. As can be seen, the simulation results show excellent agreement with the measured data. Fig. 3 reveals the capability of macro-model to emulate the temperature dependence of the hysteresis characteristics, which shows the reduction of switching threshold and TMR ratio for high temperature.

3. Conclusions

STT-based MTJ has self-read disturbance problem. Therefore, development of an accurate circuit model which can emulate major characteristics of STT-based MTJ is very important to precisely

control the amount of the current. This paper presents a novel HSPICE macro-model for STT-based MTJ element. The macro-model successfully reproduces the R-I loop with temperature-dependent hysteresis and asymmetric TMR effect of STT-based MTJ. This model allows easy integration of the MTJ memory cell with CMOS peripheral circuits in MRAM simulation using HSPICE simulator.

Random number generation by current induced magnetization switching in a MgO magnetic tunnel junction.

A. Fukushima, K. Yakushiji, H. Kubota, S. Yuasa, K. Ando
NeRI, AIST, Tsukuba, Japan

Current induced magnetization switching (CIMS) at a current pulse longer than the attempt time (~ 1 nsec), is the phenomenon which is well described by thermal activation model [1]. The switching probability increases monotonically nearby the threshold current where the switching probability is 0.5; the increasing ratio of the switching probability is roughly proportional to the inverse of the thermal stability parameter Δ ($\equiv KuV/kBT$) [2]. The lower Δ makes easy to control the switching probability. Therefore, it is possible to use a magnetic tunnel junction (MTJ) as the “random number generator” by tuning the switching current of CIMS nearby the threshold current. We named the random number generation by CIMS as “spin dice” [3], which is expected to be genuine physical number generator.

On the other hand, in accordance with recent development of worldwide network society, high security communication becomes much important. High security communication demands a high-speed cryptography which requires a high-speed physical random number generator. Because the speed of CIMS is quite fast (~ 1 nsec), “spin dice” will be one of the most prominent candidates for such a high-speed cryptography.

We generated the random numbers by the “spin dice”, where we used a single MgO-MTJ. Usage of the MgO-MTJ with a large MR ratio has an advantage of a high output signal. The MgO-MTJ structure was buffer layer / antiferromagnetic layer / pinned layer (CoFeB 3 nm) / MgO 1 nm / free layer (CoFeB 2 nm) / cap layer. The size of the junction was 60×160 nm. The resistance in the parallel state was 180Ω and the magnetoresistance ratio was 100 %. We chose the MTJ with $H_{\text{shift}} \approx 0$, then generated the random number at $H_{\text{external}} = 0$ where the MTJ had 2 states.

The switching process for a random number generation is as follows. Firstly, the magnetization of the pinned layer and the free layer is aligned in anti-parallel state by the reset pulse. Then the magnetization of the free layer will be switched by the set pulse, which has opposite direction to the reset pulse. Binary random numbers are generated by applying repeatedly a sequence of the reset and set pulses, measuring the resistance after the set pulse, and attributing the value ‘1’ to a switching event and ‘0’ to a non-switching. In this experiment, the width of both reset and set pulse was 50 μsec , and the amplitude of the reset current was -1.8 mA.

The current dependence on the switching probability was measured from every 1000 switchings by changing the set current from 1.20mA to 1.40 mA. The threshold current was 1.31 mA. We evaluated that the intrinsic critical current $I_{c0} = 1.83\text{mA}$, and $\Delta = 40$ from the fitting the switching probability to the thermal activation model [1].

Next, we generated 10000 digits numbers by the set current of 1.31mA. In the generated numbers, occurrence of “1” was 4517 and that of “0” was 5483. We evaluated the randomness of the generated numbers by a run test and a poker test. The run test is to check the probability of the series events, such as “0”, “00”, “000”, “0000” and versa, which will exponential decay as the number of series events increases. The poker test is to check the probability of the group events, such as “001”, “010”, “110”, which will have the same probability.

Figure shows the results of the both tests. In the run test, the probability of the both “0” and “1” series events decreased exponentially as the number of series events increases. In the 3-bits poker test, the probability of the group events (“001”, “010”, “100”) and (“110”, “101”, “011”) showed good uniformity.

These results indicate the random numbers generated by the “spin dice” has good randomness.

In summary, we demonstrated the random number generation by the “spin dice”, which is the random number generator by CIMS, by using a MgO-MTJ with a large MR ratio. The randomness of the generated random numbers was evaluated by the run test and the poker test. The results agreed well with the estimated values from the probability of the single event.

Because CIMS is quite fast (~ 1 nsec) phenomenon and the switching results show good randomness, “spin dice” can be expected to be a next generation high-speed genuine physical random number generator.

Towards dense regular arrays of FePt nanomagnets by gas phase deposition onto bacterial S-layers within a horizontal magnetic field.

U. Queitsch¹, D. Pohl¹, A. Blüher², M. Mertig², L. Schultz¹, B. Rellinghaus¹

1. *Metastable and Nanostructured Materials, Leibniz Institute for Solid State and Materials Research Dresden, Dresden, Germany;* 2. *Max Bergmann Center of Biomaterials, Dresden University of Technology, Dresden, Germany*

Regular arrays of ferromagnetic nanoparticles have a great potential for applications such as ultra-high density magnetic data storage media. L1₀-ordered FePt nanoparticles can be produced by gas phase preparation and subsequent in-flight annealing [1]. The random spatial distribution of the particles due to their statistical arrival necessitates the utilization of appropriate substrates to obtain regular particle arrangements. Recently, we have reported the successful application of bacterial surface layers (S layers) serving as templates for the regular arrangement of FePt nanoparticles from the gas phase [2]. In the present contribution, we report on experiments to create dense regular arrays of FePt nanoparticles. The influence of agglomeration at high particle densities is investigated and a route to reduce the degradation of regularity at high particle densities is introduced. The latter is achieved by the particle deposition in the presence of a magnetic field.

S layers are regular protein crystals with various symmetries and unit cell dimensions in the range from 3 to 30 nm [3]. The used S layer is of the type *Bacillus sphaericus* NCTC 9602. It has a p4 symmetry and a lattice constant of 12.5 nm. S layer sheets are adsorbed on carbon coated copper grids and subsequently negatively stained with 2.5% uranylacetate. FePt nanoparticles are prepared via inert gas condensation. The density of the particles on the substrate is controlled by the deposition time. The deposited particles are characterized by transmission electron microscopy (TEM). The degree of regularity of the nanoparticle arrangement is determined by statistical evaluation of the particle positions. The particles are assigned three different sites of the protein lattice: A, B, and C denote sites corresponding to the minor four-fold symmetry axis, the minor two-fold symmetry axis, and the major four-fold symmetry axis of the S-layer lattice, respectively [2]. Particles which cannot be attributed to any of these sites remain undefined (fraction D). In order to make the result of the statistical evaluation more transparent to the reader, in all statistical plots the mere random occupation of sites is indicated by shaded grey columns.

Fig. 1 a) shows a typical TEM image of FePt nanoparticles deposited in a field of 1 T applied parallel to the substrate on stained S layer sheets with a particle density of 30%. Fig. 1 b) shows the redistribution of the particle positions at increasing particle density. At ca. 3% particle density 52% of the particles adsorb at position A, 16% at B, 5% at C and 27% of the particles adsorb at undefined positions. Fourier analysis of the TEM images reveals a transfer of the symmetry and the lattices constant from the template to the particle arrangement due to the preferential adsorption at site A. With increasing particle density, the fraction of particles on site A is strongly decreased. Along with the decrease of the A site occupancy there is an increase of the fraction of undefined particles due to an increased degree of agglomeration at higher particle densities (Fig. 1 d)).

Fig. 1 c) shows the evolution of the particle arrangement with increasing density when the particles are deposited with a magnetic field of 1 T applied in the plane of the substrate. At a particle density of 3%, the site occupancy is very similar to that observed for particles deposited without magnetic field (cf. Fig. 1 b). The decrease of the occupancy of site A as observed when no magnetic field is applied and the increase of the undefined fraction with increasing particle density are strongly reduced in the presence of a field. At a particle density of 10%, still roughly 40% of the particles occupy site A. This value remains almost constant up to the highest investigated particle

density of 37%. The effect of increasing the degree of order in the particle arrangement that goes along with the preferential occupation of A sites upon applying a magnetic field is due to the field induced dipolar particle-particle interaction which helps preventing the agglomeration (Fig. 1 d)).

The storage of data in modern hard disks relies on the stability of the magnetization of magnetic bits. Reducing the size of the bits allows higher storage density. The smallest bit can be realized by a single atom and its stability by the magnetic anisotropy of the atom. We used a scanning tunneling microscope to image single Fe atoms on Pt(111) at 4 K. With inelastic tunneling spectroscopy the excitations of individual Fe atoms were measured. The excitations were detected in the second derivative of the tunneling current exhibiting a peak and a dip symmetric with respect to the Fermi energy. From the position of the extrema the excitation energy was determined. Assuming a spin of $S = 1$ for the Fe atom, the excitation energy is found to be identical to the uniaxial magnetic anisotropy. We determined the magnetic anisotropy to 5.7 ± 0.1 meV per atom in good agreement with XMCD measurements of single Co atoms on Pt(111) [1]. The experimental energy is compared with theoretical calculations of phonon energies and the magnetic anisotropy of single atoms in fcc and hcp adsorption sites.

Metallic nanoparticles (MNP) with large magnetization (such as Co, Fe and their alloys) have shown great potential in biomedical applications such as magnetic resonance imaging (MRI), bio-magnetic sensing, and magnetic nanoparticle hyperthermia [1-3]. These metallic nanoparticles are commonly synthesized by chemical routes, which are powerful but the size of nanoparticles are often limited to below 20 nm. Beyond this size, it is difficult to attain monodispersity and the onset of ferromagnetism results in coercivity, remanent magnetization and consequently magnetically induced agglomeration. Furthermore, chemical stability of metallic magnetic nanoparticles in biological medium is usually reduced. In this work, we report a direct physical fabrication of aqueous stable disk-shaped synthetic magnetic nanoparticles (SMNP) with a diameter of ~100 nm and high moment ferromagnetic constituents. The particles exhibit a vortex state with nearly zero remanence, thus preventing agglomeration while retaining high magnetization at intermediate magnetic field. Our results indicate that SMNP are promising as multi-functional materials, e.g., as contrast agent for MRI and as heating element for cancer treatment.

