The theoretically predicted tunneling magnetoresistance (TMR) in coherent tunneling magnetic multilayers is over 1000% [1, 2]. However, the experimentally reported values are significantly lower. In particular for the Fe-MgO-Fe system, the highest measured TMR is 180% [3] at room temperature. Part of the difficulty in achieving the theoretical limit are factors such as contamination, interface roughness, pinholes, defects as well as the averaging effect from multiple magnetic grain boundaries. In this work, we report the results on epitaxially grown Fe-MgO-Fe structure on MgO (001) having nanometer sized topmost Fe islands, including measurements of TMR using an in situ scanned probe microscope in ultra high vacuum.

Experiment

All experiments were performed inside an Omicron surface analysis system at a base pressure less than 8×10^{-11} mbar. A polished MgO (001) substrate was cleaned by several cycles of sputtering and annealing (930–960°C) until the carbon peak in Auger spectroscopy was in the noise and the surface roughness (RMS) as measured by the AFM was less than 0.6 nm. A 35 nm thick Fe film was deposited on the MgO substrate at 400°C, which produced crystalline Fe islands with plateaus of up to several hundred nanometers wide. Next, 3 nm of MgO was deposited at a rate of 0.11 nm/min at room temperature and subsequently annealed at 450°C for 30 minutes. The STM images showed similar morphology as the underlying Fe grains and accompanied by some rounding at the edges. This indicated uniform, layer-by-layer coverage of the MgO film on the Fe grains. A Helmholtz coil was placed outside the system, which produced up to about ± 10 Oe at plane of the sample for STM measurements.

Results and discussion

Figure 1a shows a schematic diagram of the structure and the STM wiring. Figure 1b is the STM image of a complete Fe(0.5nm)-MgO(3nm)-Fe(35nm)-MgO(substrate) structure. The top Fe aggregated into square nanoislands, some with single-atom step terraces. The base of the nanoislands was approximately 5–10 nm wide and capped with plateaus of about 2 nm wide. This is consistent with our result that showed the formation of ziggurat pyramid shaped islands of Fe on MgO [4]. The epitaxial growth of Fe is clearly exhibited by the alignment of the island edges along the MgO [110] direction. The magnetic structure of the system is shown by the MFM image in Figure 1c. Note that the MFM scale is more than 50 times larger than the STM image. It shows the magnetic ripples and domain walls emanating from the thick bottom ferromagnetic layer. The ripples are perpendicular to the local magnetization (along the easy axis of Fe) and from which we discern that the vertical line on the right center part of the image is a 90° Bloch wall that meets another 90° wall and a 180° wall oriented along the diagonal.

To measure the magnetic response of sample, we located a well-isolated Fe island on the flat plateaus of the bottom Fe structure, and measured the STM topography at various preset external magnetic field values. Since the STM is operated in constant current mode, any tunneling magnetoresistance change between the Fe layers will appear as a vertical displacement of the tip or an apparent change in the height of the surface features. Figure 2 is a series of line profiles for the island at 0 and ± 10 Oe. The measured height at zero field is 7.0 Å while for +10 Oe it is 2.1 Å and

for -10 Oe, the apparent height is 10.5 Å. Clearly, there is a change of 8 Å between the positive and negative fields. We also check the response of the system with a non-magnetic sample and found no height differences introduced by the external field. Thus, this result suggests that a very large TMR, perhaps close to the theoretical limit, may be responsible for the observed height variation. Unfortunately, it is difficult to obtain a quantitative estimate of the true contribution to the MR for the moment. In order to calculate the real magnitude we need to establish the tunneling resistance based on the displacement, as well as develop a precise model for double junction tunneling. Also, we need to completely eliminate the effects due to the possible lateral shift of the tip due to the external field. These results, as well as progress for direct quantification will be presented in the paper.

Korea Electronic Technology Institute, Korea University, Gyeonggi, South Korea; 4. Institute for Nano Science, Korea University, Seoul, South Korea

Introduction

Nanowires are widely pursued one-dimensional nanosystems and promise immense opportunities in nanotechnology, ranging from nanoelectronic devices to cell-separation and magnetic labeling in biomedicine. Fabrication of multilayered nanowires with multiple functionalities is preferred from a single solution bath [1]. Synthesis of Ni/Au multilayered nanowires is appealing not only to magnetic devices but also to bio-applications as a result of magnetic and optical multifunctionality [2]. In this work, such Ni/Au multilayered nanowires were successfully prepared and characterized from a single solution bath [1].

Experiment

Multilayered Ni/Au nanowires were fabricated in anodized aluminum oxide (AAO) templates (200 nm and 80 nm in pore diameter) by pulse dc electrodeposition. The experiment was performed from a single solution bath of Ni and Au ions. The nanowires were characterized by SEM, TEM, optical microscopy, UV-Vis spectroscopy, and VSM.

Results and Discussion

In Fig. 1, the layered nanostructure of the Ni/Au multilayer nanowire was confirmed through TEM elemental mapping and line scanning. Alternative arrangements of the Ni and Au layers are distinctly separated, with respective individual layer thicknesses of ~70 nm for Ni layer and ~60 nm for Au layer. In experiment, the segmental lengths of individual Ni and Au layers can be tailored by adjusting deposition parameters. As shown in Fig. 2, various Ni/Au segmental aspect ratios were given, i.e., disk-shape of the Ni segments (Fig. 2 (a)), intermediate-shape of the Ni segments (Fig. 2 (b)), and rod-shape of the Ni segments (Fig. 2 (c)), compared to the rod-shape of the pure Ni nanowires (Fig. 2 (d)). Correspondingly, the magnetic properties of the multilayered nanowire arrays in AAO were investigated by VSM, exhibiting a clear dependence on the aspect ratio (Fig. 3). Fig. 3 (a) is the hysteresis of the disk-shaped Ni segments (aspect ratio < 1), showing the easy axis perpendicular to the nanowire axis. As the aspect ratio changes to ~1 (intermediate-shape of the Ni segments), the multilayered nanowire array becomes isotropic (see Fig. 3 (b)). When the rod-shaped Ni segments (aspect ratio > 1) were fabricated, the easy axis switches to parallel to the nanowire axis (Fig. 3 (c)), similar to that of the pure Ni nanowire array (Fig. 3 (d)). Thus, the easy-axis of the nanowire arrays was determined by the shape anisotropy, less than the small negative magnetocrystalline anisotropy of Ni. Moreover, the UV-Vis measurements give plasmon peaks characteristic of nanostructured Au in the Ni/Au multilayers. We shall discuss in detail the finite-size and proximity effects on the magnetic properties of the Ni/Au multilayers.

Novel phenomena in multi-layer composite structure observed by anomalous Hall effect measurement.

S. Das¹, T. Ichihara¹, H. Suzuki¹, Y. Matsuda²

1. Central Research Laboratory, Hitachi Ltd., Odawara, Japan; 2. Head Development, Hitachi Global Storage Technologies, Odawara, Japan

Introduction:

Application of anomalous Hall effect (AHE) measurement is helpful to investigate the magnetization processes in perpendicular magnetic anisotropy (K_u) thin films [1]. We employed AHE measurement on a multilayer thin film structure such as one generally used in the perpendicular magnetic recording medium, which is composed of a soft underlayer (SUL) with in-plane magnetization, a non-magnetic intermediate layer (IML), a hard magnetic Co-Cr based oxide layer and a soft magnetic metallic cap layer [2]. We observed that AHE measurement can selectively detect the magnetic properties of the topmost cap layer and the anomalous Hall voltage (V_{AHE}) from this layer increases with increasing cap layer thickness (t_{cap}). This is quite different from that of a single layer case where V_{AHE} decreases inversely with increasing film thickness. Based on the empirical results we developed a simple bi-layer model that suggests that such kind of phenomena could generally be observed in any stacked structure of magnetic thin films with different anomalous Hall coefficients.

Experiment:

A soft magnetic Co-Cr-Pt (CCP) cap layer ($t_{cap} = 0 - 10$ nm) was epitaxially grown on top of a magnetically hard Co-Cr-Pt-SiO₂ (CCPS) layer (thickness fixed at 13 nm) and both the layers possess perpendicular magnetic anisotropy (with $K_{u,CCP} < K_{u,CCPS}$). A stack of metallic seed layer (SL) deposited on glass substrate ensured the c-axis orientation of the CCPS layer. AHE measurement was performed using a standard four-probe method.

Results and discussions:

A CCPS layer without a CCP on it exhibited almost no V_{AHE} (Fig. 1), while a CCP layer directly deposited on the SL (i.e. without a CCPS layer underneath) exhibited comparatively large V_{AHE} (Fig. 1). Fig. 2 compares the magnetic hysteresis loops for a CCP(8 nm)/Non-magnetic spacer (2 nm)/CCPS(13 nm) structure measured by the AHE method and a vibrating sample magnetometer (VSM). VSM loop exhibits two steps – one around 50 kA/m and another around 200 kA/m, indicating the individual magnetization reversal in the soft CCP and hard CCPS layer, respectively. This is due to the suppression of interlayer exchange coupling between these layers in presence of a comparatively thick non-magnetic spacer. However, the AHE loop reveals only one step around 50 kA/m suggesting that AHE measurement selectively detects the magnetization reversal only in the CCP layer. Measurement of the specimens without a CCP layer on the CCPS layer but with an SUL under the SL revealed large reversible V_{AHE} signal from the SUL, which implies that, though electro-conductive, CCPS does not produce any detectable V_{AHE} . This can be attributed to very small anomalous Hall coefficients (R_{CCPS}) of CCPS layer. Increase of V_{AHE} was observed with increasing t_{cap} as shown in Fig.3 for a series of CCP (0 – 10 nm)/CCPS(13 nm) specimens. This is quite different from the generally known phenomena where V_{AHE} decreases inversely with increasing thickness of a voltage producing layer [1]. In order to explain our empirical results, we considered a bi-layer model, consisted of a cap layer and the stack of other layers underneath with total thickness t_{others} . One V_{AHE} producing layer can be substituted by a voltage source and an electrical resistor connected in series and in a multilayer structure they are connected in parallel. In our bi-layer model the voltage sources are V_{cap} and V_{others} , which are characterized by the anomalous Hall coefficients, R_{cap} and R_{others} , respectively. Fig. 4 shows the change of V_{cap} and V_{others} with changing t_{cap} for $R_{cap} \gg R_{others}$. V_{cap} increases with t_{cap} (for a fixed t_{others}), becomes maximum at $t_{cap} = t_{others}$ and decreases beyond that. In the region $t_{cap} \gg t_{others}$, V_{cap} behaves the way similar to that of a single layer. Our model suggests a general conclusion: in a composite stacked structure composed of magnetic thin films with different anomalous Hall coefficients (R_{AHE}), there exists a region where V_{AHE} from a particular layer increases with increasing thickness, which is thinner than the total thickness of other layers.

Fig. 1 Measured V_{AHE} from a Co-Cr-Pt and a Co-Cr-Pt-SiO₂ layer.

Band and bubble domains in AF coupled [Co/Pt]/Ru multilayers.

Introduction

Recently, [Co/Pt]/Ru multilayers have been developed, in which the influence of antiferromagnetic (AF) interlayer coupling on otherwise ferromagnetic (FM) films with perpendicular anisotropy can be studied [1]. The strong perpendicular anisotropy originates from the Co/Pt submultilayers which can be considered as a single FM layer. The separating Ru interlayer introduces an AF exchange between adjacent Co/Pt submultilayers [2].

Domain observations find two magnetic phases for this system, depending on the balance of exchange and dipolar coupling. The magnetization of each layer is either laterally correlated in AF configuration or vertically correlated, forming FM stripe domains and depend on the coupling strength via the details of the multilayer architecture.

The detailed study of the magnetization process in such samples is thus an important contribution to understanding the coupling mechanism.

Results and discussions

In this study we focus on $[(\text{Co}(4\text{\AA})/\text{Pt}(7\text{\AA}))_8\text{Co}(4\text{\AA})/\text{Ru}(9\text{\AA})]_{18}$ multilayers which display a predominant dipolar coupling at room temperature, and we investigate the domain structure and magnetization process through the first quadrant of the hysteresis loop.

The average magnetic properties were determined by superconducting quantum interference device (SQUID) and the domain structure was characterized by MFM in magnetic field. For this, a Digital Instruments Dimension 3100 AFM/MFM has been upgraded for measurements with an external magnetic field up to 0.42 T, applied perpendicular to the sample.

A magnetic hysteresis loop with the field perpendicular to the film plane is shown in Fig. 1. Its behavior is very similar to that of simple Co/Pt multilayers with perpendicular anisotropy. In this ferromagnetic phase, the strong dipolar stray fields overcome the AF coupling between layers. The magnetization of each layer is vertically correlated from layer to layer, forming ferromagnetic band domains.

Fig 2 shows a series of MFM images for different magnetic fields applied perpendicular to the sample during the measurements. In a zero field state, due to the perpendicular anisotropy, band domains with average domain width of 180 nm are observed. By increasing the external magnetic field the domains which are aligned parallel to the field grow, while the oppositely aligned domains shrink. This process occurs gradually, until the domains transform into worms and, in the end, into a bubble domain structure at higher fields. This behavior is in principle understood by the so called bubble domain theory.

The theory was developed for single layer films by assuming a model in which the domains have cylindrical walls of zero width and it allows calculating the size and stability of the domains [3]. This leads to the prediction of a strip-out field (H_{SO}), the field in which the bubbles transform into band domains, and a collapse field (H_{CO}), the field in which the bubbles collapse. Approximating the [Co/Pt]/Ru as a thick single layer with perpendicular anisotropy, the values are $H_{\text{SO}} = 0.4\text{ T}$ and $H_{\text{CO}} = 0.47\text{ T}$, respectively.

A series of MFM images was recorded on the decreasing branch of the hysteresis loop in a narrow field range close to saturation (see Fig 3). By decreasing the field from 0.42 T to 0 T the bubbles diameter increases, until the bubbles transform into band domains. The MFM experiments show

that this strip-out instability occurs at 0.36 T. The collapse field lies above the accessible field of 0.42 T in the MFM experiment. It is estimated from the global magnetization measurements to be about 0.55 T. In between these two field values, the bubble domain diameter shrinks with increasing field.

The discrepancies of these experimental values to the predicted values mentioned above reveal the influence of the layered structure with antiferromagnetic coupling and vote for an improved theory for these complex multilayers.

Exchange-spring behavior in Fe-FePt thin films studied via synchrotron radiation.

B. Laenens¹, N. Planckaert¹, J. Demeter¹, K. Temst¹, A. Vantomme¹, C. Strohm², R. Rüffer², J. Meersschaet¹

1. *Instituut voor Kern- en Stralingsfysica and INPAC, Katholieke Universiteit Leuven, Celestijnenlaan 200D, B-3001 Leuven, Belgium;* 2. *ESRF, Rue Jules Horowitz 6, Boîte Postale 220 38043 Grenoble, France*

The exchange-spring magnet, which is based on interfacial exchange coupled soft and hard ferromagnetic materials combines the high magnetisation of the soft phase with the high magnetic anisotropy of the hard phase. This kind of material is of interest for low-cost permanent magnets and other novel functional magnetic nanostructures. Fe-FePt bilayers are the prototypes of exchange spring magnets [1-3]. FePt in the $L1_0$ -phase is a hard material with a high magnetocrystalline anisotropy [4-5] while Fe is a soft ferromagnetic material with a low anisotropy and high spontaneous magnetization. So far, experimental work has been performed on thin exchange spring bilayers with both the hard and the soft magnetic moments oriented in the film plane [3].

Nowadays, great interest goes to magnetic structures having their easy magnetization axis orthogonal to the film plane. Epitaxial FePt thin films stabilised in the $L1_0$ -crystal structure show this property when grown on MgO(100) [4-5]. Moreover, by depositing a thin Fe-film onto a $L1_0$ FePt layer, a new phenomenon emerges: while the hard FePt layer forces its magnetization perpendicular to the film plane, the soft Fe-layer prefers its magnetic moments to be in plane [1-2].

In this work we studied an Fe-FePt(30 nm) bilayer grown with molecular beam epitaxy of which the sample composition is illustrated in Fig.1. The soft Fe-layer consists of a wedged ^{56}Fe layer with a thickness ranging from 0 to 8.7 nm. Subsequently, an isotopically enriched ^{57}Fe layer with a thickness of 0.7 nm was grown onto the wedge. The sample was capped with 0.6 nm of ^{56}Fe and 3 nm of Ag. The isotopic enrichment has no influence on the electronic or magnetic properties of the bilayer, but allows us to selectively probe the magnetic structure of the ^{57}Fe layer as a function of the distance to the FePt-interface, using nuclear resonant scattering of synchrotron radiation (NRS). Synchrotron radiation, incident on the sample, will simultaneously excite the hyperfine-split nuclear energy levels of the ^{57}Fe atoms, giving characteristic beats in the temporal evolution of the subsequent nuclear decay signal. The analysis of this beat pattern, which is the time-based analog of classical Mössbauer spectra, allows a precise determination of the moment rotation through the ^{57}Fe -layer. The dependence on the distance t to the FePt-interface can be probed by moving the sample transversally with respect to the synchrotron beam.

Time spectra are recorded at 11 positions on the sample at the NRS beamline ID18 of the ESRF. Fig.1 shows a selection of the time spectra. The spectra are analysed using the fitting routine CONUSS [6]. From the analysis the angle θ , which is defined as the angle between the sample normal and the magnetic spins of the ^{57}Fe -layer, could be deduced. The right panel in Fig. 1 shows the rotation of the spins in the ^{57}Fe -layer as a function of the distance t . For a few monolayers of Fe, the magnetically hard FePt pins the magnetisation in the soft Fe layer to the out-of-plane direction. By increasing the Fe-layer thickness to 9 nm, the influence of the FePt diminishes and the magnetization cants to the in-plane Fe[001]-direction.

In addition, we performed magnetometry measurements at different positions on the wedge to investigate the strength of the exchange coupling. The external field was applied along an in-plane Fe[110] direction. From the time spectra we could deduce how the moments start to cant towards the external field as the field increases. A field of 4.5 Tesla was required to saturate the ^{57}Fe -spins in the middle of the wedge.

We thus were able to directly probe the magnetic properties of exchange-spring Fe-FePt bilayers by exploiting the isotope selectivity of NRS. Our results will be modeled in the framework of one-dimensional micro-magnetical calculations.

How to retrieve more information on magnetic films from microwave permeability measurements.

O. Acher¹, V. Dubuget^{1,2}, S. Dubourg¹

1. Département Matériaux, CEA, Monts, France; 2. UMR 6157 LEMA, Tours, France

INTRODUCTION

The growing interest in high frequency systems and ultrafast devices has boosted the investigation of the microwave permeability of ferromagnetic films in the GHz range. Efficient and reliable permeameters allow the determination of the microwave permeability of thin films with a good precision. Recently, it has been established that the integral of the imaginary part of the permeability multiplied with the frequency could be used to retrieve information on the magnitude and the orientation of the magnetization in thin films [1,2].

This paper provides experimental examples on information retrieval using this integral on soft amorphous CoZr films. This approach is compared to the conventional approach that relies on fitting the permeability spectra using the gyromagnetic equations for a uniformly magnetized thin film. It is shown that the integral approach provides a better precision, and can be used successfully even in cases where the uniform gyromagnetic model fails.