SMNP composed of 24 nm $\text{Co}_{90}\text{Fe}_{10}$ ($M_s=1600 \text{ emu/cm}^3$) sandwiched by thin layers of Ta (serve as protection layer) are fabricated using a “top-down” approach. First, nanotemplates are formed using the advanced patterning technique of nanoimprint lithography (NIL). These templates are then used as substrates for the deposition of magnetic films with precise thickness control. Finally, chemical solvents, etches and surfactants are used to release the nanoparticles and to stabilize them in solution. Fig. 1 shows monodisperse 120 nm diameter SMNP after release from the substrate.

The magnetic properties of SMNP are readily characterized by an alternating magnetometer (AGM). Hysteresis loops of vortex state are clearly observed. Based on the unique shape of the hysteresis loops, we proposed a method of applying these nanoparticles for hyperthermia. A DC bias magnetic field and an AC magnetic field are used to take advantage of hysteresis losses. Magnetic heating efficiency as a function of DC and AC field is estimated from the static minor hysteresis loop measurements and plotted in Fig. 2. A maximum of 560 W g^{-1} specific loss power (SLP) may be achieved for $fH = 4.1 \times 10^9 \text{ A m}^{-1} \text{ s}^{-1}$. MRI measurements of the transverse relaxation rate (R_2 and R_2^*) show that these synthetic nanoparticles have MRI relaxation properties more desirable than commonly used iron oxides.

For ensembles of magnetic nano-clusters to display intrinsic ferromagnetism, it is necessary that they possess either large magnetic anisotropy or that they are held at very low temperatures. This is because the ratio of anisotropy to thermal energies governs the orientational stability of the magnetic moment of the nano-clusters. This is particularly important for magnetic media where the nano-magnets must exhibit large magnetic anisotropy at room temperature and in addition perpendicular anisotropy for new perpendicular magneto-recording applications.

It has been known for quite some time that the L10 highly ordered FePt alloy exhibits the required large magnetic anisotropy and when prepared in thin film form, adequate deposition control can also ensure strong perpendicular magnetic anisotropy. But an important fabrication aspect for media applications is to achieve nano-magnets with this phase and perpendicular anisotropy.

Ion beam irradiations applied to FePt magnetic thin films have recently attracted strong interest to modify the magnetic properties in materials in useful ways for this application. Thus, control of the coercivity in Co/Pt multilayers using the irradiation of 30 keV He⁺ ions [1], and 130 keV He⁺ ions [2] has been reported. Ion beam projection onto Co/Pt multilayers using a stencil mask and fabrication of Co/Pt magnetic dots with diameters less than 100 nm [3] has also been demonstrated. Other researchers have implanted B⁺ ions onto as-deposited disordered FePt thin films and have studied the magnetic properties, surface roughness and crystalline structures before and after thermal annealing as a possible method to fabricate magnetic patterns with different coercivity without degrading the surface quality of the as-deposited films [4]. Many of these beam-induced patterning methods exhibit advantages for the fabrication of patterned media when compared with other conventional methods [5]. In our earlier work we have also demonstrated that rapid thermal annealing using synchrotron X-Ray radiation (XRTA) provides an adequate tool for modifying and probing structural modification of FePt thin films in real time. [6]

We have now investigated an alternative ion-beam approach by implanting Pt films with Fe⁺ ions followed by annealing treatments to ensure formation of the L10 phase and perpendicular magnetic anisotropy suitable for ultrahigh-density recording media. The Pt films were epitaxially deposited at room-temperature on (001) MgO substrates using DC magnetron sputtering. The ion-implantation was carried out at a heavy-ions accelerator. The microstructure, surface morphology and magnetic properties were characterized using XRD, AFM/MFM and polar Kerr magnetometry. In order to promote the formation of the L10 phase, the implanted samples were UHV annealed. Figure 1 shows the polar Kerr hysteresis loops measured on two different nano-composite ion-implanted samples. The left figure depicts hysteresis loops corresponding to one sample before and after in-situ annealing at 400C. We notice that the implanted sample exhibits paramagnetic behavior, typical of Fe nanoclusters embedded on the Pt matrix. After annealing the sample exhibits strong perpendicular magnetic anisotropy due to the onset of the L10 phase, as confirmed by XRD. The right curves correspond to various regions sampled by the light spot of the polar Kerr setup on a second sample implanted with a larger dose than the former and in-situ annealed at 400C. Both samples exhibit uncoupled magnetic nano-regions with strong perpendicular magnetic anisotropy due to formation of the L10 phase. Thus we have demonstrated that with our new experimental approach using ion-implantation and thermal treatments it is possible to tailor the magnetic anisotropy in useful ways for magneto-recording applications.

Surface relaxation and magnetism in monodisperse binary metal nanoparticles.*M. Farle**Physik, Universitaet Duisburg-Essen, Duisburg, Germany*

Monodisperse magnetic nanoparticles (2 – 15 nm) of almost any type of material and composition can be synthesized by gasphase condensation [1] or organo–metallic synthesis in well controlled sizes and different shapes (rods, tubes, spheres, cubes) [2,3]. These “building blocks” offer new exciting possibilities to create new artificial composite materials like ultra-hard (or soft) ferromagnets (or ferrimagnets), multifunctional hollow magnetic microspheres or luminescent magnetic particles. In biomedical technologies magnetic hybrid or functionalized particles find applications in site targeted therapy, diagnosis, cell separation and water purification. In this talk some of these possibilities will be briefly reviewed. While most of this work does not require a detailed understanding of the intrinsic magnetism of the nanoparticle, future nanotechnological devices based on a single nanoparticle require a knowledge of local crystal as well as electronic and magnetic structure and surface composition. Examples on how the interior and surface structure can be analysed with sub-Angstrom resolution [4,5] and with element specificity will be discussed. And finally, challenges for magnetic and electronic structure analysis [6] will be pointed out.

Magnetic nanoparticles have attracted great attention in the last years due to their interesting fundamental properties. Recently, the potential use in Biomedicine has increased the interest in these magnetic nanoparticles in the superparamagnetic region. This is because they can be used as magnetic carriers of drugs, antibodies or cells, they can be heated up by alternating magnetic fields and potentially kill the cancerous cells by hyperthermia or be used as contrast agents for MRI [1]. At present there is a big effort in synthesizing biocompatible magnetic nanoparticles with high susceptibility because this will improve the attraction and actuation of the particles by external magnetic fields.

With this aim we have synthesized Fe nanoparticles coated in a polymer. The role of the polymer coating is twofold: on one hand it prevents the Fe from oxidizing and leaching, and on the other hand it allows the functionalization of the particles. The Fe@polymer nanoparticles have been synthesized by a microemulsion method in two steps following a similar reaction route used by Zhou et al. [2].

The particles have been characterised by means of X-ray diffraction (XRD) and transmission electron microscopy (TEM). The magnetic properties have been studied by means of the 300 K hysteresis loop performed in a high-field vibrating sample magnetometer (VSM) and a zero-field cooling - field cooling (ZFC-FC) curve at 25 Oe in a SQUID magnetometer.

XRD (Figure 1) shows a clear Fe bcc phase and no presence of Fe oxides can be detected. The polymer coating is consequently properly preventing the oxidation of the Fe cores. From Rietveld fit of the data we get a lattice parameter of 2.866 Å, essentially the lattice parameter of bulk bcc Fe (2.87 Å), and a crystalline size of 35 nm. XRD can not resolve too small nanostructures and consequently this particle size can be considered an upper size limit. In fact TEM images show an important polydispersity, the smallest particles having a 7 nm core and 1.5 nm coating.

The polydispersity is confirmed in the magnetic measurements. In particular, the ZFC curve (Figure 2) displays a superparamagnetic behaviour with a blocking temperature of ~ 80 K. The peak is very broad, what means that there are multiple blocking temperatures due to multiple nanoparticle sizes. The 300 K hysteresis loop is shown in Figure 3. The saturation magnetisation is as high as 120 Am²/kg. This value is in between that of the Fe oxide with highest saturation magnetisation (magnetite, 90 Am²/kg) and bulk Fe (217.2 Am²/kg) and to our knowledge it is among the highest found in the literature for Fe nanoparticles. Zooming into the low-field region shows that the loop is not fully superparamagnetic but has a coercivity of ~ 120 Oe and a remanence of ~ 19 Am²/kg. This means that there is a non-negligible ferromagnetic phase possibly from monodomain particles that could explain the FC branch not collapsing with the ZFC one in Figure 2. Finally, the hysteresis loop shows a paramagnetic or antiferromagnetic contribution that could be due to the presence of an iron oxide. The latter hypothesis will be confirmed by Mössbauer experiments.

In conclusion, we have been able to synthesize high susceptibility Fe nanoparticles of sizes in between 7 and 35 nm coated by a polymer. The particles seem to have an oxide layer in between the core and the coating. Forthcoming Mössbauer experiments will prove the presence of Fe oxides.

Magnetic nanoparticles (NP) [1] have attracted much research over the recent years due to their potential interests in a variety of biomedical applications [2]. Recently, we demonstrated [3] that magnetite Fe₃O₄ NP synthesized by the high-temperature decomposition of an organic Fe precursor in the presence of oleic acid molecules covalently bonded to the NP surface show unusually high saturation magnetization, M_s , values (80-85 emu/g), close to the expected for bulk Fe₃O₄ (92 emu/g). Furthermore, these M_s values are much larger than those in NP prepared by the usual coprecipitation method (55-60 emu/g), for which there is no chemical bond between the coating (dextrane, TMAOH, PVA, ...) and the NP surface. In order to understand this behavior, we have studied the surface contribution to the magnetic anisotropy and the orbital contribution to the magnetic moment of Fe₃O₄ NP particles with mean diameter of a few nanometers, as a function of the coating (oleic acid versus PVA). Besides, high resolution transmission electron microscopy (HRTEM) has been used to evaluate the crystal quality of the NP. By means of ac susceptibility and time-dependent thermoremanence, we obtain a surface anisotropy constant $K_s = 3 \times 10^{-2}$ erg/cm² in oleic acid-coated NP, very similar to the values in literature for a variety of magnetite NP ($K_s = (4-6) \times 10^{-2}$ erg/cm²), suggesting that the occurrence of high M_s is not due to a decrease in the surface anisotropy. X-ray magnetic circular dichroism (XMCD) data confirm the dependence of the magnetic moment on the surface bond and suggests that the orbital contribution is smaller in covalently bonded NP, such that the latter approach a bulk-like behaviour. The occurrence of bulk M_s in Fe₃O₄ NP may thus be related to the crystal and magnetic state at the surface, as HRTEM suggests. This is of relevance in biomedical applications to reduce the strength of the magnetic field required to obtain a high magnetic response, while the issue of the orbital contribution in Fe₃O₄ is under hot debate nowadays. High density magnetic nano-dot arrays can lead to novel magnetic storage media, in particular when the preferential direction of magnetisation can be changed from the commonly observed in-plane to out-of-plane. We present results on in-situ prepared Co/Au and Co/Pt based nano-dot arrays on selforganised SiGe, exhibiting magnetic remanence at room temperature. We present in-situ Co L-edge X-ray Magnetic Circular Dichroism (XMCD) spectroscopy measurements, in combination with spectro-microscopy results. Both measurements prove the occurrence of a perpendicular Co dot array magnetization and magnetic remanence. We characterize the spin reorientation of these dot arrays between the temperatures of 300 and 100K as a function of Co, Pt and Au cap thickness. We measure the Co dot orbital and spin moments both within the in- and out-of-plane magnetic phases. The local atomic structure of the Co atoms is characterized by means of Co K-edge Extended X-ray Absorption Fine Structure (EXAFS) measurements.

In order to produce the arrays of magnetic dots, a self-organized, Si(0.5)Ge(0.5) thin film grown by molecular beam epitaxy and capped with 3nm Si was used as a template. The surface consists of isotropically arranged, {113} faceted pyramids terminated by a (001) top surface, which was characterized by Atomic Force Microscopy (AFM). Due to the lateral size of the base length of about 200 nm the features are well suited for the detection of independent magnetic areas by X-ray Photoemission Electron Microscopy (XPEEM)-XMCD and the {113} facets, which are tilted 25.3° with respect to the surface, are advantageous to generate isolated nanomagnets, with no magnetic material in-between, by shadow deposition. /1,2,3/ (Au/Co/Au) and (Pt/Co/Pt) stacks were grown by electron beam evaporation, with the base pressure in the 10⁻¹⁰ Torr range; Au was deposited at room temperature under normal incidence to cover the substrate more efficiently, whereas Co was evaporated at grazing incidence (16 degrees), to selectively cover determined areas while avoiding others ("shadow effect") as previously described. /2,3/ Pt was deposited either at normal or grazing incidence. The XMCD spectroscopy measurements in X-ray absorption were performed at the bending magnet based beamline D1011 at MAX-lab. The XMCD data are compared to XPEEM-XMCD data taken under similar conditions at 300K at ELETTRA, as described earlier by Mulders et al. /1/.

The XPEEM-XMCD results indicate the existence of both in- and out-of-plane magnetisation, for Co/Au, Co/Pt, Au/Co/Au and Pt/Co/Pt dot arrays coupled in domains at room temperature, for a Co thickness of order 2-3 atomic Co layers, in contrast to what is found earlier for the corresponding thin films. The individual dots are found to carry a magnetic moment at 300K, as found earlier by directly depositing on the SiGe surface /1/. In all cases with a Au or Pt under-layer, we find a spontaneous macroscopic remanence both out-of-plane and in-plane. This finding is in contrast to what is found in the case of thin Co films, grown on Au. Even cooling the samples at 100K does not eliminate the in-plane component completely. The range of stability of the out-of-plane phase in the case of Au appears to be larger than in the case of Pt. For both systems the in- versus out-of-plane orbital moment anisotropy, is not always related with an out-of-plane magnetization and the occurrence of a spin reorientation. For Co/Au rather an overall increase of the orbital moment is found

as one increases the amount of the capping Au layer in the range of a couple of monolayers. In particular, only a small variation of the Au cap thickness from 1.5 to 2.2 monolayers, leads to an abrupt increase of the orbital moment, indicating the strong correlation magnetism to structure for this system. For Pt/Co/Pt dots we find no such trend.

Hard x-ray near edge and EXAFS experiments were performed at beamline I811 of MAX-lab and at HASYLAB, beamline A1. EXAFS spectra were measured at room temperature over the Co K-edge in fluorescence yield mode. To maximize the signal-to-background ratio from the weak K-alpha fluorescence intensity from the dots long accumulation times were chosen. For the Au/Co/Au dots we find a strong reduction of the EXAFS amplitude for all neighbor shells versus a "standard" Co (hcp) foil. The best EXAFS fit indicates a loss of about 5 of the Co two nearest neighbor shell atoms. The EXAFS data indicate a non-pseudomorphic growth of Co on the Au underlayer. For the Pt/Co/Pt dots, the reduction of the two nearest neighbor shell atoms is found to be less severe than the one observed for Au.

Summarizing, we determine the thickness and temperature range of the spin reorientation transition for the Au/Co/Au and Pt/Co/Pt system for a regular array of nano-dots, and describe differences between the two systems. The spin reorientation can also occur with no orbital moment anisotropy, highlighting the sensitivity of the magneto-crystalline anisotropy upon small variations of the local structure.

Granular Co thin film multilayer constitute a family of nanoparticle systems for understanding size effects in Magnetism. Co clusters of nearly spherical shape can be produced by sputtering of Co on amorphous alumina. Capping with a noble metal allows us to modify the matrix that surrounds the particle, thus modifying its magnetic properties. When capping with Cu or Au the particles behave as superparamagnetic with anisotropy constants that depend on the metal capping [1]. Instead, capping with Pt has a completely different effect. In this case Co particles are strongly coupled via the polarized Pt [2]. In this paper we show that the Co/Pt granular multilayers present strong perpendicular anisotropy to the substrate plane.

The sample measured has been a trilayer of $\text{Al}_2\text{O}_3/\text{Co}/\text{Pt}$; i.e. with just one Co granular layer. The nominal Co deposition was $t_{\text{Co}} = 0.7$ nm, which produces Co particles of 3 nm diameter. The capping Pt film has $t_{\text{Pt}} = 1.5$ nm depth.

Indeed, magnetization measurements $M(H)$ measured parallel and perpendicular to the substrate plane were performed at several temperatures. There is a characteristic step near $H=0$, showing that there are two subsystems, the high coercive one and a soft component. In the direction perpendicular the coercive field is $H_C = 5$ kOe at $T = 5$ K (Fig. 1), and decreases with temperature its disappearance at 200 K (Fig. 2), while in the direction parallel to the substrate plane there is no coercive field. This implies that the anisotropy is a collective property of the Co particles, and that spontaneously the selected anisotropy direction of the Co particles is perpendicular to the plane. This conclusion is of paramount importance for application as a large density memory device.

The anomalous Hall resistivity measurements performed on the same sample at 5 K in the perpendicular direction show as well strong anisotropic behavior, with a coercive field which coincides with the magnetization measurements.

To ascertain the origin of the perpendicular anisotropy we have performed XMCD spectroscopy of the L_2 and L_3 edges of Pt and Co. The polarization of the Pt by the magnetic Co is detected as a non-zero signal of the L_2 and L_3 Pt edges. In Fig. 3 the XAS and XMCD at the Co L_2 and L_3 edge spectra at several incidence angles are shown. The orbital to spin ratio $m_L/m_S = 0.10$, is similar to that found for CoPt alloys [3], and is constant, independently of the incident angle. On the other hand, the intensity of the L_3 minimum is found to decrease clearly with increasing incident angle, which implies that the orbital moment in the perpendicular direction is larger than in the parallel one, thus proving the orbital origin of the induced anisotropy.

Magnetic particles have attracted much attention both for their fundamental interest and for their potential applications. In particular, small permanent magnets at the nano-scale would make possible ultra-high density magnetic storage devices. However, at such a size, the magnetization direction of a particle usually fluctuates at room temperature (superparamagnetism). In order to increase the magnetization thermal stability, great efforts have been directed towards an enhancement of the nanoparticles magnetic anisotropy energy (MAE). One of the preferred routes is to use magnetic alloys like FePt or CoPt: they can crystallize in the chemically ordered L10 phase, corresponding to a very high magnetocrystalline anisotropy for the bulk.

In this context, despite significant advances, it is still very difficult to produce well-defined CoPt nanoparticles in the L10 phase. Although this phase is the stable one at room temperature, an additional difficulty may come from the lowering of the order-disorder transition temperature (from the L10 phase to the chemically disordered A1 phase) due to the size reduction of the particles. Moreover, chemical ordering is in general obtained by annealing, which goes with problems of pollution or coalescence, difficult to avoid. As a consequence, in spite of a huge number of published results on these systems, there exists, to our knowledge, no convincing experimental study reporting a value of the intrinsic magnetic anisotropy for well-characterized L10 CoPt nanoparticles. Indeed, it is a tricky task to ensure that CoPt nanoparticles have a well-known magnetic size, are chemically ordered, are non-interacting, etc. to correctly deduce the intrinsic properties of well-defined nanoparticles from macroscopic magnetic measurements.

In this article, we report the synthesis and characterization of well-defined CoPt clusters, produced following a physical route, with a mean diameter of ~3 nm. We show that, despite a striking change of the Co magnetic moment, the magnetic anisotropy of chemically ordered nanoparticles increases in much lower proportions than what is observed for the bulk, with respect to the chemically disordered phase.