THEORETICAL APPROACH

The permeability tensor of a film with in-plane uniform magnetization is well known. In particular, the low-frequency permeability and the resonance frequency are related to the saturation magnetization $4\pi M_s$ by a generalization of Snoek's law to thin films (Eq. (1) in Fig. 1). In the case the magnetization is oriented at an angle θ with the direction z within the film plane (xz), Eq. (2) in Fig. 1 allows the determination of this angle. However, this holds only in the restricted framework of a uniform magnetization.

Recently, it has been established that though heterogeneities, magnetization dispersion, magnetic coupling, eddy current effects, can have large effect on the permeability, the integral of the imaginary part of the permeability μ'' multiplied with the frequency f is not affected by this complexity. In order to retrieve information from the permeability of magnetic films with complex magnetization configuration, the efficient dynamic magnetization defined by Eq. (3) (Fig. 1) is a convenient quantity. At a sufficiently high frequency, it is equal to the saturation magnetization (Eq. (4)). It is also possible to retrieve information on the dispersion of the orientation of the magnetization through Eq. (5).

RESULTS

The permeability spectra of 6 amorphous CoZr films have been measured and processed using the equations on Fig. 1. Fig. 2 compares the numerical values of the saturation magnetization retrieved using different methods. It appears clearly that the dynamic magnetization defined by Eq. (3) provides the best estimates. The magnetization dispersion is found to be close to 10° using Eq. (5).

A bilayer manufactured by depositing two CoZr layer with their easy axis rotated by 90° in the film plane is also studied. The permeability of this sample along 2 directions is given in Fig. 3. There is no simple model available to account for this behavior, and Eqs (1) and (2) fail to account for the observation. Using the integral of the imaginary part of the permeability times frequency, a saturation magnetization of 11.2kG is retrieved, within 6% of the value obtained with a VSM. Quantitative indications on the dispersion of the magnetization are also obtained.

As a conclusion, microwave permeability measurements allow the retrieval of important information on the magnetization within thin films and multilayers, when the integral of the imaginary per-

meability times frequency is properly exploited. In contrast to other techniques, this technique is not restricted to very thin films or multilayers.

The effect of FePt layer on the transition temperature of FeRh layer.

N. T. Nguyen, Y. Y. Hnin, T. Suzuki

Information Storage Materials Laboratory, Toyota Technological Institute, Nagoya, Japan

Recently, FePt/FeRh bilayers have attracted much attention because of their potential application. It is known that FeRh exhibits the first order transition from anti to ferromagnetic phase upon heating [1]. Thiele et al., showed the coercivity of a FePt/FeRh film decreased sharply at the transition temperature of FeRh layer [2]. However, there has been very little systematic study as to the detailed mechanism of the magnetization behaviors at around the first-order magnetic phase transition; Therefore, a systematic study has been carried out in order to understand their magnetization on temperature for FePt/FeRh.

Bilayers FePt/FeRh were deposited onto MgO(100) substrates by DC magnetron sputtering. Thin films of FeRh(300 nm) were first deposited onto MgO, then annealed at 700°C for 10 hours, followed by a successive deposition of FePt. As-deposited bilayers of FePt/FeRh thus fabricated were annealed for 5 min at 600°C.

Figure 1 shows XRD patterns of the four different samples, as described in the figure. Strong peaks (001) of CsCl type FeRh are observed for all the samples while the (001) peak of FePt is seen only for the annealed FePt(300 nm)/FeRh.

Figure 2 shows M-T curves with different applied magnetic fields, H_{ap} during the heating and cooling processes of FeRh(300 nm) and FePt(30 nm)/FeRh(300 nm). It is seen that the transition temperature is shifted to the lower temperature as the H_{ap} is increased. The shift is about -0.70 K/kOe for the FeRh and -0.73 K/kOe for the FePt/FeRh. The total entropy changes associated with the transition are 186 mJ/K.cc and 172 mJ/K.cc, respectively. This observation is consistent with bulk measurements where the entropy change of 142 mJ/K.cc was observed [3]. This may presumably be interpreted in term of the stabilization of the FM phase by H_{ap} during the transition leading to a lower transition temperature [2].

Shown are in figure 3 M-T curves of the four different samples. The transition temperatures of FePt/FeRh are lower than that of a single layer of FeRh. This is believed due to an exchange coupling between FeRh and FePt[4].

The dependences of magnetization and coercivity on temperature for the annealed FePt(300nm)/FePt(300nm) are shown in figure 4. At the transition temperature, the coercivity in parallel directions decreases sharply from 3000 Oe to 350 Oe. However in perpendicular directions, the decrement in H_{C-per} is not significant as compared with H_{C-par} .

Effects of perpendicular interlayer coupling on canting angles of TbCo sublattice magnetization by x-ray magnetic circular dichroism.

M. Lin¹, P. Huang¹, Y. Wu¹, H. Hou¹, C. Lai¹, H. Lin², F. Chang²

1. Department of Materials Science and Engineering, National Tsing Hua University, Hsinchu, Taiwan; 2. National Synchrotron Radiation Research Center, Hsinchu, Taiwan

Introduction:

The perpendicular interlayer coupling through oscillatory RKKY interaction has been reported between Co/Pt multilayers (MLs) and Co/TbCo bilayers with Ru spacer thickness [1]. In rare-earth and transition-metal (RE-TM) alloys, because of strong antiparallel exchange coupling between the TM and heavy RE moments, the orientation of Tb-sublattice moment was considered to be aligned in the opposite direction of Co-sublattice moment. However, the sublattice magnetizations of TbCo are not perfectly antiparallel, which depends on the competition between the exchange and the difference in the anisotropies of sublattices. Therefore, possible canting between the sublattice magnetization has been achieved by an external magnetic field [2]. In this work, we demonstrate that the canting angles between Tb and Co sublattices can be altered by the perpendicular RKKY interlayer coupling between Co/Pt MLs and Co/TbCo bilayers, the canting angle is directly measured by using x-ray magnetic circular dichroism (XMCD).

Experiment and Result:

The samples of Pt/TbCo/Co/Ru(t_{Ru})/Co/[Pt/Co]_{n=5}/Pt/Ta/Si were prepared by using UHV sputtering. All samples exhibited perpendicular anisotropy and showed oscillatory interlayer coupling with variation of the Ru spacer thickness. In Fig 1(a), the ferromagnetic (F) interlayer coupling at Ru=2 nm led to the clearly shifted minor loop of [Co/Pt] MLs. The schematic diagram in the inset showed the parallel magnetic moments in the remnant state between [Co/Pt] MLs and TbCo/Co bilayers.

In the XMCD measurement, the polarized x-ray was incident to the samples at an angle of 30 degree from the surface normal with P- and A-incidences as the schematic diagram shown in Fig 1(b). If the Tb- and Co-sublattice moments were perfectly perpendicular to the film surface, the XMCD intensity of the Tb M₅ and Co L₃ edge of P- and A-incidences should be equal ($I_p = I_A$) because the two incident X-rays had the same angle from the perpendicular moment. Therefore, the effective canting angle Φ_{Tb} and Φ_{Co} with respect to the surface normal direction can be calculated by using the equation $\tan\Phi = \cot 30^\circ (I_A - I_p) / (I_A + I_p)$ where I_p and I_A represented the XMCD intensity of the Tb M₅ and Co L₃ edge of P- and A-incidences. [3]

The XMCD spectra of Tb M_{4,5} and Co L_{2,3} for the sample with Ru=2nm were shown in Figure 1(b). The XMCD results revealed the presence of the canting of Tb and Co moments in the TbCo film of Ru spacer at 2 nm with interlayer coupling strength of $J=0.11 \text{ erg/cm}^2$. The canting angles of Tb and Co was determined to be close to $\Phi_{\text{Tb}}=10$ and $\Phi_{\text{Co}}=5$ degree. On the other hand, almost no canting effect was observed with a stronger coupling strength ($J=0.38 \text{ erg/cm}^2$) when Ru was reduced to 1 nm. Since the Co/Pt MLs possessed perfectly aligned perpendicular magnetization, the strong interlayer coupling through RKKY interaction may align the sublattices of Tb and Co along the perpendicular direction so the canting angles were close to zero.

Magnetization reversal in thermally processed Fe/SmCo spring magnets.

J. E. Davies¹, Y. Choi², J. P. Liu³, J. S. Jiang², S. D. Bader², R. D. Shull¹, K. Liu⁴
 1. Metallurgy/Magnetic Materials, NIST, Gaithersburg, MD; 2. Materials Science Division, Argonne National Laboratory, Argonne, IL; 3. Physics Department, University of Texas, Arlington, TX; 4. Physics Department, University of California, Davis, CA

Exchange spring magnets have been of intense interest due to their applications in permanent magnet,^{1,2} thermally assisted magnetic recording,³ and exchange coupled composite media.^{4,5} Recently, it has been shown that the exchange coupling between hard and soft layers in thin film Fe/epitaxial-SmCo bilayer spring magnets can be enhanced through thermal processing of the material by varying the substrate temperature during deposition.^{6,7} We perform first order reversal curve (FORC) measurements^{8,9} on samples where the Fe layer was sputter-deposited at either 100°C or 400°C (referred to hereafter as T100 and T400, respectively) after depositing the SmCo layer at 400°C in order to better understand the effects of the thermal processing. We also use FORC to measure the irreversible magnetization present in each sample and relate this measurement to the different interfacial morphologies. The T100 sample has a sharp but jagged interface while the T400 interface is uniform but diffusive.

The FORC's [Figs. 1(a) and 1(b)] and FORC distributions [Figs. 1(c) and 1(d)] show reversal behavior characteristic of Fe/SmCo spring magnets.⁹ The major loop delineated by the FORC's has two reversal steps with the first step following along the descending branch corresponding to Fe layer reversal. During Fe reversal the FORC's trace along the major loop and the FORC distribution (ρ) is zero [Figs. 1(c) and 1(d), above dashed line]. The second reversal step denoted in Figures 1(a) and 1(b) by the point labeled $\mu_o H_o$ corresponds to the reversal of the SmCo layer. Once the SmCo layer begins to reverse the FORC's deviate from the major loop and ρ becomes non-zero with two distinct features emerging. A negative/positive pair [Fig. 1(c) and 1(d), left of the solid vertical line] corresponding to the change in Fe reversal due to partial demagnetization of the SmCo layer and a high field peak [Fig. 1(c) and 1(d), right of the solid vertical line] corresponding to the SmCo reversal.

While qualitatively the same features occur for the two samples, there are clear differences. The features for T400 emerge at smaller reversal fields and are more localized. This is better illustrated in a FORC switching field distribution (FORC-SFD) obtained by projecting ρ onto the $\mu_o H_R$ (vertical) axis. The FORC-SFD for T100 [Fig. 2(a), filled symbols] is centered at $\mu_o H_R = -0.75$ T and has a half width of 0.14 T. The T400 FORC-SFD is centered at $\mu_o H_R = -0.47$ T with a half-width of 0.07 T. The smaller $\mu_o H_R$ magnitude indicates a stronger interlayer exchange coupling in the T400 sample. The narrowing of the FORC-SFD indicates smaller variations of interfacial properties. Both are results of the more uniform but diffusive interface due to the higher temperature deposition.

Integration over ρ yields the fraction of the magnetization that switches irreversibly (M_{irr}/M_s) for each sample. For T100 $M_{irr}/M_s \approx 0.37$, whereas for T400 $M_{irr}/M_s \approx 0.43$. Interestingly, the total SmCo layer contribution is only $M_{SmCo}/M_s = 0.24$. Thus the additional contribution to M_{irr}/M_s must originate from the Fe layer. In T100 this is most likely due to the jagged interface causing variations in exchange coupling. In T400 it is likely due to the interdiffusion resulting in a gradual increase in anisotropy across the interface. Also, the greater value of M_{irr}/M_s for T400 implies a thicker interfacial region is present compared to T100.

Non-invasive Measurement of Tissue Iron Concentrations with Magnetic Resonance Imaging.

T. G. St Pierre

School of Physics, University of Western Australia, Perth, WA, Australia

There is a number of human diseases and disorders that result in excessive iron being deposited in tissues in the form of nanoparticulate iron oxyhydroxides. The effective clinical management of these diseases often requires measurement of tissue iron concentrations in order to be able to determine the type and extent of iron depletion therapy required. The majority of excess iron is deposited in the liver and there is evidence to indicate that in thalassemia and hereditary hemochromatosis, liver iron concentration can be used as a surrogate measure for the total body iron stores [1,2]. Until recently, the gold standard for liver iron concentration measurement was chemical assay of a needle biopsy specimen. However, the technique is subject to large sampling errors in addition to being invasive. Over the past few years we have developed a method for the non-invasive measurement of liver iron concentrations using magnetic resonance imaging. The method is based on the measurement of the rate of dephasing of proton spin precession in liver tissue [3]. The presence of clusters of iron oxide particles with a magnetic susceptibility significantly different from the surrounding water-containing tissue results in local perturbations of the static magnetic field generated by the magnetic resonance imager. The resulting increase in the range of fields experienced by the water protons in the vicinity of the iron oxyhydroxide particles yields a greater range of Larmor precession frequencies of the water protons and hence a greater rate of dephasing of the precession of the protons.

A calibration curve relating liver proton transverse relaxation rates (R_2) to liver iron concentration (LIC) has been determined though the in vivo measurement of R_2 by a series of single spin echo measurements and the measurement of LIC by chemical assay of biopsy specimens in 105 human subjects [4]. Figure 1 shows four example liver R_2 -images together with their respective liver R_2 -distributions for four human subjects. The R_2 -distribution shifts to higher values as the liver iron concentration increases.

We have also demonstrated the ability of liver R_2 -imaging to map liver iron concentrations [5]. Figure 2(a) shows an R_2 image of an array of tissue samples taken from a single iron loaded liver post-mortem. The mean values of R_2 for each sample are plotted against the chemically measured tissue iron concentrations in Figure 2(b) showing a high degree of correlation thus indicating that an R_2 -image of the liver can be interpreted as an iron concentration map. Note the large variation in local LIC which leads to large sampling errors on the conventional biopsy method of measurement of LIC. The ability to measure the spatial variation of LIC may have applications in the detection of liver fibrosis or cirrhosis where the presence of scar tissue results in locally reduced iron concentrations.

This R_2 method of measuring liver iron concentrations has now replaced the needle biopsy method at many clinical centres. The method has been cleared by regulatory health authorities in Europe, USA, Canada, and Australia and is currently available in over 80 clinical centres worldwide with over 3000 patient measurements having been performed. It is being marketed under the commercial name FerriScan®.

Exploring the frontiers of magnetic nanoparticles prepared in microemulsions: from ferrofluids to biomedical applications.

J. Rivas^{1,2}, M. Lopez Quintela^{2,1}

1. Laboratory of Magnetism and Nanotechnology(NANOMAG), University of Santiago de Compostela, Santiago de Compostela, Spain; 2. Laboratory of Magnetism and Nanotechnology(NANOMAG), University of Santiago de Compostela, Santiago de Compostela, Spain

The production of monodisperse magnetic nanoparticles (NPs) is nowadays one of the most important challenges in Nanotechnology. The microemulsion technique is a powerful method to prepare simple metallic and oxide NPs, as well as, core-shell and “onion-like” NPs. Although microemulsions cannot be considered as real templates, they constitute an elegant technique, which can provide a very good control of the final particle size. The reason for that is a complex interplay mainly between three parameters, namely, surfactant film flexibility, reactant concentration and reactant exchange rate. By adequately choosing these three parameters one can get a homogeneous distribution of particle sizes.

In the last years it has been shown that most of materials show a dramatic change in their properties at the nanometer/ subnanometer level. In particular, metallic clusters (“particles” formed by Natoms < 100 atoms) are one of the most promising and exciting research areas because they combine the scientific with the application interest. From the scientific point of view, there are many controversial points about the exact stability, structure/geometry and properties of these tiny nanoparticles. For example, according to theoretical calculations, different geometries –very different from the bulk- seem to be stable: for Natoms < 10/12, planar geometries are preferred, whereas for Natoms>10/12, 3D structures with compact, non-compact and five-fold symmetries are found to be the most stable ones, depending upon the conditions and approximations used for the theoretical calculations. A number of new fascinating properties seem to appear at these scales. As an example, fluorescence, catalysis, magnetism, and circular dichroism have been already reported. However, all these studies are very limited because of the procedures used for the cluster synthesis. Only very small amounts of highly polydisperse samples can be obtained after difficult separation procedures. We have recently developed a novel microemulsion-based method for the synthesis of clusters which allows their production in relatively large amounts.

In this talk we will describe the microemulsion synthesis procedure showing preliminary results about the stability, structure, and properties of some magnetic clusters produced by this method. Biomedical applications of these “new” materials will be discussed.

Electrical Engineering Department, Instituto Superior Tecnico, Lisbon, Portugal; 5. INESC ID, LISBON, Portugal

Spintronic-based biomolecular recognition platforms use magnetic labels to tag biological targets (DNA strands, cells), and spintronic detectors to determine hybridization of the labeled biological targets to surface immobilized biological probes. The magnetoresistive detector (usually a spin valve or MTJ based sensor) senses the fringe field originating from the bound magnetic labels. In a spintronic biochip array, magnetoresistive detectors are fabricated on the substrate, with magnetic field guide lines (MFGs) being used to array labeled target biomolecules to the immobilized probes (magnetically assisted hybridization). DC and AC excitation fields are usually used, the DC field increasing the moment of the magnetic label, and the AC field modulating the bead moment to allow detection close to the sensor thermal background noise. For 130nm diameter magnetite labels, magnetized with 1.5kA/m fields, detection capability of the present platform runs from few labels up to few thousands. In order to allow scaling to hundreds of biological probes, a platform including a thin-film diode in series with a MTJ sensor at each probe site has been developed. The detection limits of this platform are compared with spin valve only or MTJ only based platforms. For point-of-care bioassays, a portable electronic platform was developed, allowing full control of the bioassay from a pocket PC. The noise level of this measuring platform is 140nV rms at 375 Hz, in fact determining the biological target lower detection limit. Control bioassays were done using spin valve based arrays (no diode), where e-Coli DNA strands were detected using 20mers oligo probes, immobilized on Au surfaces. Lower detection limits are at 1 pM target concentrations, and a linear response is obtained up to tens of nM (see Fig.1). Use of biomolecular target concentration using MFGs allows improving detection limit down to tens of fM. The possible integration of this biomolecular hybridization detection platform with other lab-on-chip modules is described.

In vivo sensing, moving and heating of magnetic nanoparticles in the human body.

Q. Pankhurst

London Centre for Nanotechnology, London, United Kingdom

The emerging field of 'endomagnetics' – the sensing, moving and heating of magnetic nanoparticles in the human body for diagnostic and therapeutic purposes - will be reviewed. Examples will be given for each of the modalities, including the following:

Sensing: A high-Tc SQUID based sensor system, with a room temperature hand-held probe, designed for use in a hospital operating theatre to detect breast cancer sentinel lymph nodes (Figure 1). The system is currently being evaluated in patients, and has been used successfully in seven operations.

Moving: A high field-gradient magnetic actuator designed to capture magnetic nanoparticle loaded haematopoietic stem cells for the treatment of atherosclerosis. Bench-top (Figure 2) and animal trials are under way to establish the efficacy of such a therapy, with promising results.

Heating: Magnetic field hyperthermia treatment for superficial and, as a long term goal, metastatic cancer, using antibody-targeted magnetic nanoparticles. Work is progressing on several fronts: the synthesis of improved magnetic particles for heat transduction (Figure 3), the engineering of new high-frequency drive circuits to produce rf fields in controlled geometries, and cell and animal studies of antibody-nanoparticle conjugation and tumour targeting.

Figure 1: An intra-operative medical device for breast cancer surgery which uses a novel hand held probe with a high-sensitivity, high-Tc SQUID based sensor.

Figure 2: Microscope images showing the attraction of magnetically labelled CD133 stem cells towards a magnet placed at the top of a cells-in-water droplet. Scale: each cell is ca. 10 μm in diameter.

Figure 3: Magnetic field heating characteristics of a commercial nanoparticle suspension and two lab-synthesised samples – all are magnetite/maghemite based. Measurements recording in an rf field of magnitude 140 Oe and frequency 138 kHz.

Room-temperature detection of single magnetic biomolecular labels with Hall devices*.

Superparamagnetic beads are becoming increasingly popular for labeling individual biomolecules in fundamental single-molecule biophysical studies as well as in biosensing applications. Since dimensions of such beads are typically of the order of a micrometer and smaller, the stray magnetic field distributions they generate are highly localized and often minute, thus imposing challenges on their detection. In this talk we will present our results on development of Hall devices, with sensing areas having lateral dimensions of $\sim 1 \mu\text{m}$ and $\sim 250 \text{ nm}$, fabricated from InAs/AlSb quantum well semiconductor heterostructures. In the first part of the talk we will focus on room-temperature device characterization, i.e. the frequency dependence of the magnetic field and magnetic moment resolutions obtained through Hall effect and electronic noise measurements. We will show that in the low frequency range, from 20 Hz to 1.6 kHz, the noise-equivalent magnetic moment sensitivities are of order $10^6 \mu_B/\sqrt{\text{Hz}}$ and $10^5 \mu_B/\sqrt{\text{Hz}}$ for $1 \mu\text{m}$ and 250 nm devices respectively. The sensitivity of the latter reaches the $10^4 \mu_B/\sqrt{\text{Hz}}$ range above $\sim 1 \text{ kHz}$ (Figure 1), corresponding to the detection limit of only 3 magnetite nanoparticles (16 nm in diameter)/ $\sqrt{\text{Hz}}$ at 1.6 kHz. In the second part of the talk a phase-sensitive measurement technique for detection of superparamagnetic microbeads and nanoparticles will be introduced. By using this technique and micron-sized Hall crosses we were able to achieve detection of a single $1.2 \mu\text{m}$ diameter bead with a signal to noise ratio (S/N) of $\sim 33.3 \text{ dB}$ (Figure 2), as well as detection of six 250 nm beads with S/N of $\sim 2.3 \text{ dB}$ per bead. The third part of the talk will focus on magnetic characterization of a single superparamagnetic microbead by phase-sensitive micro-Hall magnetometry. We will show the measured dependence of the bead's susceptibility on magnetic field, which can be explained quantitatively as due to the magnetic response of an ensemble of non-interacting magnetic nanoparticles with broad distribution of magnetic moments and a mean diameter of 8.6 nm. Overall our work demonstrates the efficacy of InAs quantum well Hall devices for applications in high sensitivity magnetic biomolecular detection.

Spin transfer induced microwave emission and spin diode effects in MgO based magnetic tunnel junctions.

B. Georges¹, V. Cros¹, J. Grollier¹, A. Fert¹, A. Fukushima², H. Kubota², K. Yakushiji², S. Yuasa², K. Ando²

1. UMR CNRS-Thales, Palaiseau, France; 2. National Institute of Advanced Industrial Science and Technology (AIST), Tsukuba, Japan

Since the prediction by Slonczewski [1] and Berger [2] of magnetization dynamics induced by a spin-polarized current, many efforts have been focused on the understanding of the microwave emission features of a single spin-transfer nano-oscillator (STO) under magnetic field and current bias [3–7]. The challenge is now to increase the microwave emission power, which is typically a few hundred of pW/GHz for all-metallic pillars. Solutions to increase the power emission are to synchronize several STOs, to use magnetic tunnel junctions (MTJs) or to combine both approaches [8–10]. Indeed the development of MgO based tunnel junctions has made available MTJs with high MR ratios (more than 100 % at room temperature) and low RA ratios, required for the observation of spin-transfer effects in these systems. Spin-transfer induced magnetization precessions in MgO MTJs systems have been recently announced by a few groups [11,12]. However, it is difficult to discriminate between spin transfer induced emissions and thermal magnetization fluctuations because the latter are large in MTJs with large MR ratios, contrarily to all-metallic junctions.

We present some recent experimental results on microwave emission in MgO tunnel junctions. The junction stack is PtMn 15 / CoFe 2.5 / Ru 0.85 / CoFeB 3 / MgO 1.075 / CoFeB 2 (nm). After sputtering, the junctions are etched with a 50x150 nm² elliptic section. The junctions deposition and processing are described elsewhere [13]. The RA and MR ratios of the junctions are typically 2 $\Omega \cdot \mu\text{m}^2$ and 100%. We detect the microwave emissions by a spectrum analyzer after 32 dB amplification of the signal. In our convention, a positive current corresponds to electrons flowing from the thick to the free layer. The magnetic field is applied in the plane of the layers. Our results show distinct behaviours depending on the magnetic configuration of the junctions. In the parallel (P) state, the asymmetry of the emission as a function of the dc current is small, suggesting that the measured spectra are mainly due to thermal magnetization fluctuations (see Fig. 1(a)). On the contrary, in the antiparallel (AP) state, there exists a strong asymmetry between positive and negative current increasing with the current intensity. As can be seen on Fig. 1(b), for positive currents favouring the P configuration, the peak intensity peak increases with increasing current. The linewidth shows a minimum that could be attributed to the threshold current for spin transfer induced magnetization oscillations [6]. This behaviour is in agreement with the results of Nazarov et al. [11]. We will comment on these trends.

To gain further understanding of our results, we have performed spin diode experiments on similar junctions [14,15]. An external microwave current is injected in the MTJ nanopillar and we measure at the same time the dc rectified voltage and the microwave spectra (no dc current is injected in the sample). The bias field is applied along the hard axis. On Fig 2, we show at 200 Oe the frequency of the STO microwave emission as a function of the frequency of the source. The rectified voltage is presented in the inset as a function of the source frequency. From the dc voltage, we can see that at this field value, the intrinsic frequency of the STO is about $f_0 = 2.3$ GHz. By measuring the microwave spectra, we can detect the non-zero frequency components of the mixed signal $V(f) = R(f_0) \cdot I_{\text{hf}}(f_{\text{source}})$. Our measurement shows components at $f_0 \pm f_{\text{source}}$, confirming the mixing effect.

With GHz frequencies the operation speed of MRAM has reached the frequency range of the dynamic eigenexcitations of the underlying magnetic nanoelements (spin waves), whose energies are found to be quantized due to the lateral confinement [1]. Thus, the experimental observation and the understanding of spin wave modes in nanomagnets are prerequisites for the optimization of memory cells.

We have studied the magnetic field dependence of the mode frequency of thermally excited spin waves in MgO-based MTJs at 300K by analyzing the spectral density of the magnetoresistance noise. Our devices are rectangular shaped nanopillars of size 100x200 nm patterned from MTJs [2] of composition CoFeB (2 nm, free layer)/ MgO (0.85)/ CoFeB (3, pinned layer)/ Ru(0.8)/ CoFe(2.5)/ MnIr(8). The quasistatic properties of the free layer are consistent with the uniaxial anisotropy expected from the sample's elongated shape (Fig. A,B). Saturation of the synthetic anti-ferromagnet (SAF) is not reached for hard axis fields below 1.7 kOe (Fig.A), and spin-flop transition occurs typically at easy axis fields near 900 Oe (Fig.B).

For each external field we have measured the device voltage noise power for biasing currents ± 0.5 mA. The noise spectra were obtained by subtracting simultaneously recorded zero-current reference spectra. The sweeping direction of the field was found not to affect the spectra, except for a marginal impact at low fields (below H_k). Similarly, for opposite current polarity the spectra show only minor deviations, also mainly at low fields.

For 6 devices of appropriate quasi-static properties we have measured the voltage power density versus hard axis fields from -1.4 to 1.4 kOe. One example of the resulting 2D density plots is shown in Fig. C.

Near zero field, the loops indicate the presence of several degenerate micromagnetic configurations (cf. inset in Fig. A). The corresponding noise spectra are strongly sample dependent, and will not be discussed here.

At slightly higher hard axis field (H below H_k), one or sometimes two modes are detected. The most intense mode has a frequency vanishing at H_k. The frequency of the less intense mode, when present, also vanishes at some field not corresponding to any characteristic point in the loop.

At fields saturating the free layer magnetization along the hard axis (H above H_k), we observed typically 5 to 10 peaks all below 12 GHz, none of them being a second harmonic of another. Surprisingly, the spectra were not symmetric with respect to zero field. Mode spacing was sample dependent, with modes appearing either in groups (Fig. C, positive H) or in an almost regular comb (not shown).

The mode whose frequency vanishes at H_k is generally also the most intense and the second lowest in frequency. The intensity of a mode does not systematically decrease with its index.

In some samples, modes of substantially weaker field dependence of the frequency were observed. In order to determine which of these modes may originate from excitations in the free layer or in the SAF, we have measured how the spectra are affected by a slight misorientation of the applied field. Only very few modes prove sensitive to the field misalignment.

In a first attempt to interpret the observed modes at large hard axis fields we have calculated the quantized mode frequencies of dipole-exchange spin waves propagating in a saturated single free layer of rectangular shape, following the approach of C. Bayer et al., formula (45) in [1], where we included an additional surface anisotropy to account for the considerably smaller layer thickness of only 2 nm in our samples. We have obtained qualitative agreement in the sense that the calculated modes were quantized and showed individually the observed field dependence. The effective magnetization was found to be 0.6 T.

To conclude, we have measured a large number of quantized spin wave modes in various MTJs and have obtained first insight into deterministic and statistical behaviour of the modes.

We have studied spin-transfer induced dynamics in the exchange-biased synthetic antiferromagnetic (SAF) reference layer of a spin-valve. Pillars with $150 \times 50 \text{ nm}^2$ hexagonal cross-section have been fabricated from multilayers with the following structure: buffer layer / 7 IrMn/3 CoFe/0.8 Ru/3 CoFe/4 Cu/6 CoFeB/ capping layer (where the thickness of each layer is given in nm). The long axis of the hexagons (which is the easy axis of the free layer) was oriented parallel to the pinning direction of the SAF. The static characterization of the samples was carried out via 2-point probe magnetoresistance and resistance versus current measurements. In our experimental configuration, positive fields are applied in the opposite direction with respect to the magnetization of the reference layer (thus favoring the AP state). For positive currents, the electrons flow from bottom to top. The coercivity of the free layer was about 700 Oe. The minor loop corresponding to the switching of the free layer was shifted from zero applied field with about 150 Oe, corresponding to the average magnetostatic field between the SAF pinned layer and the top CoFe layer. The magnetostatic interaction favors the antiparallel orientation between the free and the reference layer. The SAF layer starts to reverse around 1000 Oe.

The thick free layer acts as an very efficient polarizer, generating strong spin-transfer effects on the reference layer, especially considering the comparatively lower thickness of the top CoFe layer of the SAF (which translates into lower threshold currents). We have measured high frequency spectra at constant current and field, for fields between -3000 and 2000 Oe, varied in 100 Oe steps, and currents between -20 and 20 mA, with a 0.4 mA increment. The spectra exhibit strong precession signals even in 0 applied field, for currents above -10 mA. The signals are centered around 8 GHz in the absence of an external field, and shift down to less than 7 GHz as the applied field is increased to 800 Oe (Fig. 1). These peaks cannot be generated by free layer dynamics, as when the external field is increased, the total field acting on the magnetic moments of this layer increases and the precession frequency should increase as well. Consequently, we interpret these signals as the acoustic mode of the SAF pinned layer. If the field is kept constant, and the current is increased, the peaks exhibit a strong shift to lower frequency, which is typical of spin-transfer driven clams-shell precession. At 700 Oe, for example, the signals red-shift with more than 1 GHz over the investigated current range (Fig. 2). Similar to simple layers not subject to exchange-bias, the peak amplitude registers an initial increase with the current (up to about -17 mA in this case), after which value the power drops suddenly and the peak width increases. Unlike free layers, which exhibit large $1/f$ noise with increasing current, the spectra corresponding to spin-transfer driven precession in the pinned SAF layer do not show any trace of $1/f$ noise, even in zero applied field, hence their potential interest for applications. In addition, spin-transfer driven precession in the SAF layer generates an optic mode as well at frequencies above 50 GHz, making theses structures potentially interesting for very high frequency spintronics devices.

Fig. 1. Power (in Watt/Hz) of the acoustic mode of the SAF layer, versus frequency and field, measured with a constant current (-14 mA). The 32 dB amplification has not been subtracted from the data.

Fig. 2. Power of the SAF acoustic mode, versus frequency and current, measured in a constant 700 Oe field. The power scale is the same as above.

Spin-polarized current induced excitations in a synthetic antiferromagnet.

In most applications of magnetic read heads or magnetic memories, the pinned layer is composed of a synthetic antiferromagnet (SAF), see Fig. 1a, in order to insure a rigid pinned layer alignment and to minimize the dipolar stray field on the free layer. This SAF consists of two ferromagnetic layers that are exchange coupled across a thin non-magnetic spacer whose thickness is adjusted to produce an antiferromagnetic coupling.

Recently, structures that are similar to CPP spin valve read heads containing an SAF pinned layer were used to study the spin transfer effect and in particular the microwave excitations [1]. In some studies [2] excitations have been observed that were attributed to the dynamics of the pinned SAF structure.

We therefore investigate here theoretically the conditions for which steady state oscillations may occur in the current-field plane of an SAF pinned layer, by keeping this time the free layer magnetization fixed and by considering a spin torque that acts only on the 'top' layer of the SAF structure, see Fig. 1a. For this one has to keep in mind that the hysteresis loop as a function of the applied field is quite different for an SAF structure than for a single free layer of a collinear planar structure. As illustrated in Fig. 1b, for a symmetric SAF structure, three regions can be distinguished. In the field range $-H_{SF} < H_{app} < H_{SF}$ the magnetization of the top and bottom SAF layers are well aligned antiparallel AP. We label the corresponding magnetization state in-plane stable state IPS_{AP} . When the applied field is larger than the spin flop field H_{SF} , but smaller than the saturation field H_{sat} ($H_{SF} < H_{app} < H_{sat}$) the magnetizations of both layers rotate in-plane, leading to the well known shearing of the magnetization, see Fig. 1b. We label this state as IPS_{SF} . The angle between both magnetizations decreases with increasing field until they align parallel (P) for $H_{app} > H_{sat}$. We label this state as IPS_P .

In order to obtain the critical current for which these static states become unstable, we consider in an analytic macrospin approach only the top SAF layer M_{top} which is exchange coupled to the bottom layer M_{bottom} , which itself is kept fixed. Applying general stability analysis [3] by linearization of the Landau-Lifschitz-Gilbert LLGS equation augmented by the Slonczewski spin torque term [4], we find analytic expressions for the critical boundaries in all three states. These are indicated by the blue and red bold lines in Fig. 1c, labelled J_{cP} , J_{cSF} and J_{cAP} . Here lines J_{cP} and J_{cAP} are very similar to those obtained for conventional collinear planar structures in the P and AP configuration [3], where the critical current J_c is dominated by the demagnetization field $J_c \sim \alpha 2\pi M_s$, with α the damping constant. The parameters for numerical evaluation are given in the figure caption. As a new result we find the critical current in the spin flop region which is inversely proportional to the applied field $J_{cSF} \sim \alpha/H_{app}$ and which joins the critical J_{cP} at the saturation field H_{sat} . In contrast at the spin flop field H_{SF} the critical current diverges.

In order to study the unstable regions for currents larger than the critical currents, we have solved the LLGS equation numerically. In difference to the analytic derivation, here we consider the evolution of both the top M_{top} and bottom layer M_{bottom} . Although a spin torque is included only for the top layer, for all three states coupled oscillations are obtained due to the relatively strong exchange coupling. Furthermore, for all three cases M_{top} and M_{bottom} oscillate around their respective static equilibrium position where the amplitude of the top layer, which feels the spin torque, is always larger than the one of the bottom layer. Typical trajectories are shown in Fig. 1d.

The simulations results are discussed in comparison to first experiments that have been performed in our group recently which confirms the theoretical predictions.

In a magnetic multilayer sample, the spin-transfer torque from a spin-polarized DC current can excite steady-state magnetic precession at microwave frequencies [1]. This effect is of technological interest because it may allow the production of high-quality nanoscale frequency-tunable microwave sources and resonators. For applications, it is desirable that these magnetic oscillations have long coherence times, i.e. narrow linewidths in the frequency spectrum of the microwave signals. Therefore, understanding the role of thermal fluctuations and other mechanisms which may effect the coherence of these oscillators has generated considerable experimental [2, 3, 4] and theoretical interest [5]. The high-frequency dynamics of these oscillators have been studied previously in devices with nanopillar geometries [1, 2, 3] as well as point-contact geometries [4], and as a function of temperature [2] and the out-of-plane field angle [3, 4].

In this talk, we report measurements of how the linewidths depend on the in-plane angle of the applied magnetic field relative to the magnetic easy axis of nanopillar devices. We find that the most-commonly studied field orientation, in-plane and parallel to the easy axis, actually produces the broadest linewidths. As the field angle is rotated towards the in-plane hard axis, the linewidths can decrease dramatically, by almost a factor of 20-50 in some devices, thereby enabling a new and simple way to tune the coherence of the oscillations at room temperature. We also report the temperature dependence of the linewidths at the field angles giving the minimum linewidths, and compare our experimental results to macrospin and micromagnetic simulations. Micromagnetic simulations can reproduce our experimental results and help to explain the magnitude of the changes.

Our devices all have a nanopillar geometry, and we have measured two types of layer structures. In both kinds of samples, the free layer is the same material (Permalloy, Py) and it has the same thickness (4 nm). In the first type of multilayer the fixed layer (Py, 4 nm) is exchange-biased by an anti-ferromagnetic layer (IrMn, 8 nm), while in the second multilayer the fixed layer is thicker (Py, 20 nm) with no exchange bias. Our devices have an elliptical cross section, with a minor diameter of 50-70 nm and an aspect ratio of 2:1 or 3:1. We apply magnetic fields that are larger than the coercive fields of both layers, so that at $I=0$ the magnetizations of both layers are aligned approximately parallel along the field direction. We vary the field angle in-plane relative to the easy axis of the ellipse, and measure the frequency spectrum of the DC-current-driven resistance oscillations with a heterodyne mixer circuit [1].

As the applied magnetic field is rotated toward the in-plane hard axis, the linewidths of the oscillation decrease by a large factor (20-50) in the exchange-biased fixed layer devices, while the decrease is only approximately a factor of 5 for the thick-fixed-layer devices. In the thick-fixed-layer devices, the dynamics are symmetric as a function of field angle relative to the hard axis, while they are not symmetric for the exchange-biased samples, indicating that the exchange-bias of the fixed layer still plays a role even though the applied magnetic field is larger than the exchange-bias field. Since the free layer is identical in both kinds of multilayer samples, we conclude that the configuration of the fixed layer affects the degree of coherence of the free layer. We have confirmed that the precessional mode that is excited is always predominantly a free-layer

mode in both types of samples at all field angles, using spin-transfer-driven ferromagnetic resonance measurements (ST-FMR) [6, 7].