Samples made of diluted CoPt particles layers have been produced using the LECBD technique. As-prepared clusters are crystallized in the A1 phase and chemical ordering is achieved by annealing (2h at 650°C, under vacuum). We have been able to directly evidence the L10 chemical order (see Fig. 1) by high-resolution TEM (HRTEM), even for particles with a diameter down to 2 nm. Using amorphous carbon (aC) as capping layer, we have verified that annealing does not go with cluster coalescence, so that the particle size distribution is preserved.

X-ray magnetic circular dichroism (XMCD) measurements on diluted thin films of CoPt clusters embedded in aC have been performed on both as-prepared and annealed samples, at the Co L2,3 edges. The x-ray absorption spectroscopy signal does not show any oxide contribution, and there is almost no difference in the edges profile between as-prepared and annealed CoPt particles. The mean orbital and spin magnetic moments per Co atom, m_L and m_S , have been determined using the sum-rules. We find that there is a striking enhancement of both m_L and m_S (and the m_L/m_S ratio too) upon annealing: m_L changes from 0.12 to 0.18 mB/at.; and m_S changes from 1.70 to 1.91 mB/at. According to TEM observations, this evolution is assigned to the L10 chemical ordering of

the particles. Surprisingly, the values measured for chemically ordered particles are significantly higher than those reported for a presumably L10 thin film.

Magnetic measurements have been performed at various temperatures on the same samples, using a SQUID magnetometer. Hysteris loops have allowed us to check that the clusters magnetic size is the same as the geometric one and does not vary upon annealing; and that the particles are not interacting. Magnetic susceptibility measurements following the ZFC/FC procedure also indicate that chemical ordering goes with a significant increase of the CoPt clusters MAE, which is determined using a ZFC curves fit. We find a value of $K_{eff} = 0.19$ MJ/m³, respectively 0.38 MJ/m³, for the as-prepared, respectively annealed, clusters. Although the MAE displays a 100% augmentation, it remains much lower than the one reported for the CoPt L10 bulk (~5 MJ/m³). A careful examination of the various physical explanations, taking into account the combined experimental results obtained by TEM, XMCD and SQUID, lead us to the conclusion that the reduced MAE of L10 CoPt clusters must be due to the small particle size. As a matter of fact, we may never be able to reach a magnetic anisotropy as high as the bulk one, for CoPt particles of a few nanometers diameter. This would constitute a serious setback for the expected technological applications...

Magnetic Hardening of FePt Nanomagnets by Ultra Short Time In-Flight Annealing.

E. Mohn, B. Rellinghaus, L. Schultz

Institute for Metallic Materials, IFW Dresden, Dresden, Germany

The large magneto-crystalline anisotropy energy of $L1_0$ ordered tetragonal FePt has pushed the research on the preparation and characterization of FePt nanoparticles significantly during the last decade [1]. However, the necessity to subject those particles to (post-preparation) thermal annealing processes in order to initiate the otherwise kinetically hindered formation of the hard magnetic $L1_0$ phase constitutes a severe problem, since it often leads to inter-particle coalescence and sintering. Only few approaches were clearly proven to allow for the preparation of individual $L1_0$ ordered and thus magnetically hard FePt particles without sintering [2]. In our earlier experiments, the gas-phase preparation of FePt nanoparticles in combination with in-flight annealing was shown to allow for the formation of $L1_0$ ordered particles, however, with only a relatively small fraction of ordered particles and relatively poor coercive fields [3, 4].

In the present paper, we demonstrate that upon optimizing the particle trajectories within the optical annealing furnace, the fraction of $L1_0$ ordered particles can be significantly improved. The FePt nanoparticles are grown from a supersaturated metal vapour as provided by DC magnetron sputtering in an inert gas atmosphere and pass a light furnace in high vacuum prior to their deposition [4]. By laser positioning of the substrate it is assured that particles which reach the substrate have travelled within the narrow focal center of the light furnace which focuses the light of three halogen lamps onto a central tube of roughly 10 mm in diameter by means of elliptical mirrors. Owing to the construction of the light furnace any heating of the substrate is prevented as evidenced from monitoring the substrate temperature. Electrical powers of up to $P = 4.5$ kW can be supplied to the lamps of the furnace. Fig. 1 shows exemplarily the TEM image of FePt nanoparticles with a mean particle size of $d_p = 7$ nm that have been optically annealed with $P = 3.5$ kW. According to simulations of the (size dependent) interaction of the particles with the electro-magnetic field of the furnace this results in an annealing of the particles at roughly $T_A = 900$ °C for about $t = 2$ ms. As evidenced from HRTEM and electron diffraction studies and in agreement with the stability range of the $L1_0$ phase in a time-temperature-transformation diagram for the $L1_0$ ordering kinetics derived from DSC measurements of nanocrystalline FePt [5], likewise treated particles transform (partially) to the $L1_0$ phase. Statistical HRTEM investigations reveal that roughly 60% of the particles exhibit the $L1_0$ order and that larger particles order more easily than smaller ones. Fig. 3 shows the magnetization curve at $T = 15$ K for these optically annealed particles. Although the coercive field of $\mu_0 H_c = 0.65$ T is relatively small, the open hysteresis curves indicates the presence of particles with much higher individual coercivities. Accordingly, the distribution of switching fields as derived from the field derivative of the isothermal remanent magnetization $\chi_{irr} = dM_r/dH$ reveals that more than 50% of the particles' magnetization is switched only at fields above 1 T (cf. Fig. 4), and even at room temperature, roughly one fourth of the particles remain to have switching fields above 1 T.

Flying Characteristics on Discrete Track and Patterned Media With Thermal Protrusion Slider.

B. E. Knigge, Z. Z. Bandic, D. Kercher

San Jose Research Center, Hitachi Global Storage Technologies, San Jose, CA

Abstract—Future disk drives may have discretized bit patterns for increased thermal stability and higher areal density. This affects the surface topography resulting in different flying characteristics of currently used air bearing slider. The actual flying height drop vs. the pattern density and pattern depth has not been measured but simulated [1].

We have made flyable patterned media with angular sections having various topographies. This allowed the measurement of flying height modulation and clearance drop within one revolution in different sections of the disk.

Slider to disk clearance changes were measured using pulsed thermal protrusion.

I. INTRODUCTION/MOTIVATION

Patterned media and discrete track media flying characteristics have been recently simulated by Duwensee and Li [1]. Duwensee established an empirical relation between flying height as a function of groove depth, groove width and groove pitch (Eq. 1). He found that homogenization methods applied to the generalized Reynolds equation are still an excellent approximation down to groove dimensions of a few nanometers, i.e. less than the mean free path of air.

$$dFH = d \cdot (w/p) \quad \text{Eq. 1}$$

Where FH= flying height, d= groove depth, w = groove width and p= groove pitch.

Discrete Track Media (DTM) and Patterned media fabrication methods have been discussed by Bandic [2] using direct e-beam writing, nanoimprinting, and reactive ion etching. We used direct e-beam writing and optical lithography methods to generate flyable media. Using optical lithography we generated holes at various widths, depths and pitch. This paper discusses the flying characteristics as measured by a laser Doppler vibrometer (LDV) and acoustic emission (AE) sensor when flying over patterned media sections. The FH drop is compared to simulation results.

II. EXPERIMENTAL SETUP

To measure slider to disk clearance we used pulsed thermal protrusion [3]. In order to perform localized clearance measurements a computer with simultaneous signal generation and data acquisition was programmed in Matlab and synchronized with spindle index.

III. RESULTS

In Figure 1 we show one of the patterned media layouts for flyability studies. We choose a large 180 deg patterned and flat section so that there is enough time for the air bearing to settle due to air bearing damping and enough time for the protrusion to fully develop.

Figure 2 shows the RMS of the acoustic emission signal with increased thermal actuation. Increased noise due to head disk contact is detected at ~45mW TFC power on the flat portion of the disk whereas the patterned portion of the disk shows contact at already at 20mW TFC power.

In Figure 3 we show the fly-height (FH), or clearance change, as a function of pattern density for 40nm deep holes and 17nm deep holes. The lowest density (least disk coverage) pattern had about 9% disk area covered by holes.

The linear fit (when including 0) shows a FH drop of about 0.4 and 0.17nm per % change in coverage, resulting in a 20nm FH drop at 50% pattern density for 40nm deep holes and 8.5nm FH drop for 17nm deep holes. Apparently, the slope is equal to the hole depth. One could translate equation 1 from DTM media to patterned bit media:

$$dFH = d_{\text{hole}} \cdot (A_{\text{hole}}/A_{\text{flat}}) \quad \text{Eq. 2}$$

With A_{hole} =area of holes and A_{flat} =area of flat or islands and d_{hole} =hole depth.

From Figure 3 we observe that equation 2 fits the data very well for 17nm deep holes but not as good for 40nm holes. From simulation results, nonlinearity is expected to occur for grooves deeper than ~30nm [1].

The air bearing pressure that builds up at the slider trailing pad carries most of the slider lift. By containing the pressure peak (such as it is done in holes) the FH drop is small compared to open (vented) grooves as on DTM media.

Nonuniform distribution of molecularly thin lubricant caused by inhomogeneous buried layers of discrete track media.

K. Fukuzawa^{1,2}, T. Muramatsu¹, H. Amakawa¹, S. Itoh¹, H. Zhang¹

1. Micro/Nano Systems Engineering, Nagoya University, Nagoya, Japan; 2. PRESTO, JST, Kawaguchi, Japan

Introduction

Discrete track media (DTM) is expected to provide much higher recording density than conventional magnetic recording. On DTM, even if it is planarized, the layer under the carbon overcoat consists of quite different materials in the track and off-track regions (Fig. 1): magnetic metal and nonmetal material such as dielectric, respectively. Therefore, the intermolecular interactions between a lubricant molecule and the disk surface are different in these two regions. This could cause a nonuniform lubricant distribution, which would significantly affect the tribological performance of the head-disk interface (HDI) because the lubricant is a submonolayer-thick film. This paper presents a theory for the distribution of lubricant on a surface with inhomogeneous buried layers and, using it, predicts the distribution on DTM.