We have performed simple macrospin simulations and more detailed micromagnetic calculations in an attempt to understand our data. In the macrospin simulations, we found some narrowing in the predicted linewidths as a function of field angle, but only by a factor of 2-3, not by the much larger factor observed experimentally. Micromagnetic simulations, on the other hand, are in excellent agreement with our experimental results and can explain the large magnitude of the linewidth narrowing. They show that the oscillations are much more spatially uniform for an applied field along the in-plane hard axis than near the easy axis. They also show that the amplitude of the oscillations for a given current bias increases as the field angle is rotated from the easy axis to the hard axis, making the oscillations less susceptible to thermal fluctuations and giving enhanced coherence.

Phase locking of a Spin Transfer Oscillator to an external microwave current : a milestone for the synchronization of a large assembly of STOs.

B. GEORGES¹, J. Grollier¹, M. Darques¹, V. Cros¹, C. Deranlot¹, G. Faini², A. Fert¹

1. Unité Mixte de Physique CNRS/Thales (CNRS-UMR137), Palaiseau, France; 2. Phynano team, Laboratoire de Photonique et Nanostructures, LPN - CNRS, Marcoussis, France

STOs (Spin Transfer Oscillators) are non-linear oscillators very promising for applications in next generation telecommunication devices[1,2]. However the increase of the output power is a major challenge since the emitted power by a single STO is far too weak (< 1 nW). A solution is to achieve the synchronization in frequency and phase of an array of STOs [3]. Experimentally a first proof of synchronization of two close packed STOs has been given in 2005, independently by Kaka et al. and Mancoff et al [4,5]. In both cases, the coupling needed for synchronization was mediated by interacting spin waves generated by the spin transfer torque in a common magnetic layer. However the spatial extension of the spin wave excitation, of the order of the μm , could be a strong drawback for its integration in large assemblies of STOs.

We have recently proposed an alternative scheme for the synchronization of STOs [6], that has the advantage to rely on a global coupling : each oscillator of the assembly is equally interacting with all the others. In fact, STOs are simply electrically connected to each others either in series or in parallel. The coherent emission of all STOs is governed by the coupling through the common self-generated (in each STO) microwave current that imposes a phase locking of the ensemble.

Here, we successfully demonstrate the phase locking of a single STO to an external source generated by a microwave source. As an example, we display in Fig 1 the map of the microwave emission in color scale of nanopillars without (Fig1a) and with injection of a microwave current (Fig1b) as a function of the dc current and frequency. These results are in agreement with experiments made by the NIST group in Boulder on STO nanocontacts [3].

To go further, we study in detail the influence of the intrinsic characteristics of the STO such as the linewidth, the agility in current or the power amplitude on the coupling efficiency. We clearly observe the major role played by the noise on the ability of STOs to phase lock to external signals. Moreover, we analyze our results in the frame of the model of weakly forced oscillators [7,8]. From our calculations, we extract the coupling parameter e , that determines the coupling strength between the STO and the external microwave signal. The predicted e depends on experimentally available parameters such as linewidth, agility, dc current etc. On Fig 2, we show the experimental variation of the coupling strength as a function of the amplitude of the microwave current (that is linked to the MR ratio in STOs). We also observe that the coupling efficiency increases with the agility in current of the excitations. Our experimental results are in very good quantitative agreement with our calculations.

We believe that we gain through our study a clearer understanding of the conditions for successful synchronization of a large amount of STOs via a non local coupling such as the self emitted microwave current but also via a local coupling such as spin waves or hf dipolar field.

Magnetic point-contact precession frequency vs. magnetic field angle – The prospect for spin torque oscillator operation at 65 GHz.

S. Bonetti¹, J. Persson¹, F. B. Mancoff², J. Åkerman¹

1. Microelectronics and Applied Physics, Royal Institute of Technology (KTH), Kista-Stockholm, Sweden; 2. Technology Solutions Organization, Freescale Semiconductor Inc., Chandler, AZ

Interest in Spin torque oscillators (STOs) [1–3] is rapidly increasing due to their potential use for microwave generation over large frequency ranges. In these devices, the transfer of spin angular momentum between a spin polarized current and a thin (on the order of few nm) magnetic layer generates a precession of the magnetization, and as a consequence oscillation of the device resistance, either through giant magnetoresistance (GMR) [4,5] or tunneling magnetoresistance (TMR) [6–8]. These devices are compact (~100 nm in lateral size), can be tuned in frequency in an approximately linear way by varying the applied current and magnetic field magnitude, and the tuning range is rather large, on the order of tens of GHz [9].

Besides current and field magnitude tunability, the frequency can also be tuned by varying the angle at which the magnetic field is applied [9]. In this work we study this dependence in GMR based magnetic point contacts and find that extrapolation of the angular dependence to entirely in-plane magnetic field predicts STO operation to frequencies as high as 65 GHz. Samples are point contact $\text{Co}_{81}\text{Fe}_{19}$ (20 nm)/Cu(6 nm)/ $\text{Ni}_{80}\text{Fe}_{20}$ (4.5 nm) spin valves. The contact shape is elliptical, with minor axis $a = 130$ nm, and aspect ratio 3:1 between major and minor axes.

In order to perform measurements, samples are mounted, together with non-magnetic ground/signal/ground RF probes and xyz micromanipulator, on a turntable. The entire holder can be rotated, so that the direction between a fixed magnetic field and the sample can be varied from in-plane to out-of-plane. The RF signal detected by the probes is then amplified by a broadband (0.1 – 26 GHz) amplifier (+45 dB), and transmitted to a spectrum analyzer, capable of resolving power spectra up to a maximum frequency of 26.5 GHz. The magnetic field is kept constant at a value of 1.3 T in all measurements

Oscillation peak positions vs. field angle is presented in Fig. 1 for low current densities (close to the onset of oscillation). Since these samples have rather high oscillation frequencies to begin with and our spectrum analyzer is limited to 26.5 GHz, we only resolve the angular dependence some 25 degrees away from the film normal. In this angular range the frequency increases almost linearly with decreasing field angle. Assuming a ferromagnetic resonance (FMR) behavior [9], we can fit this behavior and extrapolate to an expected maximum operating frequency of about 55 GHz if the field were to be applied along the plane of the film. If we further increase the current and move away from the onset of oscillation towards an intermediate regime, we find oscillations at about 26 GHz (limit of our spectrum analyzer) when the field angle is 80°. FMR extrapolation from this point leads to a predicted frequency of 65 GHz for in-plane applied field. To the best of our knowledge, this is the highest estimated operating frequency of any STO to date and may open up for suggested high-speed consumer applications in the 57–66 GHz range [10].

We do not exclude that the magnetization dynamics may turn into complex regimes when such frequencies are approached. However, continuous single mode operation up to 35 GHz has been shown in earlier studies [9] when the typical frequencies for out-of-plane fields were around 5 GHz. Furthermore, we are not aware of intrinsic fundamental limits to the achievement of frequencies up to 100 GHz.

With more experimental data available, we also plan to present a study of the linewidth and of the integrated output power dependence on the applied field angle. Furthermore, we are in the process

of extending the range of our experimental capabilities to 40 GHz, in order to investigate if the expected trend is followed up to that frequency. Final confirmation of actual oscillations at 65 GHz will be attempted by down converting the STO signal with an intermediate frequency generator. Thermal noise plays a defining role in the dynamics of auto-oscillatory systems. This is particularly relevant in nanoscale systems in which the thermal energy is comparable to the energy of the auto-oscillations. In such systems, there are two important consequences of noise. First, thermal noise leads to a broadening of the power spectrum. Second, thermal noise blurs the transition between the damped and auto-oscillatory states.

The spin-torque nano-oscillator (STNO) is an important auto-oscillatory system of present interest. In the context of nanomagnetism and spin-dependent transport, the auto-oscillations of magnetization in magnetic heterostructures are the result of the interplay between the intrinsic magnetic torques and dissipation, and an additional torque furnished by spin-polarized currents. In a wider physical context, the oscillator represents a unique system in which the frequency nonlinearity is typically much larger than the intrinsic relaxation rate. As we will show, this last feature leads to significant qualitative differences between the power spectra of spin-torque nano-oscillator and other conventional oscillators, namely, significant line broadening and lineshape asymmetry occurs in STNOs.

We have developed a stochastic theory of spin-torque nano-oscillators [1,2] based on a classical Hamiltonian spin-wave formalism [3]. Based on a single-mode assumption in which the excited mode is the one which possesses the lowest relaxation rate, we derive a nonlinear oscillator equation from the Landau-Lifshitz equation of motion with Gilbert damping and thermal noise. From this stochastic nonlinear differential equation, the spectral power density of the STNO is computed with a Fokker-Planck formalism, and we demonstrate how to construct the necessary spin-wave correlation functions that are related to the voltage correlation functions measured experimentally from the Green's function of the Fokker-Planck equation [4].

We show that the power spectrum of the STNO near the generation threshold is broadened, non-Lorentzian, and asymmetric. This is a result of two important physical processes: (i) the large frequency nonlinearity of the oscillator; (ii) the coupling between phase and amplitude fluctuations, leading to a colored noise source for the oscillator phase. We argue that such line broadening and line asymmetry are key signatures of the threshold region, and give a simple means of determining the threshold in experiment. This point is especially significant for STNOs in which the influence of noise on device performance is of qualitative importance.

Our theory gives a good qualitative description of lineshape distortion measured in a recent STNO experiment. In the figure, we present a comparison between the calculated and measured power spectra for a spin-valve nanopillar system [5]. Dark solid lines represent fits to the experimental data (circles) using multiple Lorentzians, which are shown as shaded curves. Based on the linewidth and power variations, the critical current in the experimental system is estimated to be $I_{th} = 5.2$ mA. Below threshold ($I = 5.0$ mA), the experimental data (circles) are well described by a single Lorentzian curve, while for small to moderate above-threshold currents ($I = 5.4, 6.0$ mA) a second Lorentzian peak is required to account for the line asymmetry. The salient features of the measured lineshape distortion are well reproduced by the theory.

Spin-polarized DC currents injected into nanoscale magnetic multilayers lead to spin-torque effects that can excite magnetization self-oscillations. Due to thermal fluctuations, experimentally observed self-oscillation power spectra always exhibit finite linewidth. The linewidth dependence on the exciting current can be rather complex, with non-monotone changes by orders of magnitude. In this paper, we compare analytical predictions for the linewidth dependence on applied field and current with measurements of the power spectrum of current-induced microwave magnetization oscillations.

Measurements were performed on a point contact (<40 nm in diameter) made at the top of a continuous 8 μm by 12 μm spin valve structure. The spin valve structure consisted of SiO₂/Ta 2.5 nm/Cu 50 nm/Co90Fe10 20 nm /Cu 5 nm /Ni80Fe20 5 nm/Cu 1.5 nm /Au 2.5 nm. The Co90Fe10 layer plays the role of "fixed" layer for the spin-torque effect due to its larger volume and larger saturation magnetization relative to the "free" Ni80Fe20 layer. The device is current-biased so that current flows from the "fixed" into the "free" layer and changes in the relative orientations of the magnetizations of the two layers lead, via GMR effect, to voltage changes across the device. The device is contacted with a microwave probe, and a bias tee is used to separate the injected dc current from the high-frequency device response. The output is amplified and measured using a 23 GHz spectrum analyzer. The center frequencies f and linewidth of the excitations are determined from Lorentzian fits to the measured spectra. All measurements were performed at room temperature, subjecting the sample to an out-of-plane external magnetic field. In particular, the case where the field is at 60 degrees with respect to the film plane was investigated in detail in order to obtain data suitable for direct comparison with model predictions. A minimum linewidth of 10.6 MHz at 19.49 GHz was measured under a field of 0.75 T and a current of -6.43 mA. In Fig.1, the power spectral density (PSD) of the measured voltage is reported for various values of the injected current. For intermediate current values ($I = 8$ mA) the PSD exhibits two peaks. In Fig.2 the linewidth of PSD peaks is reported as a function of the injected current. In the region around $I = 8$ mA, there are two distinct linewidth curves associated with the two peaks present in the PSD. In order to model the measured data, we assumed that the free-layer is uniformly magnetized and that the magnetization dynamics in the free layer is governed by the Landau-Lifshitz-Gilbert equation with the addition of the spin-transfer term in the form proposed by Slonczewski. Fluctuations are taken into account by adding a Gaussian white-noise term to the effective field. In this model, conservation of magnetization amplitude leads to stochastic magnetization dynamics on the unit sphere. The problem was studied without simplifying assumptions by solving the Fokker-Planck equation associated with the stochastic dynamics on the unit sphere. Solutions were obtained by using separation of variables and eigenfunction expansion techniques, along with appropriate numerical discretization techniques. From the solution of the Fokker-Planck equation, the autocorrelation function and the power spectral density of magnetization were computed.

By using the above theory, it is possible to explain the presence of multiple peaks in the PSD as a consequence of the presence of multiple attractors in the underlying magnetization deterministic dynamics. The non-trivial behavior of the linewidth as a function of the current is the consequence

of the bifurcations the system undergoes under varying current. The ensuing richness of qualitative changes in the response of the system is captured well by the Fokker-Planck analysis. This would not be the case for simple classical oscillator noise models which cannot deal properly with the strong nonlinearity of the system dynamics.

Magnetization dynamics has attracted much attention due to its potential for application in microwave oscillator. The microwave oscillation (MO) induced by spin polarized current has been observed in current-perpendicular-to-plane giant magnetoresistance (CPP-GMR) [1] and MgO magnetic tunnel junction structures [2]. At the same time, the magnetoresistance (MR) has been observed on CPP-spin valve (SV) structure which has $\text{Fe}_{0.5}\text{Co}_{0.5}\text{-AlO}_x$ nano-oxide layer (NOL) as a spacer layer [3]. The NOL has metallic conductive channels with nano-meter size in an 1–2 nm oxide insulator. The origin of this MR can be attributed to confined domain walls in ferromagnetic metal nano-contacts in the NOL, which is called as domain wall MR (DWMR). Therefore, we proposed to apply our original nano-confined structure formed by NOL to the microwave oscillator [4]. In our previous work, we denoted that a peculiar MO was observed in DWMR elements, and the peak frequency was ~ 7 GHz at antiparallel (AP) configuration of free layer (FL) and reference layer (RL) magnetization. Here, we report another type of MO in DWMR elements, which shows higher MO frequency of over ~ 10 GHz. The SV films were prepared by the dc magnetron sputtering method. The design of SV film is underlayer/PtMn 15/Co_{0.9}Fe_{0.1} 3.3/Ru 0.9/Fe_{0.5}Co_{0.5} 0.5/Fe_{0.5}Co_{0.5}-AlO_x NOL/Fe_{0.5}Co_{0.5} 2.5/cap layer (nm). The Fe_{0.5}Co_{0.5}-AlO_x NOL was formed by using the ion assisted oxidation (IAO) method [3]. We fabricated samples which had NOLs formed by different IAO conditions. One of them was formed by strong oxidation (sample S), and the other was oxidized weakly (sample W). The elements presented in our previous report belonged to sample S. The samples were fabricated into pillars with size of $0.3 \times 0.3 \sim 0.6 \times 0.6 \mu\text{m}^2$ by the photolithographic method. The microwave spectrum was measured by spectrum analyzer from 0.1 \sim 18 GHz applying dc current (I) and magnetic field (H). The direction of I is defined as positive for current flow from FL to RL. The positive H denotes opposite direction to the magnetic alignment of RL. We measured MO spectra of some elements in both sample S and W, and estimated peak frequency (f) from highest peaks of each element. Fig.1 shows resistance area product (RA) dependence of f of sample S converged on 6 \sim 8 GHz. On the other hand, f of sample W was dispersed but higher than sample S in average. Here we focus on one of the elements in sample W. MR ratio, RA , and an interlayer coupling field between FL and RL (H_{in}) of the element was 3.7%, $0.73 \Omega\mu\text{m}^2$, and 65 Oe, respectively. To confirm the magnetic configuration of FL and RL in high I , we measured R - H curves at I (Fig.2). With increasing I , intermediate state between parallel (P) and AP configuration was observed and shape of FL hysteresis got tilted. This state is considered to be due to the magnetic field induced by sense current and spin transfer torque. Fig.3 shows MO spectra at $I = +33$ mA. For $H = +500$ Oe, a small peak was observed at 8.2 GHz. As H was increased to +600 Oe, the peak jumped to 9.8 GHz and was sharpened drastically. As H was further increased, f increased slightly, and the peak height decreased. From Fig.2, FL magnetization was expected to be in the intermediate state below $H = +500$ Oe, and in AP configuration above $H = +600$ Oe. Therefore, the MO was considered to be separated into two modes according to the magnetic configuration. For sample W, f at AP configuration were mostly over ~ 10 GHz, but it gathered at ~ 7 GHz for sample S. This difference might be due to difference of an effective magnetic field on magnetic layers and nano-contacts.

Spin wave Doppler shift.

V Vlainck, M. Bailleul
GEMME, IPCMS, Strasbourg, France

As recently predicted, forcing a DC current through a ferromagnetic metal could induce a change of its spin-wave spectrum [1, 2, 3]. A transfer of angular momentum is indeed expected when spin-polarized electrons flow through an inhomogeneous magnetization configuration, such as that occurring if a spin-wave is propagating in the medium. This transfer of angular momentum induces an additional torque acting on the magnetization. In the so-called adiabatic approximation, this simply results in a frequency shift for the spin wave modes [4]. The expected shift is proportional to the spin current J_s and to the wave-vector k of the spin wave, (i.e. $\Delta\omega_{\text{doppler}} = k \cdot J_s / M_s$), which suggests an analogy with the well-known Doppler shift. Additionally it appears as a convenient way of measuring the polarization of the spin current in the bulk of the ferromagnet.

In this communication, we report an experiment dedicated to the observation of this “spin-wave Doppler shift”. The experiment is based on the propagating spin wave technique [5]. Spin waves of wavelengths of the order of 800nm are emitted and detected inductively using submicrometer conducting patterns (“spin wave antennae”), which are connected to a network analyzer (10MHz-20GHz). The spin waves propagate along a thin permalloy micro-stripe (width: 1.5-7 μm , thickness: 20nm), subjected to a saturating out-of-plane field H_0 and through which a large DC current density can be forced. Fig.1 is a scanning electron microscope image of our device showing the pair of antennae coupled to the ferromagnetic stripe.

Firstly, we demonstrate how the spin waves are emitted by an antenna by measuring its self-inductance ΔL_{11} . A typical curve obtained under a field $\mu_0 H_0 = 0.869\text{T}$ is shown in Fig.2a ($\text{Re}(\Delta L_{11})$, $\text{Im}(\Delta L_{11})$). Typical ferromagnetic resonance spectra is observed, from which the characteristic parameters of the ferromagnet can be estimated: the gyromagnetic factor $g \sim 2.18$, the Gilbert damping parameter $\alpha \sim 0.02$ and the effective magnetization $\mu_0 M_{\text{eff}} \sim 0.8\text{T}$.

Secondly we characterize the propagation of the spin waves between the two antennae by measuring the variation of mutual-inductance (ΔL_{12}). This is shown in Fig.2b where one recognizes clear oscillations arising from the phase delay accumulated along the propagation. We can extract the group velocity of the spin wave from the period of this oscillation: $\text{VSW} \sim 1\text{ }\mu\text{m/ns}$.

Finally we present our results of spin waves spectroscopy under a DC current, which constitute up to now the first experimental evidence of a Doppler shift for a spin wave. As can be seen in Fig.3 we perform spin wave propagation by measuring the mutual-inductances ΔL_{12} , ΔL_{21} in conjugation with a large DC current flow along the stripe. We observe that the frequencies of the spin waves are shifted in accordance with the sign and the intensity of the current, namely toward higher frequencies when the propagation is in the same way as the electron flow and toward lower frequencies in the opposite direction. Additionally we show that a spin-torque term added into the Landau Lifshitz equation of motion of the magnetization gives a correct description of this phenomenon.

The transport mechanisms in crystalline magnetic tunnel junctions (MTJ) attracted the interest of the international scientific community after the theoretical predictions of Butler et al [1] of giant tunnel magnetoresistance (TMR) effects, reaching several thousands of percents in single-crystal MTJ employing bcc ferromagnetic electrodes and MgO insulating barriers. In these model systems the electrons are classified with respect to the symmetry of their associated electronic Bloch wave function. The large predicted TMR ratio is related to a symmetry dependent attenuation rate within the MgO single crystal barrier combined with a half metallic property of a specific symmetry in the Fe electrode.

Within this topic, in 2001, our group started the experimental study of TMR in crystalline magnetic tunnel junctions, elaborated by Molecular Beam Epitaxy, combining single crystal bcc Fe, Co electrodes and MgO barriers. In 2002, we pointed out for the first time experimentally an intrinsic antiferromagnetic coupling effect in Fe-MgO-Fe tunnel junctions by spin polarized tunneling [2]. This effect, theoretically predicted by Slonczewski [3] can be explained today as a zero bias torque effect [4].

In 2004 we reported tunnel magnetoresistance effects whose amplitude overcame the expectations within the free-electron model. These results provided a first experimental evidence of the complex physics of tunneling in single crystal MTJs. A further deep understanding of fundamental aspects related to symmetry dependent tunneling [1] enabled us to gradually boost the TMR ratio at room temperature from 67% in 2003 [5] to 200% in 2006 (340% at 10K) [6]. Simultaneously, more and more spectacular results have been obtained in other laboratories [7]. Today, MTJs involving CoFeB electrodes show record TMR ratios approaching 1000% [8]. The MgO based MTJs represents nowadays the elementary brick either for data storage applications or fundamental physics studies concerning charge and spin transport by tunneling.

Over the last years, our research activity in Fe-MgO MTJs was mainly devoted to the engineering of new functionalities by playing with the electronic structure at the interface. In 2004 we demonstrated the role of the interfacial electronic structure on the tunneling [9] and subsequently that Fe/MgO interface engineering is a powerful tool to get high output voltage [10], large breakdown voltage and extremely low noise [11]. Detailed studies have been dedicated to carbon and oxygen [12] influence on tunneling when these impurities are located at the Fe-MgO interface.

Recently, we exploited the symmetry dependence of the tunnel conductivity to engineer novel MTJs functionalities. We demonstrated that, a suitably chosen Cr(001) epitaxial metallic spacer layer sandwiched in between the Fe ferromagnetic layer and the MgO, quenches the transmission of particular electronic states, therefore acting as an additional symmetry dependent tunnel barrier for electrons at the Fermi level [13]. Moreover, we show that this ultrathin Cr metallic barrier can promote quantum well states in an adjacent Fe layer.

In this presentation, we will give an overview of the experimental achievements of our group in parallel with advances on the same topics reported in literature. Within the framework of the symmetry filtering, we analyze in detail the difference in terms of TMR amplitude between the epitaxially grown MTJs and the sputtered CoFeB/MgO MTJs showing larger TMR ratios. The mechanisms of tunneling in our Fe-MgO MTJs will be discussed in detail, both in the equilibrium and the out-of-equilibrium regimes. Noise [11, 14] and ferromagnetic resonance experiments [15] will provide further evidence of direct tunneling. The influence of the interfacial electronic structure on the equilibrium coupling effect by spin polarized tunnel will be also addressed. Perspectives for out-of-equilibrium spin-torque experiments will be anticipated.

Current induced magnetization switching using spin transfer torque (STT) continues to generate interest for spin electronic applications such as MRAM, spin torque oscillators and detectors.^{1,2}

Among the most favorable candidates for realization of STT devices are epitaxial magnetic tunnel junctions (MTJ).^{3,4} Thus, understanding the fundamental mechanisms that can affect the dependence of Tunneling Magnetoresistance (TMR) and STT on the applied voltage in MTJs is critically important.⁵ Unlike fully metal-based nanostructures, at finite applied voltage, the total perpendicular (field like) component of the STT (T_{\perp}) in MTJs is not negligible⁶ and in the ballistic regime exhibits quadratic behavior as a function of applied voltage⁷ while the parallel STT term T_{\parallel} could behave non-monotonically as a function of applied voltage.⁷ Our predictions were recently confirmed experimentally.^{8,9}

Here we provide a systematic study of the influence of majority and minority band filling on the applied voltage dependence of both the parallel (T_{\parallel}) and perpendicular (T_{\perp}) terms of STT in MTJs consisting of two ferromagnetic electrodes (FM and FM') separated by the insulator (Fig.1a). The calculations have been performed within the tight-binding model using the non-equilibrium Green function technique in the framework of the Keldysh formalism. The electrodes and the barrier are characterized by on-site energies ϵ^{\uparrow} , ϵ^{\downarrow} , ϵ^B with corresponding hopping parameters in each region as well as at the interfaces. The potential profile of the MTJ under applied voltage is shown in Fig.1b. For simplicity we put all hopping parameters $t=-1\text{eV}$ and all calculations performed and presented here are for three monolayers of barrier thickness. The corresponding band width for both spin channels is therefore equal to $12t$.

In order to show the effect of majority and minority band filling on the behavior of STT we fix the majority band by setting its on-site energy at three values corresponding to the $1/4$, $1/2$ and $3/4$ filling, i.e. $\epsilon^{\uparrow}=+3$, 0 and -3eV , and shift the minority band by changing ϵ^{\downarrow} to trace the effect of the exchange splitting until ending up with the half-metallic case for which $\epsilon^{\downarrow}-6|t|$ exceeds the Fermi level (which is set to zero and shown by dashed lines in Fig. 1b). The corresponding results for T_{\parallel} and T_{\perp} are shown in Figs. 2(a,b,c) and 2(d,e,f), respectively. For the case of $1/4$ majority band filling (Fig.2a) the parallel component of the STT exhibits a wide range of behavior from being a quadratic even function of applied voltage at $\epsilon^{\downarrow}=4.2\text{eV}$ to an odd one for the pure half-metallic case with $\epsilon^{\downarrow}=7\text{eV}$. These are two limiting cases in the interplay between two collinear longitudinal spin currents $I_s(0)$ and $I_s(\pi)$ which define the parallel torque^{5,7} since $I_s(0)$ and $I_s(\pi)$ are odd and even parity functions of applied voltage, respectively.⁷ For the case presented in Figs. 2b and 2c the magnitude of T_{\parallel} decreases and it is impossible to obtain a situation for which $I_s(0)$ vanishes, moreover, T_{\parallel} is mostly defined by $I_s(0)$ and the odd parity voltage dependence dominates over even parity. It is interesting to note that in the half-metallic situation, the parallel torque (dT_{\parallel}/dV) is negative for $1/4$ majority filling (Fig. 2a) and changes sign in case of $1/2$ and $3/4$ filling (Figs. 2b and c). All of these curves can be explained in terms of the spin and charge current dependence on the interplay between evanescent states in the insulator and the Fermi surfaces of the ferromagnetic electrodes comprising the junction. In Figs. 2(d-f) we show the same effect of the band fillings on the voltage dependence of T_{\perp} . The zero voltage values correspond to the exchange coupling between FM and FM' through the barrier while the voltage induced part is always quadratic.

Since the discovery of spin dependent tunnelling, Magnetic Tunnel Junction (MTJs) have been widely investigated also in view of relevant applications like Magnetoresistive Random-Access-Memory (MRAM), magnetic sensors and novel programmable logic devices. Different class of materials, like half metals, have been tested in the past years. Nowadays it is well recognised that symmetry filtering in structures employing MgO barriers epitaxially matched with ferromagnetic electrodes FM(Fe, FeCo, FeCoB), provides better results in terms of stability and performances at room temperature. However, also in this case there is still a sizable gap in between theoretical predictions [1] of the TMR and experimental values,[2] probably to be ascribed to the non ideality of the interfaces.[3] In this spirit we have performed a detailed analysis and optimization of the formation of the FM/MgO interface with the aim of improving heteroepitaxy, reducing oxidation and maximizing the spin dependent properties of the interface electronic structure.

MgO/Fe and MgO/FeCo interfaces have been grown by MBE in a dedicated UHV system with different recipes for the growth of the MgO barrier, while monitoring in-situ the structural, chemical, electronic and magnetic properties of the interfaces via appropriate surface science techniques: low energy electron diffraction (LEED), photoelectron diffraction (PED), X-ray photoemission spectroscopy (XPS), ultraviolet photoemission spectroscopy (UPS), spin polarized inverse photoemission (SPIPE), absorbed current spectroscopy (ACS) and magneto optical Kerr effect (MOKE).

For both Fe and FeCo electrodes we found reliable recipes for the growth of the MgO overlayer ensuring only the minimum surface oxidation inherent with the formation of a chemical bonding between the FM electrode and MgO, as seen by detailed analysis of the Fe 2p peaks in XPS. Epitaxial MgO layers with high crystallinity have been obtained by stoichiometric evaporation from MgO single crystals, as revealed by LEED and PED analysis. The electron spectroscopy investigation of valence band states via UPS gives the expected electronic structure of the MgO barrier, without sizable modification of the FM electronic structure. The same holds true for the unoccupied part of the electronic structure we have investigated also with spin resolution via SPIPE and ACS. In fig. 1 we report SPIPE spectra from 2 ML of MgO grown on Fe(001) (filled dots) and FeCo(001) (empty dots). The experimental features reflect transitions from $\Delta 1$ states to $\Delta 5$ states, whose splitting is connected to the exchange splitting of the bands and we assume as index of the quality of the interface.[4] The electronic structure of the two electrodes is inherently different due to the different symmetry and chemical composition. Fe(001) presents the well known doublet B1–B2, related to $\Delta 5$ final states close to H25' just above the Fermi level, with the good exchange splitting which is maintained upon MgO deposition as well as the splitting of C peak reflecting the exchange splitting of the bands at H15. D and E are characteristic peaks of the MgO overlayer, with E in particular related to the onset of the MgO conduction band. Q1 and Q2 are instead assigned to fully polarized majority resonance states localized at the interface. For FeCo the situation is quite similar, except for the B1 peak which is missing as the corresponding $\Delta 5$ state is now inaccessible to SPIPE being under the Fermi level. Also in this case we observe that the surface exchange splitting is unaltered upon MgO deposition.

According to the optimized procedures, complete Fe/MgO/Fe and FeCo/MgO/Fe MTJs have been realized first by shadow mask (with junction areas of 200x200 microns) and now by optical lithography at the micrometer scale. The bottom FM electrode (100 nm) is epitaxially grown on MgO and

presents a very low defect concentration, as confirmed by a square hysteresis loop with a coercive field of only 0.8 Oe along the easy axis of the typical uniaxial anisotropy displayed by these films. The barrier thickness is 2 nm, while the top electrode is 10 nm thick with a coercive field of the order of 15 Oe. Preliminary transport measurements on Fe/MgO/Fe junctions shows state of the art values of the TMR at room temperature (of the order of 100 %), and high sensibility in the linear branch of the TMR (typically 3%/Oe).

In the paper we will give a complete comparison in between the performances of MTJs obtained employing different combinations of electrodes and interface preparation recipes, establishing a strong connection between the bias dependence of the TMR and the measured spin dependent electronic structure.

Introduction

The magnetic tunnel junctions (MTJs) consisting of MgO tunnel barriers are of great importance for MRAM application because they exhibit high TMR ratio. We employed NiFeSiB/CoFeB hybrid free layers to substitute traditionally used CoFeB layers with an aim to reduce switching field (H_{sw}) while maintaining high TMR ratio. Ni₁₆Fe₆₂Si₈B₁₄ has a lower saturation magnetization (M_s : 878 emu/cm³) compared to CoFeB (M_s : 1170 emu/cm³), and a higher anisotropy constant (K_u : 2,700 erg/cm³) than Ni₈₀Fe₂₀ (K_u : 1,000 erg/cm³) [1].

Experiment

The MTJs consisting of Si / SiO₂ / Ta(5) / Ru(40) / hybrid free layer / MgO (1.0~1.9) / CoFeB (4) / Ru(0.85) / CoFe(3) / IrMn(7.5) / Ta(5) / Ru(50) (in nm) were prepared by dc magnetron sputtering under typical base pressure below 5×10^{-9} Torr. The hybrid free layer consists of CoFeB(4), NiFeSiB(1.33) / CoFeB(3), NiFeSiB(2.66) / CoFeB(2), NiFeSiB(3.99) / CoFeB(1), or NiFeSiB(5.32). For all free layer structures, the $M_s t$ value was kept same. MgO tunnel barriers were formed by rf sputtering using a MgO target. All of MTJ samples were annealed in vacuum at 360°C for 1 hr with 3 kOe of magnetic field. TMR ratio was investigated by current-in-plane-tunneling (CIPT) measurement and two-probe method after fabricate junctions by a photolithographic patterning and ion beam etching. The junction sizes were varied from 10 $\mu\text{m} \times 10 \mu\text{m}$ to 100 $\mu\text{m} \times 100 \mu\text{m}$.

Results and Discussion

Figure 1 shows the TMR ratio dependence on the MgO thickness for various free layer structures. The TMR ratio of the MTJ with a NiFeSiB-only was poor. To improve this, a CoFeB layer was placed between the MgO barrier and the NiFeSiB layer. When the thickness of NiFeSiB was 1.33 nm and CoFeB was 3 nm, the TMR ratio becomes 209%, which is comparable with that of the CoFeB-only free layer (204%). Moreover, the H_{sw} became 6 Oe which is lower compared to 12 Oe obtained from the MTJ with CoFeB-only free layer (not shown here). Figure 2 shows the in-plane XRD profiles of Si / SiO₂ / Ta (5) / Ru (40) / hybrid free layer / MgO (10) films. The XRD peak intensity ratio of MgO (200) and MgO (220) should be 4 in case of (001) oriented MgO films [2]. The ratio of the MgO layer on the CoFeB layer was 3.6, whereas that of the MgO on the NiFeSiB was nearly 1. This means that the amorphous NiFeSiB layer located just below the MgO layer can not induce (001) orientation of MgO. The peak intensity ratio of the MgO layer on the hybrid NiFeSiB (1.33) / CoFeB (3) layer was 3.5.

Lately, an MTJ with a NiFe / CoFeB hybrid free layer was studied [3]. In this case, the CoFeB layer crystallized into the textured fcc (111) structure instead of bcc (001) after annealing, and as a result, the TMR ratio was reduced because the coherent tunneling of $\Delta 1$ electrons could not occur [3]. On the contrary, because the NiFeSiB layer maintained amorphous after annealing, the amorphous CoFeB layer could be crystallized into the bcc (001) following to the orientation of the MgO. As a consequence, the NiFeSiB / CoFeB free layer resulted in a high TMR ratio. In addition, since NiFeSiB has lower M_s compared to CoFeB, the NiFeSiB-containing MTJs exhibited lower H_{sw} values [1]. In summary, the NiFeSiB / CoFeB hybrid free layer approach was effective in terms of maintaining high TMR ratio and decreasing H_{sw} at the same time.

We show experimental evidences of interface resonant states (IRS) tunnel transport in fully epitaxial Fe/MgO/Fe(001) magnetic tunnel junctions (MTJs). The presence of 100% spin polarized interface states in the energy gap of minority $\Delta 1$ states [1] has been theoretically predicted. Those states are coupled with the bulk Fe states and become available for conduction for small bias above the Fermi energy. When activated, their opposite spin-polarization with respect to the bulk $\Delta 1$ states of Fe, responsible on the large tunnel magneto-resistance (TMR) of Fe/MgO/Fe junctions, can drastically affect the TMR amplitude and sign.

Our Fe/MgO/Fe MTJs are grown by using ultrahigh vacuum MBE [2]. They present two different Fe/MgO interfaces. The annealing at 700K of the bottom Fe electrode provides a flat bottom interface with almost no defects. This atomically flat interface promotes IRS states. On the other hand, the top interface shows higher roughness, determined by the growth of the metallic Fe on the MgO insulator. Consequently, the IRS of the top Fe layer is expected to be quenched due to their high sensitivity to interface defects [2].

The transport measurements are done by conducting AFM tip after patterning mesa structure by e-beam lithography. By changing the bias voltage, the different density of states of top and bottom Fe/MgO layer is selectively probed. The d^2I/dV^2 characteristics measured on our samples point out two peaks: the first one at about 0.2eV [3] and the second one at 0.95V. These spectroscopic features are only present in the anti-parallel MTJ configuration being completely absent in the parallel one. Neither the observed peaks nor the asymmetry of the anti-parallel $I(V)$ curve can be explain by the Fe bulk density of states. Therefore, we associate these peaks to the surface electronic structure of the bottom Fe. The IRS represent the stationary states in a quantum well (QW) where the minority spin $\Delta 1$ wave function is confined between the MgO insulator and the Fe $\Delta 1$ bulk gap. These surface states of the minority spin will provide a 100% negative polarization.

Moreover, our spectroscopic data show a significant increase of IRS-related conductivity when the thickness of the MgO is reduced from 3 to 2nm. Due to the opposite sign polarization of the IRS with respect to the 100% positive polarization of the bulk $\Delta 1$ Fe, it is obvious that their activation affects drastically the TMR amplitude.

Thus, the control of the IRS contribution to the tunneling in single crystal MTJ devices is a key parameter to control the TMR amplitude and sign in thin barrier Fe/MgO devices needed for low RA sub-micrometer MTJs in MRAMs.

Second derivative of current in Fe/MgO(t)/Fe(001) MTJs for different thickness ($t = 2.2, 2.4, 2.6$) of the single crystal MgO barrier. We point out the peaks at about 0.2V and 0.9V in positive bias voltage when the electrons are flowing from the top Fe electrode towards the bottom atomically flat Fe/MgO interface.

Transport characterization of the single and double magnetic tunnel junctions using point contact spectroscopy.

A. Iovan, S. Cherepov, A. von Bieren, S. Andersson, V. Korenivski
Nanostructure Physics, KTH, Stockholm, Sweden

The high potential of the magnetic tunnel junctions (MTJ) for microelectronic devices [1] justifies the intensive research efforts worldwide to understand and improve their properties. The studies of the transport properties of the junctions require a patterning process, which often is the standard multi-step lithography[2]. The junctions can be defined also by one-step lithography and measured with the aid of a conductive AFM [3]. However, if the number of junction to be measured increases the turnaround time of the AFM technique becomes long. Worledge et al. [4] developed a fast surface probe technique for measuring tunnel magnetoresistance of multilayered films, though the lateral geometrical aspects of the devices cannot be studied using this method.