Estimation of thickness distribution on inhomogeneous buried layers

First, the estimation method was theoretically developed. In Fig. 1, at hydrodynamic equilibrium, the lubricants in the track and off-track regions have the equal disjoining pressures. This leads to different film thicknesses in the two regions because the regions consist of different materials and the disjoining pressures are not balanced if the lubricants in the two regions have the same thickness. Formulating the balance of the disjoining pressures by using the theory on intermolecular force [1], we obtained the thicknesses in the two regions. Next, the validity of the theoretical estimation was experimentally verified. A 2.3-nm-thick oxide layer on a silicon surface was locally fabricated by probe oxidation, and 10.3-nm-thick nonpolar lubricant (PFPE-Z03) was then applied onto it (Fig. 2). The intermolecular interaction in the oxide region is lower than that of the silicon region. AFM images show that the thickness in the oxide region decreased by 0.4 nm due to the decrease in the interaction. In addition, the lubricant thicknesses on the oxide regions were measured for combinations of oxide layers and lubricant films with various thicknesses of the order of 1 nm. Comparing the estimated thickness with the experimental ones, we found that the difference in the thickness was about 0.26 nm in the standard deviation. This indicates the validity of our estimation.

Thickness distribution of lubricant on DTM

Using the above theory, we estimated the lubricant thicknesses on DTM. Even if lubricant with an initial thickness of h_0 is uniformly applied onto the disk, the lubricant moves from the off-track to track regions due to the pressure balance. Therefore, the lubricant is thicker in the track regions than the off-track region at equilibrium, as shown in Fig. 3. This shows that the difference in thickness is smaller when the carbon thickness h_c is rather large. This is because the thick carbon shields the intermolecular interaction from the underlying layer. On the other hand, the difference is larger when h_c is small. Reducing the magnetic spacing requires a thinner carbon overcoat. Thus, the nonuniform distribution will be an important issue in designing HDIs of DTM.

Summary

A method of estimating the thickness distribution on a surface with inhomogeneous buried layers was presented. It revealed that the lubricant distributes nonuniformly on DTM.

Parametric Study of Contact Performance for Discrete Track Recording Media Using Finite Element Analysis.

C. Yeo, A. A. Polycarpou

Mechanical Science and Engineering, Univ. of Illinois at Urbana-Champaign, Urbana, IL

ABSTRACT

As the pattern size of discrete track recording media is required to be smaller for achieving higher recording densities (Tb/in² and beyond), geometrical parameters such as land width, ratio of land width to track pitch, and groove depth become very important in improving head-disk-interface reliability. Computational simulations using finite element analysis have been performed on representative patterned surfaces to investigate the contact behavior of the discrete patterns. To recommend design trends for the geometrical parameters for improved contact performance, design-of-experiment analysis has been performed and a prediction model of critical contact force is proposed as a function of the relevant geometrical parameters.

INTRODUCTION

Pattern media have been widely investigated in the hard disk drive (HDD) industry to achieve higher recording densities. Discrete track recording (DTR) media is manufacturable with lower fabrication cost and higher accuracy, which enables DTR media to be more attractive for mass-production, compared to bit pattern media [1]. For these reasons, research on DTR media in relation to magnetic performance, fabrication techniques, and head slider flyability has been conducted [2-3]. However, there have only been few works on the head-disk-interface (HDI) contact mechanics of DTR media. In this paper, computational contact simulations using finite element analysis (FEA) have been performed on DTR media. Based on specified pattern dimensions such as land width (w), groove depth (d), and the ratio of land width to track pitch (w/p), the elastic and plastic contact performance of DTR media has been investigated. Through design-of-experiment (DOE) analysis, dimensional design directions of DTR media are proposed to achieve recording densities of 1 Tb/in² and beyond.

SIMULATIONS

Two-dimensional plane strain elements were used to model the DTR media in the FEA simulations. The nominal contact width of the rigid plane was chosen to be 3.12 microns moving downward (loading) and upward (unloading), while the deformable patterned media body was stationary. The finite element mesh of DTR media consists of 36,046 – 228,104 nodes and 34,688 – 228,195 elements depending upon the specific pattern dimensions examined. The radius of the pattern top curvature was 134 nm for small land width ($w = 40$ nm) patterns and 834 nm for large land width ($w = 100$ nm) patterns. The material type was isotropic and elastic-perfect plastic, and the friction coefficient was 0.2. The DTR media consisted of two layers. A 2.5 nm thick carbon overcoat (COC) was applied onto the pattern top made of “bulk” magnetic material.

RESULTS AND DISCUSSION

Based on the FEA simulation results, it was found that the outer located patterns exhibit higher contact stresses and deformations, and thus the material yield initiates on the outermost pattern as shown in Fig. 1. The material behavior during contact caused the outer patterns to have lower normal (downward direction) surface displacements but higher tangential movement to the contact center, which resulted in severe contacts. Once after the material yield initiated on the outermost patterns, the contact stiffness values of DTR media showed decreasing trend due to the growing plastic region on the patterns. To establish design guidelines, 2³-factorial DOE was performed using the aforementioned FEA contact simulations, thus investigating the effects of the three geometri-

cal factors on the DTR contact performance. The analysis of the main effects showed that the larger the land width, the larger the ratio of land width to pitch, and the smaller groove depth, they all improve the contact performance. However, based on the model analysis of the critical contact force in relation to the three geometrical factors, it was found that under some restrictions of one geometrical factor, the design directions of the two geometrical factors were not the same as those from the main effects analysis, but they were dependent on the given restrictions. Therefore, for optimum contact performance of DTR media, the three geometrical factors should be carefully determined based on the restrictions given by requiring recording density or nanofabrication methodologies.

Introduction

To achieve storage densities near 1Tbit/inch², discrete track recording (DTR) media are being investigated presently. DTR media reduce magnetic “cross-talk” in the radial direction by physically separating adjacent recording tracks from each other [1]. Fig.1 shows a scanning electron microscope (SEM) image of typical discrete track recording media.

The flying behaviour of a slider over discrete track media is affected by the presence of the grooves on the disk. In particular, the steady state flying height of a slider flying over discrete track media is lower than that of a slider over smooth media. Numerical investigations by Duwensee et al. [1, 2] have shown that the “flying height loss” Δh of a slider over discrete track media can be determined by $\Delta h = dxw/p$, where d is the groove depth, w is the groove width, and p is the track pitch.

In this study, an experimental investigation of the flying characteristics of magnetic recording sliders over discrete track media is performed. In addition, experimental measurements of “flyability” of two types of recording sliders are compared with numerical predictions.

Experimental setup and results

The flying characteristics of magnetic recording sliders over DTR media was investigated using acoustic emission (AE) sensors and laser Doppler vibrometer (LDV) instrumentation. Fig. 2 shows the schematic of the experimental setup. Fig. 3 and Table 1 illustrate the DTR media parameters used. To investigate the flying characteristics of magnetic recording sliders over DTR media, two pico sliders were used as showed in Fig. 4. Slider “A” is designed to fly at 11 nm over “smooth” media, while slider “B” flies at 20 nm.

Fig. 5 shows the standard deviation of flying height for sliders “A” and “B” as a function of groove depth. For slider “A”, designed to fly at 11 nm over smooth media, a small standard deviation of flying height is observed for a groove depth of 20 nm, indicating that the slider flies stable on this media. However, for a groove depth of 30 nm and 40 nm, large flying height fluctuations are observed, showing that the slider does not fly stable for those conditions. For slider “B”, designed to fly at 20 nm over smooth media, stable flying behavior is observed for a groove depths of 20 nm and 30 nm, respectively. However, for a groove depth of 40 nm, a large standard deviation of flying height is observed, indicating the slider is not flying stable.

Numerical model and results

To correlate the experimental results with numerical predictions, we have simulated the flying characteristics of the two sliders over DTR media using the “CMRR” finite element air bearing simulator [3]. Figure 6 shows the numerical predictions for the steady state flying height of sliders “A” and “B” for the three different DTR media used. We observe that slider “A” is predicted to fly at a flying height of 5 nm on DTR media with a groove depth of 20 nm. However, the predicted flying height is near zero for a groove depth of 30 nm and 40 nm, i.e., slider “A” cannot be expected to fly stable on DTR media with a groove depth of 30 nm or 40 nm. The above predictions are in excellent qualitative agreement with the experimental measurements of Fig. 5 which show that slider “A” flies stable on DTR media with a groove depth of 20 nm but does not fly stable on DTR media with a groove depth of 30 or 40 nm, respectively. For slider “B”, the numerical predictions show

that this slider flies on DTR media with a groove depth of 20 nm and 30 nm, respectively, while it cannot fly on DTR media with a groove depth of 40 nm. This result is likewise in excellent qualitative agreement with the results of Fig. 5, i.e., slider “B” flies stable on DTR media with 20 or 30 nm groove depth, respectively, but does not fly stable on DTR media with 40 nm groove depth.

From the above numerical and experimental results we conclude that very good qualitative agreement exists for the numerically predicted and experimentally measured flying characteristics of magnetic recording sliders on DTR media. Additional experiments should be performed using DTR media with different groove characteristics to “fine-tune” the comparison between experimental and numerical results.

Dynamic analysis schemes for flying head sliders over discrete track media.

S. Fukui, T. Kanamaru, H. Matsuoka

Dept. of Applied Mathematics and Physics, Tottori University, Tottori City, Japan

Introduction

Recently the spacing between the slider and the disk has been reduced to 10 nm or less and the recording media with grooves such as the discrete track media (DTM) is estimated one of the most promising media for achieving ultrahigh track density. Analyses of the static and dynamic characteristics of flying head sliders over DTM by the molecular gas-film lubrication (MGL) equation [1] become increasingly important. To obtain the dynamic characteristics of the air bearing, the perturbation method in frequency domain had been established [2].