In this report we discuss the use of the point contact spectroscopy (PCS) technique for the characterization of MTJ's using one step lithography for patterning nanopillars. The key of this technique is to produce a sample with a large array of tunnel junctions which are closely spaced on a substrate buffered with metallic layer for making the bottom electrical contact to the nanopillars. A top nano-contact is made mechanically using a conductive tip, at room temperature or in liquid helium. A large number of junctions can be measured just by moving slightly the tip on the surface of the sample. Single tunnel junctions were characterized using this method. However, the possibility of screening electrically a large number of junctions is particularly interesting for the study of coherent transport in double tunnel junction [5]. We observed such transport in our double magnetic tunnel junction (DMTJ) samples, where the measurements show that the magnetoresistance can increase by up to one order of magnitude.

Single tunnel barriers and double tunnel barriers were produced using sputtering. In order to pattern the samples, a 150-nm ZEP520A positive resist is spun on top of the multilayer samples and subsequently baked. A rectangular matrix can be drawn in the resist by e-beam lithography. The resist mask is then transferred to the stacks by using Ar ion beam etching. The process is finalized by removing the resist mask using oxygen plasma and the final structure is a large array of MTJ stacks, separated by trenches etched through the top electrode.

Figure 1(a) shows the measured I-V characteristics and the Brinkman fit [6] for a tunnel junction from the stack of SiO/NiFe(50nm)/MgO(3nm)/Co(10). The typical size for a single tunnel junction used in the design is 10 by 10 micrometers and the same value for the area is obtained from the fit curve. The barrier height extracted is 0.489 eV which is a reasonable value for MgO, where 0.3–1 eV barrier heights [7], [8] are expected. In addition the good matching between the deposited thickness of MgO (2nm) and fitted value (2.119 nm) indicate the measurement of a single tunnel junction.

This technique is very useful for the study of coherent transport in DMTJ's where typically a large number of samples must be screened to find the desired behavior. If the thickness of the intermediate layer is sufficiently small, effects of coherent transport can be observed. Figure 1(b) shows a staircase current voltage characteristics obtained for a double junction with the area of 170 nm by 800 nm. At the points of resonant transmission (steps in current) the magnetoresistance versus voltage (not shown) exhibits rapid changes in value as well as sign. We interpret this behavior as due to an activation of discrete transmission levels in the middle layer of the DMTJ caused by the magnetic transition in a sweeping external magnetic field. This activation is due to the changing potential in the intermediate layer caused by the change of the resistance of the magnetic tunnel junction.

In conclusion, in this work we use a novel method for a transport characterization of magnetic tunnel junctions including double barrier structures in the coherent transport regime. This study can be important for further development of magnetic nano-devices with new functionality.

First-principle theories predicted a giant tunneling magnetoresistance (TMR) in fully epitaxial magnetic tunnel junction (MTJ) with a crystalline MgO(001) barrier due to coherent spin-dependent tunneling [1,2]. We have experimentally achieved giant room-temperature MR ratios of 180%, 271% and 410% at in fully epitaxial Fe/MgO/Fe, Co/MgO/Fe and Co/MgO/Co MTJs, respectively [3-5]. In addition to the giant TMR effect, these fully epitaxial MTJs are a model system in studying novel phenomena such as an oscillation of MR ratio as a function of MgO barrier thickness (t_{MgO}) with a period (λ) of about 0.3 nm [3,6]. The theory proposed a model of interference between tunneling states, in which an oscillation of tunneling conductance with respect to t_{MgO} is expected [1]. In our previous study on fully epitaxial Fe/MgO/Fe-MTJs [6], both the tunneling resistance in the parallel magnetic state (R_p) and that in the antiparallel magnetic state (R_{AP}) exhibited short-period oscillations as a function of t_{MgO} with the same λ of 3.2 Å and different phases. R_{AP} also showed a long-period oscillation with $\lambda = 9.9$ Å. As a result, t_{MgO} -dependence of TMR is expressed as a superposition of the short- and long-period oscillations. However, the origin of the short-period oscillation is still unclear although this is an essential issue in understanding the physics of coherent tunneling. To clarify the origin of the short-period oscillation, we studied MgO-based epitaxial MTJs with a non-magnetic or a paramagnetic top electrode layer. In this study, we fabricated epitaxial Fe(001)/MgO(001)/Cr and Fe(001)/MgO(001)/Ru MTJs with various MgO thicknesses. Cr is antiferromagnetic (SDW) below about 300 K, while Ru is non-magnetic at any temperature. We performed high-precision measurements of the tunneling resistance as a function of t_{MgO} in these MTJs to investigate whether the tunneling resistance oscillates with respect to t_{MgO} . We fabricated the 2 kinds of MTJ films with a wedge-shaped MgO layer on a single MgO(001) substrate by using molecular beam epitaxy growth except for sputter-deposited Ru layer. *In situ* RHEED observations showed that the Cr electrode layer grown on MgO is (001)-oriented single-crystalline while the Ru electrode layer on MgO is poly-crystalline. The growth conditions of the bottom Fe and MgO barrier layers were the same as in our previous studies [3,6]. The films were fabricated into MTJs using a high-precision micro-fabrication process which was also used in our previous study [6]. Tunneling resistance at a bias voltage of 10 mV was measured at 20 K, room temperature and 350 K with the dc 4-probe method.

The tunneling resistance per unit junction area (RA product) for both Fe/MgO/Cr-MTJs and Fe/MgO/Ru-MTJs exponentially increases with respect to t_{MgO} , which is a typical tunneling characteristic, as observed in our previous studies[3-6]. We tried to extract an oscillatory component in the $RA - t_{\text{MgO}}$ relationship by removing the exponential t_{MgO} -dependence from the $RA - t_{\text{MgO}}$ relationship (*i.e.*, by dividing RA by $C \exp(\alpha t_{\text{MgO}})$ which is obtained by fitting $RA - t_{\text{MgO}}$ relationship). The t_{MgO} -dependences of $RA / C \exp(\alpha t_{\text{MgO}})$ for the 2 kinds of MTJs at 20 K are shown in Fig. 1. The tunneling resistance of the Fe/MgO/Cr-MTJs exhibited the short-period oscillation with $\lambda = 3.0$ Å. The same oscillation was also observed at 350 K, where Cr is paramagnetic. In Fe/MgO/Ru-MTJs, on the other hand, no oscillatory feature was observed. This indicates band structure of electrode rather than spin angular momentum is responsible for the short-period oscil-

lation. The results contain an important clue in clarifying the detailed mechanism of coherent spin-dependent tunneling.

This study was supported by New Energy and Industrial Technology Development Organization (NEDO).

Magnetic tunnel junctions (MTJs) are nowadays one of the most active areas of material science and spintronics. Our recent studies have demonstrated that combined measurements of conductance and noise as a function of applied bias could be a powerful tool to investigate electron tunneling in MTJs [1-3]. We have also recently found that carbon-doping of the bottom Fe/MgO interface leads to strongly asymmetric TMR vs. bias, providing new root to create high-output voltage MTJ devices [4]. Present contribution reports on study of high bias (above 2V) dynamic conductivity, shot noise (10K) and room temperature 1/f noise in epitaxial Fe(100)[45nm]/Fe-C/MgO(100)[2.6 and 3nm]/Fe(100)[10nm] MTJs as a function of the magnetic state.

Our junctions show large tunnel magnetoresistance (up to 185% at 300K and above 300% at 4K). Multiple sign inversions of the magnetoresistance are observed for bias polarity when the electrons scan the electronic structure of the bottom Fe-C interface (Fig.1). Reduction of the barrier thickness mainly affects negative TMR by reducing TMR inversion bias voltage. These experiments demonstrate the role of the minority spin Fe interface resonance state (IRS) to the tunneling.

The experiments on shot noise (Fig.2) clearly indicate absence of electron correlations and/or sequential tunneling phenomena for negative bias when the electrons are injected from the top Fe/MgO toward the bottom Fe-Fe-C/MgO interface in carbon doped MTJs. This proves that both parallel (P) and anti-parallel (AP) spin-dependent conductance and the shot noise are due to direct tunneling between electron bands, as expected for a coherent tunneling. When electrons are injected from bottom to upper electrodes, the shot noise also shows Fano factors close to 1 except the bias voltage close to 0.5V when resonant tunneling (presumably through asymmetrically situated oxygen vacancies) weakly suppresses the shot noise (Fig.2, AP state). In general, our shot noise measurements validate the high quality of our epitaxial MgO barriers. The high MTJs quality is furthermore confirmed by the large breakdown voltage of the MTJs (up to 3 V) [2].

The low frequency noise analysis performed on our MTJs show extremely low 1/f noise levels at 300K [3]. We have found that the normalized noise (Hooe factor) asymmetry between parallel and antiparallel states may strongly depend on the applied bias and its polarity. Fully epitaxial Fe/C/MgO/Fe(001) MTJs exhibit record low Hooe factors being at least one order of magnitude smaller than previously reported (Fig.3).

FIG. 1. Comparison of the high-bias TMR measured at 10K for MTJs with two different MgO thicknesses.

Fig.3 Room temperature normalized noise measured in Fe(100)[45nm]/MgO(100)[2.6nm]/Fe(100)[10nm] MTJs at +200mV as a function of Resistance by Area (RA) product. The dashed line indicates the lowest Hooe factor previously reported for the MTJs.

Fig. 2 Shot noise measurements in the P and AP states at 10 K in Fe/C/MgO(2.6nm)/Fe MTJ. Negative bias corresponds to electrons injected from the top Fe/MgO toward the bottom. For comparison, the solid curves show the theoretical expectation for the shot noise with electron tunneling having Poissonian character. Arrow indicates bias interval with suppressed shot noise.

1/f magnetic noise dependence on free layer thickness in linear MgO magnetic tunnel junctions.

P. Wisniewski, J. M. Almeida, P. P. Freitas
INESC-MN, Lisbon, Portugal

Utilization of MgO based magnetic tunnel junctions as low field sensors requires besides high sensitivity, low noise level that ultimately determines sensor detection limit. The noise level of junction is the highest in the most sensitive region of transfer curves, which is usually a working region, and is dominated by 1/f magnetic noise. A reduction or cancellation of the noise is of primary importance in view of developing low field MgO based sensors. It was shown that thinning CoFeB free layer in MgO magnetic tunnel junctions allows to obtain linear junctions with sensitivity as high as 7.7 %/Oe [1]. The use of these high sensitive junctions as low frequency field sensors is determined by their noise spectra, which is a topic of this study.

Magnetic tunnel junctions with varying thickness of CoFeB(t_F) free layer from 14.5 Å to 30 Å with structure glass/Ta(50)/Ru(180)/Ta(30)/PtMn(160)/CoFe(22)/Ru(9)/CoFeB(30)/MgO13.5/CoFeB(t_F)/Ru(50)/Ta50 (thickness in Å), were deposited by magnetron sputtering (Nordiko 2000 system). The nominal layer thickness is given in angstrom. The easy axis of the magnetic layers was set by applying 20 Oe field during deposition. Before microfabrication, the films were passivated with 150 Å of Ti10W90(N2) deposited in another magnetron sputtering system. The samples were patterned by direct write laser lithography and ion beam milling with areas ranging from 4.5 μm^2 to 144 μm^2 . Patterned samples were annealed in high vacuum at 330 °C, for 1 h in a magnetic field of 5 kOe applied along the easy axis, and furnace cooled in the field. The electrical properties were measured using a dc four-probe setup. Noise measurements were made in a magnetically shielded system.

Figure 1 shows dependence of TMR on CoFeB free layer thickness and corresponding transfer curves. TMR decreases gradually as free layer decreases and the junctions show linear response for CoFeB(t_F) \leq 15.5 Å. For CoFeB(t_F) = 14.5 Å junctions present sharp drop in sensitivity as compared to thicker free layers and 40 % TMR. The junctions with CoFeB(t_F) = 15.5 Å and CoFeB(t_F) = 14.5 Å show up to 7.7 %/Oe and 0.2 %/Oe sensitivity respectively. The change in the response of the free layer and drop in sensitivity for CoFeB(t_F) = 14.5 Å is due to onset of its superparamagnetic behavior.

To evaluate noise of the linear junctions noise spectra were measured along transfer curves. The extracted noise power density and detection limits show Fig. 2. The noise power of the two junctions is distinctive different at all frequencies and is essentially flat along transfer curve for CoFeB(t_F) = 14.5 Å. This is contrast to junctions with CoFeB(t_F) = 15.5 Å and thicker (not shown here) that exhibit sharp increase in noise power in the sensitive region. The absence of 1/f magnetic noise in junctions with CoFeB(t_F) = 14.5 Å is attributed to stabilizing effect of demagnetizing field of the pinned layer on magnetic fluctuations in the free layer.

The results show that reduction of three layer thickness can be used as an effective way to cancel 1/f magnetic noise in magnetic tunnel junctions, at the expense of sensitivity. In terms of field detection limit, the junctions with thin and thick free layer show the same detection limit of 25 nT/Hz^{1/2} at low frequency (500 Hz). At high frequency (100 kHz), however, junctions with thicker free layer show detection limit of 1.5 nT/Hz^{1/2}, which is three times better than for thin free layer.

 1. INESC-MN, Lisbon, Portugal; 2. Instituto Superior Tecnico, Lisbon, Portugal

It was previously shown that it is possible to suppress 1/f noise in spin valve (SV) sensors, by modulating an external DC magnetic field at high frequency through the movement of a MEMS cantilever with an incorporated magnetic flux guide. This shifts the operating frequency and enables the detection of DC magnetic fields in the high frequency thermal noise regime, where the 1/f noise is typically 2 orders of magnitude lower. This past work presented a dc detection limit of 0.54 $\mu\text{T}/\text{Hz}^{1/2}$, being limited by the low cantilever magnetic field modulation efficiency, which was only 0.11 % . [1]

In this digest a major improvement is presented, where MgO based magnetic tunnel junctions (MTJ) and MEMS torsionators are now used, allowing a DC field detection limit of 27 $\text{nT}/\text{Hz}^{1/2}$ and an improved MEMS magnetic field modulation efficiency of 20 %.

MgO based MTJ sensors were deposited in an automated sputtering machine with the following structure: Glass/ Ta[50] / Ru [180] / Ta [30] / MnPt [200] / CoFe [20] / Ru [9] / CoFeB [30] / MgO [15] / CoFeB [15.5] / Ru [50] / Ta [50] / TiW(N₂) [150], (thickness in Å). The TMR ratio was 30 %, lower than the expected 60 % found in standard samples. This decrease can be explained by the use of an alternative annealing (flash annealing). The MTJ sensors were patterned down to a dimension of 1.5x15 μm^2 . A 4000 Å thick CoZrNb flux guide concentrator was patterned close to it, to convey and focus the external field to the sensor area. Finally, after passivating the sensor with an oxide layer, a 30x20 μm^2 MEMS torsionator was fabricated with a double layer of a-Si:H (4000 Å)/Al (1000 Å) and an additional 2000 Å thick CoZrNb flux guide. The MEMS torsionator is actuated by a gate electrode at frequency f, causing it to oscillate at 2f. This oscillation produces a 2f AC magnetic field, which is read by the MTJ in a spectrum analyzer. Fig.1 shows a SEM micrograph of the integrated device and a cut view diagram.

Noise measurements in the 2 kHz – 500 kHz range were performed in the MTJ sensor. For a bias current $I = 10^{-5}$ A and at 500 kHz (close to the thermal noise background) the magnetic field detection limit is $B_{\text{detect}} = 4 \text{ nT}/\text{Hz}^{1/2}$ (Figure 2).

With this MTJ-MEMS hybrid device the minimum detectable DC field (B_{detect}) is given by:

$$B_{\text{detect}} = S_B / e_{\text{tors}} \quad (1)$$

where S_B is the MTJ noise in $\text{T}/\text{Hz}^{1/2}$ at the modulated frequency, and e_{tors} the magnetic field modulation efficiency of the MEMS torsionator.

Figure 3 shows the MTJ output, when the MEMS gate is actuated by a 20 V_{pp} AC signal at 230 kHz. The MEMS torsionator oscillates at 460 kHz. For a DC external field $B_{\text{ext}} = 0.36 \text{ mT}$ entering the flux guide, the MTJ sensor detects the generated AC field at 460 kHz, showing a magnetic output of 240 $\mu\text{V}/\text{Hz}^{1/2}$.

The total MTJ output is given by 2 contributions, one magnetic - resulting from the AC detected magnetic field, and one electric – coming from direct capacitive coupling between the gate electrode and the MTJ sensor:

$$\Delta V_{\text{MTJ}} = \Delta V_{\text{magnetic}} + \Delta V_{\text{electric}} \quad (2)$$

$$\Delta V_{\text{magnetic}} = S I e_{\text{tors}} B_{\text{ext}} \sin(2\pi(2f)t) \quad (3)$$

where S is the sensitivity of the MTJ sensor (Ω/mT), I the MTJ biasing current, e_{tors} the MEMS torsionator modulation efficiency of the external static field B_{ext} and f the frequency of the signal applied to the torsionator.

Using Eq. (3), the MEMS torsionator modulation efficiency (e_{tors}) was calculated and found to be 20 %. Putting this together with the noise of the MTJ sensor at the modulated frequency – S_B (4.4 $\text{nT}/\text{Hz}^{1/2}$ at 460 kHz) we can estimate from Eq. (1) the DC detection limit of this hybrid-device, $B_{\text{detect}} = 27 \text{ nT}/\text{Hz}^{1/2}$.

Further work is being developed, mainly to improve the intrinsic detection limits of the MTJ sensors, so that its further integration in this hybrid-device would lead to pT DC field detection.

Strong perpendicular anisotropy systems consisting of Co/Pt multilayer stacks that are antiferromagnetically coupled via thin Ru or NiO layers have been used as model systems to study the competition between local interlayer exchange and long-range dipolar interactions [1,2]. Magnetic Force Microscopy (MFM) studies of such systems reveal complex magnetic configurations with a mix of antiferromagnetic (AF) and ferromagnetic (FM) phases. However, MFM allows detecting surface stray fields only and can interact strongly with the magnetic structure of the sample, thus altering the original domain configuration of interest [3,4].

In the current study we combine magnetometry and state-of-the-art soft X-ray transmission microscopy (MXTM) to investigate the external field driven FM phase evolution originating from the domain boundaries in such antiferromagnetically coupled perpendicular anisotropy films. MXTM allows directly imaging the perpendicular component of the magnetization in an external field at sub 100 nm spatial resolution without disturbing the magnetic state of the sample [5,6]. Here we compare the domain evolution for two similar $[\text{Co}(4\text{\AA})/\text{Pt}(7\text{\AA})]_x-1/\{\text{Co}(4\text{\AA})/\text{Ru}(9\text{\AA})/[\text{Co}(4\text{\AA})/\text{Pt}(7\text{\AA})]_x-1\}$ 16 samples with slightly different Co/Pt stack thickness, i.e. slightly different strength of internal dipolar fields. After demagnetization we obtain AF domains with either sharp AF domain walls for the thinner multilayer stacks or “tiger-tail” domain walls (one dimensional FM phase) for the thicker stacks. When increasing the external field strength the sharp domain walls in the thinner stack sample transform into the one-dimensional FM phase, which then serves as nucleation site for further FM stripe domains that spread out into all directions to drive the system towards saturation (Fig. 1). Energy calculations reveal the subtle difference between the two samples and help to understand the observed transition, when applying an external field.

This work was partially supported by Lavoisier fellowship. The soft X-ray microscope was supported by the Director, Office of Science, Office of Basic Energy Sciences, Materials Sciences and Engineering Division, of the U.S. Department of Energy.

Magnetization indicator film for Lorentz transmission electron microscopy measurements of perpendicularly magnetized nanostructures.

J. W. Lau

Metallurgy Division, National Institute of Standards and Technology, Gaithersburg, MD

Lorentz transmission electron microscopy (TEM) has been invaluable towards understanding the relationships between material properties and magnetic behavior in magnetic nanosystems. Samples magnetized orthogonal to the electron beam (in-plane magnetization) generate magnetic contrast by causing electrons to deflect, due to the Lorentz force. However, in the case of samples magnetized parallel to the electron beam direction (perpendicularly magnetization), no magnetic contrast is possible, because the Lorentz force, F , as in $F = qV \times B$ is zero. Here, q is the electron charge, V is the electron velocity, and B is the magnetic induction of the sample. One way to solve this problem is by tilting the sample. However, even for the best-case scenario where the nanostructures are magnetized in-plane, obtaining Lorentz contrast is a challenge at best for nanostructures below 100 nm. For similarly sized perpendicularly-magnetized nanostructures, the signal would be indistinguishable from noise even with modest tilts.

This work is driven by the need for in situ magnetic and microstructure characterization of perpendicularly magnetized nanostructures. Such systems are under scrutiny for bit-pattern media and magnetic sensor applications. In order to visualize magnetization orthogonal to the electron beam, we propose using a single-layer magnetic indicator film to detect such magnetization. We use micromagnetic simulations to demonstrate the feasibility of such an indicator film for an array of 100-nm nanodots consisting of a perpendicularly magnetized material such as Co/Pd multilayers. Fig. 1a shows the top-view of the simulation geometry and Fig 1b shows the side-view. White dots are magnetized out-of-plane while black dots are magnetized into the plane. The nanodots rest on a 30-nm thick non-magnetic layer. The perpendicular-magnetization indicator film, PMIF, rests on the opposite surface of the non-magnetic layer. Experimentally, such geometry can be achieved by first, fabrication of the nanodots on an electron transparent silicon nitride membrane window, followed by the deposition of a uniform film Permalloy film on the underside of the nitride membrane. For the layer containing the nanodots, we assume equal thicknesses in Co and Pd multilayers, and so the saturation magnetization of the nanodots, $M_s(\text{dot})$, is 850 kA/m, the uniaxial anisotropy strength, $K_u(\text{dot})$, is 530 kJ/m³, and an exchange coupling constant, $A(\text{dot})$ as 1.0e11 J/m. For the PMIF layer, we assume the saturation magnetization of Permalloy, $M_s(\text{PMIF})$, is 800 kA/m, the uniaxial anisotropy strength, $K_u(\text{PMIF})$, is 0, and an exchange coupling constant, $A(\text{PMIF})$ as 1.0e11 J/m. Elsewhere the material is taken to be non-magnetic.

Each of the nanodots within the dotted square of Fig 1a is switched in turn and the subtracted Lorentz images are shown in Fig. 2. The subtracted image is the difference between the before-switch image and the after-switch image followed by a low-pass filter. The dots outside of the dotted square of Fig. 1 were not switched in order to avoid aperiodic artifacts. The circle outlines in Fig.2 shows the original positions of the nanodots. We see in Fig.2 that the PMIF can clearly distinguish the nanodot that had switched from the ones that had not.

In summary, we have devised a method of observing magnetization orthogonal to the path of the electron beam in Lorentz TEM by the means of an indicator film. PMIF will allow us access to in situ perpendicular magnetic information that is not previously possible within in the TEM.

1. NUS Graduate School for Integrative Sciences and Engineering, National University of Singapore, Singapore, Singapore; 2. Department of Electrical and Computer Engineering, National University of Singapore, Singapore, Singapore; 3. Data Storage Institute, Singapore, Singapore

Spin configurations of micron and nanometer sized ferromagnetic elements are being studied intensively due to their fundamental importance in nanomagnetism [1, 2] as well as potential data storage applications [3, 4]. The spin configuration of magnetic nanostructures with negligible anisotropy has been demonstrated to be largely determined by their geometrical shape, lateral size and thickness [5]. In the work reported so far, generally, the variation of thickness was realized by fabricating different structures with a pre-determined thickness. Here, we explore the effect of successive in-situ focused ion beam (FIB) milling on the spin configurations of hexagonal shaped ferromagnetic elements at remanent state. The advantage of this approach is that the results obtained will be based on same structures, reducing the influence of irregularities caused by the fabrication processes.

The hexagonal shaped NiFe elements, with a thickness of 30 nm, a diagonal length of 2 μm and in 10×5 hexagonal array arrangement with an edge to edge spacing of 200 nm, were fabricated by electron-beam lithography and liftoff techniques. The sample was first saturated in-plane and then the magnetization configurations were imaged at remanent state using scanning electrons microscopy with polarization analysis (SEMPA). The SEMPA imaging experiments were performed in an ultra-high vacuum system consisting of a SEMPA and a FIB, which allows us to perform in-situ surface cleaning and thickness reduction by FIB prior to each SEMPA measurement. Micromagnetic simulation using the OOMMF code was carried out to obtain the remanent state magnetization configurations of individual elements at different thicknesses.

Figure 1 shows the in-plane magnetization configurations of the same dot arrays with different FIB trimmed thicknesses, obtained from SEMPA imaging: (i) longitudinal and (ii) transverse, as well as (iii) the topographic images captured simultaneously with the magnetic configurations. Panels (a) to (d) correspond to thicknesses of 30 nm, 20 nm, 12 nm and 8 nm, respectively. The images in panel (d) were obtained at a higher magnification as compared to those shown in (a) to (c). As can be seen from the images shown, panels (a) to (c), a single vortex state is observed in all elements with thicknesses of 12 nm, 20 nm and 30 nm. Interestingly, the elements from second to eighth columns were found to exhibit column-wise alternate sign of sense of rotation whilst the elements at the two side columns show random signs. This indicates that there is a strong magnetostatic coupling between the adjacent elements. As the thickness is reduced further to 8 nm, a double vortex structure was observed, as shown in panel (d). The slight distortion in both the magnetic and topographic images is due to the drift caused by long imaging duration. Unlike the previous report [5] on circular dots with diameter smaller than 500 nm showing a single domain state below a critical thickness, our results of the micron size elements show a multi-domains state. As the FIB milling could also cause alteration of the magnetic properties of the ferromagnetic elements, micromagnetic simulation has been performed for elements with different saturation magnetizations and thicknesses. Figure 2 shows the simulated magnetization configurations of the hexagonal elements with different thicknesses and magnetizations. The simulated results show a flux closure state with six regions of different contrast for elements with larger thickness, Fig. 2(a), but a double vortex

structure for elements with much reduced thickness, Fig. 2(c), agreeing well with the SEMPA images. Work is on-going to modify the structures in-situ by FIB and study their magnetic configurations using SEMPA.

Ballistic electron magnetic microscopy on Co/Cu/NiFe spin valves.

A. Kaidatzis, S. Rohart, A. Thiaville, J. Miltat
Laboratoire de Physique des Solides, Orsay, France

The advent of hot electron devices like the spin-valve transistor (SVT) [1] and the magnetic tunnel transistor (MTT) [2] creates the need for locally probing the spin dependent ballistic transport. Moreover, the research of magnetic systems with reduced dimensions implies the capability of imaging magnetic structures down to the nanometer scale. In this context, using a Scanning Tunneling Microscope and realizing a three terminal device sample structure, we have performed Ballistic Electron Magnetic Microscopy (BEMM) [3,4] measurements on Co/Cu/NiFe spin valves. Hot electron transport through Cu/Co/Cu and Cu/NiFe/Cu stacks was similarly studied by Ballistic Electron Emission Microscopy (BEEM).

Multilayers were deposited in a UHV chamber (base pressure $<10^{-9}$ mbar) using an e-gun evaporator. The hydrogenated Si(111) surface was used as a substrate. Initially a 7 nm Au layer was deposited to form a homogeneous Schottky interface (barrier height > 0.8 eV). Afterwards, a 1.5 nm Cu seed layer was deposited, before the growth of the Co/Cu/NiFe spin valve. Then the film was covered by a 1.5 nm Cu and a 3 nm Au capping layers for ex-situ transfer. For the present study, the spin valve consisted of a 2 nm Co and a 2 nm $\text{Ni}_{80}\text{Fe}_{20}$ layers, separated by a 6 nm Cu spacer. For BEEM study, instead of the trilayer stack, single Co or $\text{Ni}_{80}\text{Fe}_{20}$ layers having various thicknesses were deposited ($t_{\text{Co}}=1, 2, 3.5$ and 4.5 nm, $t_{\text{NiFe}}=1.4, 2, 4, 6$ and 8 nm). All the experiments were performed at room temperature using a UHV-STM.

The spin independent hot electron attenuation length λ in Co and NiFe was determined by studying the variation of the transmission as a function of magnetic layer thickness. For both metals λ remains relatively invariable in the range 1 to 2 eV above the Fermi level, with a value 2.3 ± 0.2 nm for Co and 3.4 ± 0.1 nm for NiFe (see figure 1)

Spin dependent ballistic transport was studied in Co/Cu/NiFe trilayers. The Co and NiFe layers have coercive fields sufficiently different to reverse their magnetization independently. BEEM spectra in the parallel (P) and anti parallel (AP) configurations revealed a significant difference of ballistic electron transmission. A magnetic contrast of up to 70 % was measured (see figure 2). Finally, imaging of magnetic domains during the magnetization reversal process was achieved. The magnetic contrast switches from bright (magnetic saturation) to dark (anti parallel configuration). This study shows the non homogeneous reversal of the NiFe layer, which occurs by nucleation and propagation of domain walls (see Figure 3).

In conclusion, the spin independent attenuation length was determined for Co and NiFe layers. Ballistic transport in a Co/Cu/NiFe spin valve was shown to strongly depend on the relative orientation of the two magnetic layers. A magnetic contrast up to 70% was achieved and enables imaging the magnetic reversal of a NiFe thin film at few tens of nanometer scale.

Figure 3: Successive BEMM images of the magnetization reversal in the spin valve. The sample was first saturated at -40 Oe. The images at 0, 2 and 4 Oe show the nucleation and growth of a magnetic domain (black area) in the FeNi layer. The images are $0.6 \times 1 \mu\text{m}^2$

Mapping Atomic-Scale Spin Structures on Insulators by Magnetic Exchange Force Microscopy.

R. M. Wiesendanger

Institute of Applied Physics, University of Hamburg, Hamburg, Germany

A fundamental understanding of magnetic and spin-dependent phenomena requires the determination of spin structures and spin excitations down to the atomic scale. The direct visualization of atomic-scale spin structures [1-4] has first been accomplished for magnetic metals by combining the atomic resolution capability of Scanning Tunnelling Microscopy (STM) [5, 6] with spin sensitivity, based on vacuum tunnelling of spin-polarized electrons [7]. The resulting technique, Spin-Polarized Scanning Tunnelling Microscopy (SP-STM), nowadays provides unprecedented insight into collinear and non-collinear spin structures at surfaces of magnetic nanostructures and has already led to the discovery of new types of magnetic order at the nanoscale [8]. More recently, the detection of spin-dependent exchange and correlation forces has allowed a first direct real-space observation of spin structures at surfaces of antiferromagnetic insulators [9]. This new type of scanning probe microscopy, called Magnetic Exchange Force Microscopy (MExFM), provides a powerful new tool to investigate different types of spin-spin interactions based on direct-, super-, or RKKY-type exchange down to the atomic level. By combining MExFM with high-precision measurements of damping forces [9] localized spin excitations in magnetic systems of reduced dimensions now become experimentally accessible.

In contrast to magnetic force microscopy (MFM) which probes the magnetic dipole forces between a magnetic sample and a ferromagnetic tip at a typical tip-to-surface distance of 10-20 nm [10, 11], MExFM combines the technique of non-contact atomic force microscopy (NC-AFM) [12, 13] with atomic-scale spin resolution by making use of an atomically sharp magnetic probe tip with a very well defined spin state at its apex. Based on the knowledge gained during the development of SP-STM in preparing such tips we have recently succeeded in resolving the surface spin structure of the antiferromagnetic insulator NiO(001) [9]. Atomic-resolution topographic NC-AFM images reveal chemical contrast between the oxygen atoms (bright sites) and the Ni atoms (dark sites) which results from a different total charge density above O- and Ni-sites. No contrast is observed between magnetically non-equivalent Ni sites, i.e. Ni atoms with a different orientation of their magnetic moments. By approaching the out-of-plane magnetized Fe-coated tip closer to the surface atoms, the spin-dependent exchange interaction between the rather localized Ni d-states of the sample and the Fe d-states of the tip leads to a different force or force gradient above Ni atoms with a different orientation of their magnetic moments. As a result, a superperiodicity corresponding to an antiferromagnetically ordered state of the NiO(001) surface is observed in the MExFM image. The apparent height difference between the magnetically non-equivalent Ni-sites only amounts to 1.5 pm, corresponding to the different magnitude of the spin-dependent quantum-mechanical forces felt by the tip above the different Ni atoms. To resolve such tiny signals, the AFM instrument has to be operated at low temperatures in order to reduce the thermal excitations of the AFM cantilever (force sensor).

More recently, MExFM has been applied to the antiferromagnetically ordered ground state of a single atomic layer of Fe on a W(001) substrate [14] for which a direct comparison with SP-STM results [3, 4] could be made.

120° antiferromagnetic Néel structure of Mn monolayer on Ag(111).

C. Gao¹, W. Wulfhekel^{1,2}, J. Kirschner¹

1. Max Planck Institute of Microstructure Physics, Halle (Saale), Germany; 2. Physikalisches Institut, Universität Karlsruhe (TH), Karlsruhe, Germany

In magnetic materials, the competing exchange interactions between neighboring atoms often lead to frustrated spin structures. Magnetic frustrations are not only responsible for noncollinear antiferromagnetism, but also play an important role in determining the exchange bias effect at the interface between ferromagnets and antiferromagnets. The latter is of essential technological relevance. Magnetic frustrations may have chemical or topological origins. A classical example of a topological frustration is a 2-dimensional triangular lattice of antiferromagnetic atoms in which a non-collinear 120° Néel structure stabilizes as shown in Fig. 1a. Experimentally, the Néel structure has not been observed in real space because traditional magnetic imaging techniques have limited resolution. Only with the development of spin-polarized scanning tunneling microscopy (Sp-STM), it has become possible to resolve antiferromagnetic spin structure on the atomic scale [1].

In this contribution, we resolved the 120° Néel structure of a Mn monolayer on Ag(111) using Sp-STM with magnetically coated tungsten tips operating in the constant current mode. Sp-STM operating in the constant current mode has demonstrated its atomic resolution in 2-dimensional antiferromagnetic systems, such as Mn/W(110), Fe/W(001). The presence of a magnetic super cell lowers the translational symmetry resulting in a much slower decay of surface magnetic corrugation than the atomic corrugation. Thus, a constant current image taken with a magnetic tip reflects the magnetic superstructure rather than the atomic unit cell. The magnetic contribution in the Sp-STM image is proportional to the projection of the magnetization of the sample on the magnetization direction of the tip such that collinear and non-collinear antiferromagnetic spin structures of an antiferromagnetic monolayer on a fcc(111) surface can be distinguished experimentally as has been proposed by Wortmann et al [2]. In the case of a non-collinear spin structure, for example the 120° Néel structure, the relative magnitudes of the projection of the sample moments on two orthogonal directions are strongly different (cf. Fig. 1 (b) and (c)) which results in different Sp-STM images when the spin sensitive axis of the STM tip is rotated by 90° [2].

The first layer of Mn grows pseudomorphically on Ag(111) forming monolayer height islands in triangular shapes. Two kinds of islands are found distinguished by the orientation of the triangles which correspond to fcc and hcp stacking as identified by atomically resolved STM images. Using a Cr coated W tip which has an in-plane spin sensitivity, the Néel structure was demonstrated. The existence of at least two different magnetic domains of the structurally equivalent Mn islands is observed. The fcc and hcp islands are found to have the same 120° Néel structure but with different orientation of the moments which means the fcc and hcp islands have different magnetic anisotropy.

Spin-resolved scanning tunneling microscopy (spin-STM) exploits the dependence of the tunnel current and of the differential conductance on the relative spin orientation between tip apex and sample to image spin structures, even with atomic resolution

[1]. A change of the spin orientation of the tip apex and/or that of the sample induces a corresponding change of the tunnel current and of the differential conductance, which is the basis of the spin contrast. This entanglement between the spin orientation of sample and tip for the observed magnetic contrast is cumbersome for measurements in field, as it interferes with a clear identification of sample and tip contributions to the spin contrast.

We resolve the contributions of both a Co-sample and a Cr-covered W-tip to the contrast of spin-STM by spin-polarized STM measurements of the differential conductance during a complete magnetization cycle of Co-nanoislands on Cu(111).

The differential conductance is measured by applying a small AC voltage (10 mV, 4 kHz) to the gap voltage of the STM, and we detect the resulting modulation of the tunnel current with a lock-in amplifier. To obtain a spin contrast, we cover the electrochemically etched and subsequently flashed (2100 C) W-tip of the STM with 100 layers of Cr at 300 K. Spin-polarized STM measurements are then performed on double layer high Co islands at 8 K and in fields of up to 6 T, which are oriented normal to the sample surface. The Co islands were produced by the deposition of sub-monolayer quantities of Co onto the atomically clean Cu(111) surface at 300 K.

We measure the differential conductance during a scan of the magnetic field from 0 T, to -4 T, to +4T, and back to 0 T. We observe symmetric differential conductance curves with respect to the magnetic field. The differential conductance measurements during a cycle of the magnetic field show a hysteretic behavior, e.g. at +/- 1 T we observed two different values for the differential conductance, depending on the magnetic field history. These plots resemble a shape which is well known from the so-called butterfly curves of tunnel magnetoresistance (TMR) measurements. For fields smaller than a critical value, we observe a gradual change of the differential conductance with increasing field. At a critical field, the signal changes abruptly. This critical field depends on island size, and it is larger for larger islands. Its magnitude of appr. 1.5 T suggests that it is due to the magnetic switching of the Co islands along the sample normal in response to the external magnetic field [3]. We have performed dozens of tip preparation with a Cr-coverage between 40 and 100 ML and find consistently symmetric hysteresis cycles of the differential conductance. We conclude that the gradual change of the differential conductance at fields smaller than the switching field, which is similar for all islands, is due to the field-induced change of the spin orientation of the Cr-tip apex.

This result indicates that both Cr-covered W-tip and Co-island change their spin orientation in response to the applied magnetic field. A sudden switching of the magnetization direction of the Co-island and a reversible change of the spin orientation of the tip are extracted from the measurements. A change of the spin-orientation of the Cr-covered tip in response to the external field comes as a surprise, as usually one of the electrodes of a spin-STM experiment, be it the tip or the sample, has been assumed to exhibit a fixed spin orientation. This assumption is not valid in general, as our results suggest that the spin-orientation of the tip follows the external field. We can

exploit this finding to rigorously identify the parallel (P) and anti-parallel (AP) states of our tunnel junction composed of a Cr-tip, a vacuum barrier and the Co-sample.

Theoretical description of the high-frequency magnetic force microscopy (HF-MFM) technique.