In this paper, the highly accurate and numerically stable cubic interpolated propagation (CIP) method in time domain [3,4] was newly applied to fundamental MGL problem and slider dynamics. Moreover, the perturbation method in frequency domain was also applied to obtain air bearing stiffness and damping coefficient of the air bearing over DTM.

Dynamic air film pressures caused by a running single projection

Figure 1 shows the projection position on the running disk under the fixed slider and corresponding pressure distributions calculated by the CIP method. Negative pressure regime follows at approximately half the speed of the single projection, which agrees well with the theoretical result. Static and dynamic pressures by the DTM (Fig. 2)

Figure 3 shows an example of the static pressure distributions with/without groove (groove depth=10nm) for plane inclined slider with the minimum spacing of 10 nm. Figure 4 shows the corresponding dynamic pressure distributions in phase (stiffness) caused by 10 kHz translational excitation calculated by the perturbation method. It is found that DTM groove decreases both the static pressure and air film stiffness.

Conclusion

The numerical schemes to obtain the static and dynamic pressures and slider dynamics caused by DTM are established by the use of the CIP method in time domain and the perturbation method in frequency domain.

Effect of van der Waals Force on Ultimate Head-to-Disk Interface.

K. Ono

Storage Technology Research Center, Hitachi Central Research Laboratory, Fijisawa-shi, Japan

1. Introduction

To achieve a stable and reliable head-to-disk interface in the near-contact recording regime, a sphere-to-flat interface is indispensable for reducing the adhesion and friction forces and the contact pressure [1]. Such an interface seems to be realized by using thermal protrusion resulting from thermal flying height control. The areal density of 2 Tb/in² requires a mechanical spacing of 2–2.5 nm and a clearance of less than 0.5 nm, meaning that the slider will frequently come into contact with the disk. When the separation between head and disk decreases to less than 1 nm, van der Waals (vdW) force begins to play an important role in addition to the lubricant meniscus force. This paper describes an analytical study of the touchdown of a spherical pad slider to a disk due to elastic deformation when the two surfaces are attracted to each other by vdW force under static air-bearing pressure.

2. Analytical Model and Method

The thermally protruded surface of the center pad is modeled as a spherical pad with radius of curvature R , height δ , and base radius a (see Fig. 1). If R is 10–30 mm, the maximum possible meniscus force, $4\pi R\gamma$, is 3–9 mN. Since the air-bearing lift force (>20 mN) overcomes the meniscus adhesion force, the slider can stably fly over the disk surface. Therefore, an additional attractive force between the two surfaces is caused by van der Waals force when the pad contacts the disk. Thus, only the vdW force and static air-bearing pressure, P_{ab} , on the center pad was considered. The minimum gap at the tip of the pad is denoted by d . For analytical simplicity, the center pad is assumed to be circular with radius b , and P_{ab} is applied within this area. Elastic deformation of the mating surfaces is calculated numerically based on boundary finite element method. The vdW pressure is given by $A/(6\pi h^3)$ (A : Hamaker constant, $h(r)$: local spacing). Hertz pressure is applied to the contact area. For various values of initial separation d_0 from un-deformed disk surface, the convergent solutions for disk deformation, attractive pressure, final separation d , etc. were iteratively calculated. Parametric analysis of the effects of R , P_{ab} , and roughness height σ on attractive force F_a , disk deformation, and attractive pressure was conducted for $\delta = 10$ nm, $b = 30$ μ m, $A = 10^{-19}$ J, and $\gamma = 22$ mN/m.

3. Analytical Results and Discussion

Figure 2 (a) and (b) show attractive force F_a versus final separation d and disk deformation versus radial position for $P_{ab} = 3$ MPa and $R = 20$ mm, taking σ as a parameter. In the calculation, d_0 was changed from 0.7 nm to -0.5 nm by 0.1 nm. Meniscus force $F_m = 4\pi R\gamma$ and vdW force $F_v = AR/(6d^2)$ for a rigid sphere-to-flat interface are also plotted in Fig. 2(a) for comparison. In a rigid-surface interface, $F_m > F_v$ when $d > 0.25$ nm. The disk height beneath the spherical pad was less than -1 nm, and the adhesion force F_a was -8 mN before touchdown due to the 3-MPa air-bearing pressure. When d decreases from 1.1 nm, it jumps to σ and F_a changes abruptly to a higher value since the disk surface adheres to the spherical pad surface because of elastic deformation. This critical separation corresponds to the touchdown height. After the disk touches down on the pad, the attractive pressure is determined by the roughness height σ , whereas F_a is affected by σ and R . F_a increases further with a decrease in d_0 because of the increase in adhering area. Note that F_a immediately after touchdown is less than F_m at $\sigma = 0.55$ nm, whereas F_a is nearly equal to F_m at $\sigma = 0.50$ nm and substantially larger than F_m at $\sigma = 0.45$ nm. Assuming that F_a should be less than F_m for wear durability, σ must be more than 0.50 nm. The similar calculated results for $R = 10$ and 30 mm

are shown in Fig. 3. It is found that the allowable minimum roughness height satisfying $F_a < F_m$ at touchdown was 0.55, 0.50, and 0.45 nm for $R = 30, 20$, and 10 mm, respectively. The effects of other parameters on the head-to-disk interface will be discussed in the presentation and full paper.

4. Conclusion

The minimum possible touchdown height for non-contact recording is ~ 1 nm and the allowable minimum glide height is 0.5 nm if the pad radius is 20 mm. They can be reduced by reducing the pad radius of curvature.

STUDY ON CONTACT OF THERMAL ACTUATED SLIDER AND DISK.

M. Zhang¹, B. Liu^{1,2}, S. Hu¹

1. Spintronics, Media and Interface Division, Data Storage Institute, Singapore, Singapore; 2. Nanyang Technological University, Singapore, Singapore

Thermal actuated sliders provide better reading/writing properties and HDI stability in HDD. With the increase of recording density, the flying height of slider should be reduced gradually, which increases the possibility of contact between slider and disk. On the other hand, the contact recording technology is being explored in order to realize the maximum reduce of magnetic spacing for extremely high-density magnetic recording. In this paper, the contact between thermal actuated slider with disk was studied experimentally.

The contact was tested on a spindrive integrated with a Laser Doppler Vibrometer (LDV) and an Acoustic Emission (AE) sensor, as shown in Fig. 1.

When a thermal actuated slider contacted with disk, it was found single mode frequency (corresponding to air bearing resonance frequency of pitch mode) dominated the vibration, as shown in Fig. 2. It also was observed the lubricant redistribution after short time contact, the lubricant modulation frequency corresponds to slider resonance frequency, as shown in Fig. 3.

The testing results with different driving voltage showed: when the voltage was less 3V, no contact happened; the both LDV and AE signals showed the contact happened around 4V; when the driving voltage further increased from 4V to 8V, the strongest signal did not happen at the maximum driving voltage and corresponded to the voltage (~4V) at which contact just happens, as shown in Fig. 4. These results showed contact signal was strongest when the slider changed from flying to contact or from contact to flying. When the frequency of driving voltage increased from 20Hz to 80Hz, the above phenomena was same, only the amplitude of contact signal decreased with increase of the driving frequency as shown in Fig. 5.

The comparison of contact between the thermal actuated slider and disks with and without mobile lubricant showed the thermal actuated slider contacted the mobile lube disk with lower voltage than that of bonded lube disk; and the AE signal for the contact of the thermal actuated slider with bonded lube disk was higher than that with the free lube disk with same (large) driving voltage, as shown in Fig. 6. The comparison of AE, LDV and reader signal showed the reader signal was very sensitive for the contact monitoring. When a slight contact happened between slider and disk, AE signal had little difference with/without contact, LDV signal obviously has three peaks (correspond to slider's resonance frequency) after contact happened and reader signal strength increases at all frequency (0-2MHz) besides a few peaks after contact happened, as showed in Fig. 7.

Flying height (FH) control using thermal actuation has been introduced recently in HDD products as a new technique for compensating static FH variations of magnetic heads and reducing the risk of harmful head-disk contact. The cycle time of wafer and slider fabrication is long and some key parameters are not easily measurable, such as minimum and writer FH, and in-situ slider protrusion profiles. Therefore, it is of great importance to develop a model that can predict the actuation performance of different designs more accurately and reduce the product development time. For a flying slider, the performance of thermal actuation is determined not only by the head/heater structure and materials, but also by the ABS-dependent thermal boundary condition, forming a complex nonlinear thermal-structural coupled-field problem. The write pole-tip and read sensor protrude differently under different ambient temperatures, heater, and write settings. This paper describes a comprehensive model and validates it by measurements under various conditions.

Simulation and Measurements

In the first step we create a 3-D finite element model of the entire slider with detailed head/heater structure, and then conduct electrical-thermal-structural analysis using velocity slip and temperature jump boundary conditions to formulate the heat transfer across the head-disk interface when the slider flies on a spinning disk (Fig. 1). An iteration procedure, proposed earlier, is used to obtain the equilibrium solution. The slider and disk deformation due to air-bearing pressure is included since the pressure increases significantly when the FH is reduced to sub-5nm regime. Another critical parameter, pole-tip recession (PTR), created by lapping and etching processes, is also included in the model. Comparisons between simulation and measurements were made in both nonflying and flying conditions. In the nonflying condition, the slider is attached to an aluminum plate, and the protrusion profile is obtained by the difference of two images taken by Wyko (interferometer) tool when the heat source is turned on and off. The simulation shows excellent agreement with the measurement for the whole bulge profiles at all three conditions as shown in Fig.2. To measure the FH and clearance change profiles of the head element area in the flying condition, we have developed a new measurement method based on principle of conventional flying height tester (FHT). The FH is typically measured by detecting the interference light intensity, which may be expressed by refractive index (n , k), wavelength and FH. The element area consists of various materials with different optical properties. However, for a low flying slider the FH is proportional to the intensity in spite of the mixture of various materials. The FH profile including the element area can then be measured by using a microscopic light spot. Figure 3 shows a comparison of clearance change between simulation and FHT with a heater power of 65mW. It is seen that the model prediction agrees reasonably well with the FHT over the entire shape of the bulge. The clearance drop of the reader predicted by the model is ~ 0.5 nm more than the average value of measured data, which has a standard deviation of ~ 0.56 nm. The effect of slider and disk deformation on the FH due to the air-bearing pressure is shown in Fig. 4. The minimum FH of the case with rigid disk and slider is ~ 0.5 nm lower than that of the more realistic one, and the effect of the slider is more noticeable than that of the disk, even though the disk may deform up to about 2nm. However, only a portion of the disk and slider compression contributes to the FH increase because of the self-compensation of an air-bearing.

Dynamics of Fly-Contact Head-Disk Interface.

Introduction

Reducing the mechanical spacing between the head and the disk in hard disk drives is critical for achieving ultra-high recording densities. Realizing the flying interface with less than 2 nm clearance will be a significant challenge due to the instability induced by the adhesion forces between the slider and the disk. Therefore, a breakthrough is necessary to further reduce the mechanical spacing.

In-contact recording scheme, as proposed by many researchers, is a possible choice. However, the conventional ABS designs for in-contact recording, such as the tripad contact slider [1], have some drawbacks. For example, the contact force between the slider and disk is high, which may cause the serious wear and slider vibrations in fly-height (FH) and off-track directions.

To overcome the above-mentioned drawbacks, a new head-disk interface (HDI) scheme, i.e. fly-contact interface, is proposed by combining the major advantages of the fly and the in-contact recording schemes [2]. It allows the most of slider's air-bearing surface (ABS) to fly while having the tiny read/write head area in contact with the lubricant on disk the surface. The thermal nano-actuator technology can help to realize fly-contact scheme with the contact-on-demand mechanism. There are two main challenges for making a stable and reliable fly-contact interface. One is the sliders' bounce and the other is the wear between the slider and the disk. A key factor for minimizing the bounce and wear is to control and minimize the normal contact force and adhesion force exerted between the slider and the disk.

In this study, a series of simulations were carried out to investigate the contributions of contact force and adhesion force on the stability and reliability of the fly-contact HDI, and how to achieve a low contact force and a small flying-height variation.

Simulation on dynamics of fly-contact head-disk interface

In this study, the effects of different surface profiles of the contact pad on performance of fly-contact interface were investigated. A femto slider with a sphere-topped cylinder pad at the trailing center is used in this study, as shown in Fig. 1. The radius of the cylinder is 25 μm . The crown height varies from 1 nm to 20 nm, while the total height of the sphere-topped cylinder pad keeps constant. So the sphere-topped cylinder pad has the same height but different curvature radius. The slider flies over a disk with surface waviness. The DSI's self-developed air bearing simulation program, ABSolution, is used to simulate the dynamics of the head disk interface.

Fig. 2 shows the FH and FH variation of slider when the crown height h varies from 1 nm to 20 nm. It can be seen that the slider will keep contacting with disk when h is smaller than 6 nm, but will bounce when h is between 6 nm and 17 nm. When h is larger than 17 nm, the slider will keep flying status. From Fig. 3, it can be seen that the best choice of the sphere height is around 5 nm, as it can achieve both the low FH variations and the low contact force. In addition, it can be seen that the FH modulation due to the disk waviness in the fly-contact interface is much smaller than the one in the flying interface.

Conclusion

ABS design for fly-contact HDI needs to consider the balance of minimizing both the FH variation (bounce) and contact force (wear). The best choice of the ABS design is that the slider keeps a slight contact with disk without any bounce, because such design can achieve both the low FH variations

and the low wear. In addition, the fly contact interface has much better capability in following disk waviness than the flying interface does.

As the linear density increases continuously, the head medium spacing decreases down to nm level. The absolute flying height (FH) value is very important to evaluate the stability and reliability of HDI. The white light interferometry method has been used to measure FH for many years. Due to the strong negative pressure in modern slider design, the unload calibration process becomes unstable and has a big concern on the testing repeatability. To improve it, the latest version FH tester adopts the laser phase detection method and can achieve on-flying calibration. It significantly improves the repeatability of FH testing on the same spot. But the accuracy of FH measurement still largely depends on the dispersion range of optical constant.

The slider wafer material is the composition of TiC and Alumina. The optical constant ($n+ik$) of two materials has a big difference, which is $3.5+2.5i$ for TiC and $1.7+0i$ for Alumina. The effective n and k values largely depend on the area composition ratio of two materials. With 60X25 mircon spot size of Ellipsometer mapping over slider ABS, more than 1 thousand points were captured and the point by point plot of n and k is shown in Fig. 1. Both n and k values scatter in a certain range due to the change of the composition ratio of two materials at each individual spot. When the n value of each point is plotted versus the k value at the same point as shown in Fig. 2, it shows there is a quasi-linear relationship between n and k.

The current commercial FH tester only takes a pair of the averaged n and k values for FH calculation. If it's assumed that the FH of all the testing spots is at 5 nm, the calculated testing FH by the input of averaged n and k is plotted in Fig. 3. At 650 nm wavelength, the white light interferometry method produces more FH testing errors than the laser phase detection method for this type of slider.

In Fig. 4, the dispersion range of both n and k measured in Fig. 1 is used, but the n and k value can be combined freely, then the mesh of testing FH versus n and k is plotted (only k axis is shown) in the same way of Fig. 3. The line 1 in Fig. 4 is the measured n and k correlation. The n and k correlation varies when there is a change on slider roughness, overcoat thickness, and the optical constant of overcoat. If the n and k correlation takes line 2 in Fig. 4, the laser phase detection method can generate ± 3 nm FH testing error.

In this work, a model to calculate the n&k dispersion versus the composition ratio of TiC and Alumina, slider roughness, and Si/DLC overcoat thickness was developed. The slider samples with different roughness and overcoat thickness were prepared and measured to verify the model. From both theoretic and experiment study, the laser phase detection method has smaller FH error at current roughness and overcoat thickness. As the overcoat thickness decreases, the FH error of phase detection method tends to increase. The accuracy of both optical methods largely depends on slider fabrication process defined n&k correlation rather than the absolute value of n&k dispersion.

Introduction: In a hard disk drive, the slider flies on the rotating disk with about a 10 nm gap between the slider and the disk by balancing between the air pressure on the bearing surface and gramload (GL) and static torques (PST, torque in pitch direction, and RST, torque in the roll direction) from the suspension. The torques come from the pitch/roll static attitudes, PSA/RSA, and the X/Y offsets between the slider and the dimple. PST from PSA can be calculated as a product of PSA and the pitch stiffness, Kp, of the gimbal structure. Similarly, RST is the product of RSA and Kr. A large Kp and/or Kr results in a large flying height (FH) distribution, which hurts drive yield and/or reliability, so Kp/Kr are key parameters. One question is how to measure them. In fact, there are many ways to measure the gimbal stiffness, and each of them has pros and cons. The main requirements of Kp/Kr measurement are: 1) Same boundary condition as inside drives, such as mounting at the baseplate; 2) Under the gramload; 3) At the designed Z-height (ZH) to assure the gimbal legs have the correct profile; 4) Non-destructive; 5) Accurate, quick, easy and cheap. Few methods can meet all those requirements. Here, we propose a method to identify the Kp/Kr under the flying condition that meets almost all of those requirements. The basic procedure is that we use the slider flying attitudes measured by an optical FH tester to back calculate the Kp and Kr values with an air bearing simulation code. The key idea is using multiple states (such as two different ZH) to cancel effects of unknown parameters and model offset to obtain accurate results.

Measurement procedure: The procedure of Kp identification: 1) Measure the slider flying attitudes (pitch angle) at different ZH. A ZH change will change GL and PSA, but keep other parameters unchanged. 2) Measure or calculate the suspension dGL (gramload change due to ZH change) and dPSA (PSA change due to ZH change); 3) Using an air bearing code to find PST value to match the measured pitch angle for the different ZH; 4) Then we can calculate the pitch stiffness: $K_{pij} = (PST_i - PST_j) / [(ZH_i - ZH_j) * dPSA]$, (i is ZH index) n ZHs give $n*(n-1)/2$ of Kp values. Then, we can average these values to obtain the final result, and also can check its non-linearity. Using the two ZH data can eliminate effects of many unknown factors. Kr identification is similar. Instead of changing ZH, we use additional fixtures with different RSA biases for the FH test.

Case studies and results: Kp identification of HGA1 is shown in Fig. 1. First, dGL and dPSA were measured, and shown in the figure. Assuming gramload and PSA meet the designed values, 2.5 gram and 1.50 deg respectively; we can calculate the GL and PSA values at each ZH with dGL and dPSA. Then, FH at five ZH of ten samples were measured, and the averaged measured pitch angles were shown in column 4 of the figure. Third, back calculations of PST to match measured pitch angles were done at each ZH with the correspondent GL. The calculated PST was shown in column 5. Finally, we can calculate the Kp with each combination of two different ZHs. Averaging all Kp values gives the final result, which is about 0.73 uN*m/deg. Averaging three Kp values with negative ZH change gives the 0.85 Kp, and the 0.61 Kp by averaging three Kp values with positive ZH changes. These two Kp values are quite different. This could be due to a non-linearity. At each ZH, a Kp value can be calculated by PSTi/PSAi. They are shown in Column 6, and it looks “unreasonable”. However, if we assume mean PSA is 1.85 degree instead of 1.50 degree, values in Column 6 are much “reasonable”, as shown in Fig. 2. The true PSA is unknown. Fortunately, both PSA values give the same Kp value (0.73) with the proposed method, so the method is robust.

Figure 3 shows the comparison between the measurement and FE model. The small difference between them was expected, and it could be due to GL effects. Figure 4 shows differences between measurement and model, and between different measurement methods. The differences are quite large, and they are also HGA design dependent. Looks like it is difficult to model and measure the Kp value correctly, so we should pay more attention to it. The proposed methods have been applied in many cases. It was found that quite consistent results can be obtained with the method, and it is good for flying height targeting.

Context

Understanding the relation between microstructure and magnetism is a key element to steel manufacturers such as Arcelor Mittal, as they open the way to exhaustive characterization of the properties consistency. Despite numerous preceding efforts [1-7], only parametric models have operated for bulk magnetic behavior. Finite element simulations are on their side limited to typically the size of recording heads [8-11].

Simulations

With a specific self adapting mesh refinement strategy, 2D finite element simulations were run on $72 \times 45 \mu\text{m}$ structures. In figure 1, the frame around the sample simulates the magnetic yoke used in experimental determination of hysteresis loops.

A simulation step consists in starting from an initial condition with an applied external field H_{ext} , and finding the magnetic microstructure which minimizes an energy function adapted from iron's constants. With initial saturation-like conditions, iterating the steps by gradually decreasing H_{ext} allows deriving the hysteresis cycle :this requires to plot the average magnetisation M vs H_{ext} .

Such simulations were applied to 3 cases to derive hysteresis cycles displayed in fig. 2 : a single crystal, with easy magnetization parallel to the edges of the material ; an 80 grain polycrystal, with and without inclusions. In each case, the simulations outlined 2 major phases as the applied external field H_{ext} decreases:

First the material, which is initially close to saturation, goes through the creation of large domains with continuous 180° walls across the whole sample's length.

Second, the 180° walls move, thus changing the volume of the large domains.

Discussion and conclusion

As its initial conditions correspond to a deep magnetic energy well, the large domain creation phase for the single crystal requires a higher decrease of H_{ext} than the 80 grain polycrystal. However, when the large transgranular 180° domains walls are created, both structures feature similar magnetization rates, i.e. the slopes of the curves are equivalent.

For the microstructure with non magnetic inclusions, a higher decrease of the external field seems required for the creation of the transgranular 180° walls. However, when these are created, the magnetization rate is similar to the case without inclusions. This could suggest the simulation conditions don't report pinning of the domain walls by the inclusions. This may be a limitation of the 2D approach, which does not reflect the true nature of domain walls. To overcome this issue, 3D simulations at similar scale are required.

Rotational saturation properties of isotropic vector hysteresis models using vectorized stop and play hysterons.

T. Matsuo

Electrical Engineering, Kyoto University, Kyoto, Japan

1. Introduction

Stop and play models are efficient and precise hysteresis models. There are two types of their vector versions: one is represented by the superposition of scalar models along the azimuthal direction [1], [2] whereas the other is given by the geometrical vectorization of stop and play hysterons [2]-[5]. The latter is more efficient than the former that requires integration along the azimuthal direction. This article discusses rotational hysteretic properties of latter vector models under saturated condition. A modification to improve their rotational properties is proposed.

2. Vector stop model

A vectorized stop hysteron \mathbf{s}_η is given as

$$\mathbf{s}_\eta(\mathbf{B}) = \eta(\mathbf{B} - \mathbf{B}^0 + \mathbf{s}_\eta^0) / \max(\eta, |\mathbf{B} - \mathbf{B}^0 + \mathbf{s}_\eta^0|) \quad (1)$$

where η is a hysteron radius and \mathbf{B}^0 and \mathbf{s}_η^0 are the vectors \mathbf{B} and \mathbf{s}_η at the previous time-point. For a rotational input of \mathbf{B} , \mathbf{s}_η becomes perpendicular to $\mathbf{p}_\eta = \mathbf{B} - \mathbf{s}_\eta$ at steady state as is shown in Fig. 1(a) when $|\mathbf{B}| > \eta$.

Vector hysteresis model using (1) is given as

$$\mathbf{H} = \int_0^{B_s} \mathbf{g}(\eta, \mathbf{s}_\eta(\mathbf{B})) d\eta \quad (2)$$

where $\mathbf{g}(\eta, \mathbf{s})$ is a shape function vector that is parallel to \mathbf{s} , B_s is the saturation magnetic flux density. This vector model exhibits hysteretic property even when $|\mathbf{B}| > B_s$. To suppress the hysteretic property for $|\mathbf{B}| > B_s$, \mathbf{s}_η is redefined as

$$\mathbf{s}_\eta(\mathbf{B}) = \eta(\mathbf{B} - \mathbf{B}^{0*} + \mathbf{s}_\eta^0) / \max(\eta, |\mathbf{B} - \mathbf{B}^{0*} + \mathbf{s}_\eta^0|) \quad (3)$$

$$\mathbf{B}^{0*} = B_s \mathbf{B}^0 / \max(B_s, |\mathbf{B}^0|) \quad (4)$$

This is a natural extension of the scalar version discussed in [6]. For a rotational input of \mathbf{B} , \mathbf{s}_η given by (3) and (4) becomes parallel to \mathbf{B} at steady state as is shown in Fig. 1(c) when $|\mathbf{B}| > B_s$.

Another way to prohibit the hysteretic property after the saturation is given by

$$\mathbf{s}_\eta(\mathbf{B}) = \eta(\mathbf{B} - \mathbf{p}_\eta^{0*}) / \max(\eta, |\mathbf{B} - \mathbf{p}_\eta^{0*}|) \quad (5)$$

$$\mathbf{p}_\eta^{0*} = (B_s - \eta) \mathbf{p}_\eta^0 / \max(B_s - \eta, |\mathbf{p}_\eta^0|), \quad \mathbf{p}_\eta^0 = \mathbf{B}^0 - \mathbf{s}_\eta^0 \quad (6)$$

The stop hysteron (5) is equivalent to (3) for the alternating input. The response of (5) differs from those of (1) and (3) for a rotational input of \mathbf{B} when $B_T < |\mathbf{B}| < B_s$, where $B_T = \{(B_s - \eta)^2 + \eta^2\}^{1/2}$. $|\mathbf{B} - \mathbf{s}_\eta|$ becomes $B_s - \eta$ at steady state as is shown in Fig. 1(b) when $B_T < |\mathbf{B}| < B_s$.

Vector relations for rotational inputs of \mathbf{B} are summarized in Table 1, where three types of stop hysterons are compared; [i] original type using (1), [ii] the modified type using (3) and (4), and [iii] the modified type using (5) and (6). The angle between \mathbf{B} and \mathbf{s}_η discontinuously changes from $\cos^{-1}(\eta/|\mathbf{B}|)$ (Fig. 1(a)) to 0 (Fig. 1(c)) at $|\mathbf{B}| = B_s$ when the stop hysteron [ii] is used. The stop hysteron [iii] achieves a continuous angle change, which naturally corresponds to the fact that \mathbf{B} becomes parallel to \mathbf{H} for a large rotational magnetic field.

A rotational property of non-oriented silicon steel sheet (JIS: 50A1300) is represented by three vector stop models using stop hysterons [i], [ii], and [iii]. Because of the lack of measured data for large B , B_s is artificially set to 1.9 T for the vector stop models. Fig. 2 (a) shows the simulated and measured rotational hysteresis losses. The model [i] gives monotone increasing in the rotational loss. The model [ii] results in a sharp decrease in the rotational loss at B_s . The model [iii] achieves an acceptably natural loss property. The discrepancy from the measured loss can be reduced by using a weighting function proposed in [2]. The rotational loss given by both models [ii] and [iii]

becomes 0 when $|\mathbf{B}| > B_s$ because \mathbf{s}_η becomes parallel to \mathbf{B} . B_s used in the simulation is, however, too small for the rotational loss to become 0.

3. Vector play model

A vectorized play hysteron \mathbf{p}_η is given as

$$\mathbf{p}_\eta(\mathbf{B}) = \mathbf{B} - \mathbf{s}_\eta(\mathbf{B}) = \mathbf{B} - \eta(\mathbf{B} - \mathbf{p}_\eta^0) / \max(\eta, |\mathbf{B} - \mathbf{p}_\eta^0|) \quad (7)$$

where \mathbf{p}_η^0 is the vector \mathbf{p}_η at the previous time-point. Vector hysteresis model using (7) is given in a similar way to (2). Similarly to the stop model, \mathbf{p}_η^0 can be replaced by \mathbf{p}_η^{0*} given as (6). Fig. 2(b) shows the rotational hysteresis losses simulated by two vector play models; [i] original model using (7) and [ii] the modified model using \mathbf{p}_η^{0*} instead of \mathbf{p}_η^0 . The model [i] yields a constant rotational loss for $|\mathbf{B}| > B_s$ (=1.9T). The model [ii] gives an acceptably natural loss property. The discrepancy from the measured loss can be reduced by using a weighting function proposed in [2].

The time delay of the magnetization M (magnetic induction B) behind the applied field H is observed over the whole time range. It is a common concept that in a short time domain the time lag is caused by diffusion aftereffect whereas over longer times temperature dependent magnetic viscosity takes place [1]. Each of these phenomena is characterized by a set of time constants which may overlap. For this reason, different types of the relaxation mechanisms are often described by the same expressions and studied by similar experiments.

It should be noted that the viscous behavior of the magnetic medium manifests itself under any excitation conditions, including the current-driven regime used in the viscosity experiments [2] and voltage-driven magnetization typical for testing soft magnetic materials. For example, the losses and B-H loops given by steel manufacturers are measured in regimes when the derivative dB/dt is a controlled sinusoidal variable. Since in the conducting media this derivative determines the macroscopic eddy currents, the presence of the magnetic viscosity leads to changes in the hysteresis loop, which cannot be explained by these "classical" eddy currents. So the additional widening of the dynamic hysteresis loop and corresponding excess loss can be viewed as the consequence of the magnetic viscosity [1]. The purpose of the paper is to link the current- and voltage-driven regimes in electrically conducting media from the magnetic viscosity viewpoint. We also draw attention to the fact that different magnetic materials have similar viscous behavior which is observed over time domains ranging from fractions of microseconds to tens of seconds.