M. R. Koblishka, U. Hartmann

Institute of Experimental Physics, University of the Saarland, Saarbruecken, Germany

In this contribution, we present a theoretical description of the high-frequency MFM (HF-MFM) technique [1-4]. HF-MFM is a further development of the MFM technique, enabling the measurement of (i) high-frequency currents via their stray field and (ii) the stray fields emanating from hard disk writer poles. For the measurement of high-frequency magnetic fields, an amplitude-modulation technique is employed. Figure 1 shows a schematic view of the HF-MFM setup.

The description of the measurement of a HF current is the simpler case as there is a direct relation between the amplitude-modulated current and the HF field. To calculate the force acting on the cantilever, we employ the dipole model for the cantilever and assume a point-shaped conductor. As the cantilever can only carry forces in z -direction, we can simplify the resulting equation. Regrouping and taking all parts depending on position but being independent of the current together, yields

$$F_z = c_1 I - c_2 I^2.$$

The quadratic dependence of the force acting on the cantilever on the flowing current enables the use of the modulation technique. Both constants c_1 and c_2 contain geometry factors, c_2 the initial susceptibility of the magnetic coating of the cantilever, $\chi(\omega)$. This implies that the ideal HF-MFM cantilever material should have a large χ , which is also reasonably high in the high-frequency range. This condition could e.g. be fulfilled by the head material itself. However, to avoid skin effects, an ideal candidate for such a material are ferrites, which can be prepared in form of thin films onto the cantilevers [5].

The current is characterized by its carrier frequency, ω_c . The modulation current has a lower frequency, ω_m , and their relation is the modulation depth, $m = \omega_m/\omega_c$. Inserting the current into eq. (1), we obtain the force acting on the cantilever. The cantilever is acting like a low-pass filter, so that all components comprising a high-frequency part can be disregarded as illustrated in Figure 2.

The optimum frequency to achieve the maximum force on the cantilever is to choose the modulation frequency like the cantilever resonance frequency, ω_{res} .

In the case of the HF-MFM measurements of hard disk writer poles, the situation is somewhat different: The amplitude-modulated current being sent into the coil of the writer pole is then transferred into a high-frequency magnetic field via the magnetic core material. As a consequence, there is another modulation step due to the non-linear relation between the gap field and the applied current. This means that the effective frequency components are not known a priori. Using the description given in [3], we can calculate again the forces acting on the cantilever for an amplitude-modulated current. As a result, we find that the optimum frequency to operate the HF-MFM in this case is always smaller than the resonance frequency of the employed cantilevers. This explains the earlier finding that a maximum HF-MFM signal is obtained at a modulation frequency corresponding to about 1/3 of the cantilever resonance frequency [6].

We would like to thank A. Cazacu and A. D. Johnston (SEAGATE, U.K) for the writer poles and valuable discussions.

Imaging a single domain wall position by Extraordinary Hall Effect in nanostructured thin films with perpendicular anisotropy.

M. Miron, P. Zermatten, G. Gaudin, S. Alain
SPINTEC (CNRS/CEA), Grenoble, France

The recent experimental evidence of the effect of current on domain wall (DW) motion opens the possibility of acting locally on a single DW. Lately, several types of device using this effect were proposed for magnetic mass storage and magnetic logic. They all use [1], [2], materials with in plane magnetic anisotropy. An alternative to this kind of materials would be to use thin films with out of plane anisotropy exhibiting at the same time a strong Extraordinary Hall Effect (EHE) [3]. This would allow a simple detection of the DW motion by a simple EHE measurement. For studying the effects of current and field on such a DW it is important to be able to control and to know precisely its position.

We propose a technique that allows pinning a DW at a stable position as well as, in certain conditions imaging it with a better precision than a typical MFM image.

We use a thin film that has an out of plane magnetic anisotropy, and in addition, a high EHE. The film is patterned to obtain a shape like the one depicted in figure 1. By passing a current through the central line and measuring the voltage between the side wires, magnetization reversal can be detected due to the EHE. If the magnetization is switched by DW motion, the displacements of the DW are evidenced by changes in the measured voltages. Due to the fact that the spatial sensitivities to DW position are different for the four voltage measurements, the movement of the DW will cause four different voltage changes. We will show how, based on these differences and knowing precisely the sensitivities, it is possible to find the position and shape of the DW.

We make a precise SEM image of our sample. Then this image is divided into cells. By simulating the current flow into the sample, we compute the contribution of the magnetization switching of each cell δV_i for the four different EHE voltages. Afterwards, using a minimizing algorithm we find the combination of cells that need to be switched to fit simultaneously the four measurements. In order for this method to work, several conditions must be fulfilled:

- i. The DW must have a negligible volume compared to the sensitive volume.
- ii. The sample has to be magnetically and electrically homogenous.
- iii. The magnetic switching of any pack of cells will not significantly change the current lines.

This imaging technique has the particularity of being size independent. The fact that only the proportions are important allows two methods of testing: one uses a real sample large enough to be imaged easily by MFM, and the other one uses only simulations done with COMSOL.

We applied this technique for sample to small to be imaged by MFM with a good resolution (typically 100nm line width). The sample was prepared with a DW geometrically pinned between the two crosses. The displacements of the DW under an applied field were imaged. Evidence is found that the intrinsic pinning sites dominate the DW motion for small displacements.

We have developed a method that enables us to find the shape of a single DW trapped in an artificial pinning center, just by EHE measurements and electrical simulations. The main advantage of this method over classical imaging techniques like the MFM is that its absolute resolution is, to a certain limit (see the imposed conditions), increasing when decreasing the size of the sample. This is a consequence of the fact that the method is size-independent. The observation of DW displacements as small as 100nm are then possible in samples of comparable size (100nm).

2. The Blackett Laboratory, Imperial College of Science, London, United Kingdom

Although materials with Giant Magneto Caloric Effect (GMCE) have been investigated intensively with respect to their performance as magnetic refrigerant, it is still a controversial matter of how to evaluate correctly the cooling power [1,2]. In general a magneto-caloric material is characterized by the entropy change $\Delta s(T,H)$ as a function of magnetic field and temperature [1,3]. While in thermodynamic equilibrium $\Delta s(T,H)$ is a unique function, a first order magneto-structural phase transition (as in GMCE materials) exhibits hysteresis in field and in temperature and so the value of $\Delta s(T,H)$ depends on the history. Therefore it is indispensable for the correct evaluation of the performance of a material to carefully control the sequence of changing T and H when preparing for or during a measurement. Otherwise results cannot be compared.

In this paper we show $\Delta s(T,H)$ obtained by different field and temperature sequences. The sample is polycrystalline Gd₅Si₂.09Ge₁.91 undergoing a first order magneto-structural phase transition at 288.5K from orthorhombic ferromagnetic (FM) to monoclinic paramagnetic (PM). In sequence A we start from the FM low temperature phase, increase the temperature up to 292K (slightly above the transition temperature) and then apply a field of 1.8T and remove it (field rate 23mT/s). In sequence B we start again from the FM low temperature phase, apply first a field of 1.8T, increase then temperature up to 292K and remove the field. The entropy change $\Delta s(\mu_0\Delta H=1.8T-0T)|_{T=292K}$ is measured directly during the field removal at constant temperature using a laboratory Peltier cell calorimeter [4]. Sequence A gives an entropy change of $\Delta s_A = -4.6J/kgK$ while sequence B gives $\Delta s_B = -7.1J/kgK$. The different results can be explained qualitatively by the difference in phase fractions involved in the transition. In sequence A good part of the sample is transformed during heating in the PM phase and applying a field transforms back to the FM phase. If the applied field at the given temperature was not sufficiently high to complete the transformation to the FM state (saturation) only a small phase fraction takes part at the transformation to the PM state when removing the field (minor loop). In sequence B the field applied during heating stabilizes the FM phase and the material remains in the saturated FM state up to higher temperatures. Removal of the field reverses the transformation along the saturation loop and therefore the maximum entropy change is obtained.

This picture can be experimentally evidenced by using magnetic imaging techniques. The difference in FM and PM fractions after the different preparation sequences was observed by hall imaging [5] (see Fig.1). The magnetic moments over the imaged area have been integrated and gave a ratio of the total moment after sequence B to the one after sequence A as 1.64:1. This agrees well with the ratio of the entropy changes obtained by the direct measurement of $\Delta s_B/\Delta s_A = 1.54:1$.

A quantitative comparison can be obtained by employing a Preisach type hysteresis model for thermodynamic transformations, which accounts for hysteresis in field and temperature [6]. The phase fractions and entropy changes can be calculated and qualitatively observed in the Preisach plane.

This study demonstrates the importance of hysteresis for the correct determination of the magneto-caloric effect in first order phase transition materials. Different measurement methods expose the sample to different field and temperature histories. Two common indirect measurement methods of $\Delta s(T,H)$ serve as example: the magnetization curve at constant temperature by using Maxwell's relations (first increasing temperature then field) and the heat capacity at constant field

(first applying field then increasing temperature). It is known from literature that these methods lead to different results, due to errors in the data evaluation [2]. We show that in addition there are also inherent properties, as hysteresis, leading to difficulties in comparison of the methods if the state of the material and its history is not well specified. This result is of special importance for a typical thermodynamic cycle, which is always performed as in sequence A, so that a much lower effective efficiency than predicted by the maximum available entropy change may be obtained.

Fig.1 Hall images at 292K and H=1.8T (magnetic field applied normal to the sample surface) after applying sequence A (left) and sequence B (right). The same scale is used in both images where black is 1.8T and bright yellow is 2.05T. These values are the magnetic induction at the surface which includes the constant background applied field of 1.8T. The image window was 1.2mm x 1.2mm with a resolution of ~0.01mm.

Imaging perpendicularly recorded data with servo feedback control.

C. Tseng¹, P. McAvoy¹, I. D. Mayergoyz¹, C. Krafft²

1. Department of Electrical and Computer Engineering, University of Maryland, College Park, MD; 2. Laboratory for Physical Sciences, College Park, MD

Recently, a spin-stand-based magnetic imaging technique has been developed for high-speed massive imaging of bit patterns recorded on hard disk media [1, 2]. This imaging technique provides a much faster imaging rate than that of MFM and has been recognized as a useful tool for detailed evaluation of bit patterns on perpendicular recording media [3]. However, for track densities above 100 kilo-track-per-inch (ktpi), non-repeatable run-out (NRRO) due to spindle vibration can result in appreciable distortion of spin-stand images acquired from commercial disks removed from their native environments. The purpose of this paper is to demonstrate that the NRRO distortion of the spin-stand image can be removed by using servo feedback control to drive a piezoelectric transducer (PZT) as a positioning actuator.

In spin-stand imaging, along-track scanning is performed by means of the rotation of the disk, while cross-track scanning is performed by stepping the head to progressively increasing or decreasing radii with the PZT. While the hysteresis exhibited by the PZT itself can be compensated [4], the presence of NRRO creates a situation in which cross-track steps cannot be made with a constant desired magnitude. Therefore, the spin-stand image resulting from a scan without using any feedback is corrupted to some extent by this irregular cross-track scanning step size. However, by using the position error signal (PES) generated from servo patterns already present on the disk, the actual position of the head (corrupted by NRRO) can be ascertained with respect to the target position. This PES can then be used to control a PZT, which displaces the read head in the cross-track direction toward the target position. By iteratively seeking on this target position (a given offset from the track center), a constant cross-track step-size can be achieved by rejecting measurement iterations whose computed offset PES is above some small predetermined bound. Once the desired accuracy is achieved for a particular radius, the measurement is kept and the next scanning step attempted.

Experiments have been performed to illustrate this technique in which two-dimensional images of commercial perpendicular media hard disk platters with an average track pitch of 145 ktpi are acquired on a Guzik spin-stand. In these experiments, a platter is first pre-written with data and servo patterns in its native drive, and then removed and mounted on a spin-stand. For a particular experiment of this kind, Figures 1a and 1b show the position error signals with respect to scanning steps in the cross-track direction before and after the servo feedback control is implemented. A total of 20 cross-track steps are made for each track. It can be observed (see Figure 1a) that the scanning step size is irregular without servo feedback control due to NRRO because the PES extracted from the image deviates from linearity. Therefore, the spin-stand image resulting from this scan without using servo feedback is corrupted by its irregular cross-track scanning step size. Conversely, the PES extracted from the spin-stand image produced by using servo feedback control is shown in Figure 1b. This PES approaches the ideal linear form desired, which illustrates the positioning accuracy of the cross-track steps in the spin-stand image. The spin-stand image of the servo data corresponding to the PES in Figure 1b is shown in Figure 1c. Figure 2 illustrates the result of imaging with servo feedback for user data written on a similar recent commercial perpendicular disk. It is apparent that significant distortion (due to intersymbol interference and cross-track interference) is present in Figure 2 as a result of the high density of user data. This contrasts with the clear two-level image of lower density servo data in Figure 1c. The image in Figure 2 thus demonstrates the neces-

sity of powerful PRML-type signal processing algorithms to recover the binary information recorded in the depicted user data tracks.

Reversible exchange bias in ideal antiferromagnetic alloys.

D. Lederman, M. Cheon

Department of Physics, West Virginia University, Morgantown, WV

Most exchange bias (EB) theories rely on uncompensated spins in the AF to have a AF/FM coupling mechanism [1]. Uncompensated spins have been detected at the AF/FM interface in oxide and metallic AFs [2]. In dilute AF/FM bilayers an enhancement of EB can occur as a result of uncompensated spins that naturally form at AF domain boundaries [3]. The AF magnetic anisotropy is also important because 1) a weak AF anisotropy can cause a low blocking temperature (T_B); and 2) the direction of the cooling and measurement fields with respect to the AF anisotropy axis alter significantly the EB [4,5] and the domain reversal mechanism in the FM [6,7].

In order to address these issues we have studied EB using $\text{Fe}_x\text{Ni}_{1-x}\text{F}_2$. NiF_2 and FeF_2 share the rutile crystal structure, but the localized Ni^{+2} spins lie in the (001) plane, in contrast to FeF_2 , where spins align along the [001] direction. NiF_2 is also a weak ferromagnet with $T_N=73.2$ K [8] in bulk and 80 K in films [9]. FeF_2 is a classic AF with $T_N=78.4$ K. Because of the perpendicular magnetic easy axes of NiF_2 and FeF_2 , the $\text{Fe}_x\text{Ni}_{1-x}\text{F}_2$ alloy has a variable magnetic anisotropy that depends on x , thus providing an ideal system to probe the effects of AF magnetic anisotropy on EB.

$\text{Fe}_x\text{Ni}_{1-x}\text{F}_2$ (110)/polycrystalline Co bilayers capped with Al or Pd, were grown via molecular beam epitaxy. The typical thickness of the AF, Co, and capping layers were 44, 17, and 2.5 nm, respectively. The roughness values were ≈ 0.7 nm for the MgF_2/AF , 1.0~nm for the AF/Co, 0.7~nm for the Co/cap, and 1.0~nm for the cap/air interfaces. A commercial SQUID magnetometer with the magnetic field H applied along the [001] direction was used to measure hysteresis loops.

Figure 1(a) shows the hysteresis loops measured at $T = 30$ K, after cooling from $T=95$ K to $T = 5$ K with $H_{CF} = 2$ kOe along the [001] direction. The loops were measured between $H = \pm 10$ kOe for $\text{Fe}_x\text{Ni}_{1-x}\text{F}_2$ samples with $x = 0.05, 0.21$ and 0.49 . They had $H_E < 0$ and an uncompensated magnetization (defined as the shift of the hysteresis curve along the magnetization axis M) $\Delta M_S > 0$ at $T < T_B = 50$ K (40~K) for $x = 0.05$ (0.21). For the $x = 0.49$ sample, $H_E < 0$ and $\Delta M_S < 0$ for $T < 20$ K and $H_E > 0$ and $\Delta M_S > 0$ for $T > 20$ K. When M was measured in the $H = \pm 70$ kOe range as shown in Fig. 1(b), there were two superimposed loops: one had a relatively small coercivity H_C , corresponding to the Co layer, and the other had a large H_C with M corresponding to ΔM_S . Therefore, the uncompensated magnetization measured in the small field range was reversible at high fields and confined to the AF, as determined from micromagnetic calculations [10]. Because the EB was correlated with the “pinned” magnetic moments which are reversible at high fields, it was possible to reverse the sign of H_E at $T = 5$ K after field-cooling by performing asymmetric hysteresis loops. ΔM_S disappeared close to the T_N [Fig. 1(c)], indicating that it originated within the bulk of the AF. We believe that H_E can be reversed in all EB systems at low T (compared to T_B) if high enough fields are available. The magnitude of this field depends on the magnitudes of ΔM_S , the anisotropy of the AF, and T . For example, with a $\text{Fe}_{0.36}\text{Zn}_{0.64}\text{F}_2$ dilute AF sample, at $T = 5$ K it was impossible to reverse H_E in fields up to 70 kOe despite a large ΔM_S . However, at $T = 20$ K ($T_N = 28$ K), the effective anisotropy of the pinned magnetization was weak and the sign of H_E could be reversed in fields of only 10 kOe [Fig. 1(d)]. A reversible EB in magnetoelectronic devices could be achieved by creating an antiferromagnetic alloy with unpinned moments and a random anisotropy.

An important issue in exchange-biased ferromagnetic-antiferromagnetic (FM/AFM) systems is the intrinsic asymmetric behavior of the magnetization reversal [1]. Around the easy direction there is a range of angles in which the evolution of magnetization shows an asymmetric behavior in the descending and ascending branches of the hysteresis loop. In general, magnetization reversal via rotation processes is more relevant in one of the two branches of the hysteresis loop, in which a larger density of domains during the irreversible processes is also observed. This manifest in the magnetization hysteresis loops by the occurrence of more rounded transitions of the parallel component of the magnetization (M_{\parallel}) and/or by larger values of the transverse component of the magnetization (M_{\perp}). Experimental data do not, however, agree on the pathways dominating the reversal in each of the two field branches. For some of the systems, rounded M_{\parallel} transitions and/or larger M_{\perp} values are found in the descending branch, where the field is applied parallel to the bias direction, while for other systems the opposite behavior was found.

We have studied the influence of the anisotropies on the magnetization reversal in exchange biased Co/IrMn and FeNi/IrMn bilayers and shed light on the aforementioned discrepancy on the asymmetric reversal phenomena, by pursuing a detailed magnetization reversal study of exchange biased thin films with well defined uniaxial anisotropy. Our findings show that the competition between the uniaxial K_U (FM) and unidirectional K_E (interface) anisotropies and the interfacial spin frustration play the main roles that explain such behavior.

Angle dependent measurements have been performed with high resolution vectorial Kerr magnetometry for the two FM/AFM bilayers with different thicknesses. Reference FM samples present a well defined uniaxial magnetic anisotropy, promoted by a Ta buffer layer deposited at oblique incidence. The effective anisotropy of the Co films is about one order of magnitude larger than the one of the FeNi films with similar thickness. The FM/AFM samples were field cooled simultaneously with the external field aligned parallel to the easy-axis of the FM layer to render samples with collinear anisotropies, i.e., parallel K_U and K_E .

In general, the reversal is governed by irreversible (sharp) and/or reversible (smooth) transitions, which are correlated with nucleation and propagation of magnetic domains and rotational processes, respectively. Close to the easy axis, the reversal is asymmetric in the descending and ascending branches of the hysteresis loop (see Fig.1). The angular range where the asymmetry is found is much smaller in the FeNi case, as expected by its low intrinsic anisotropy. However, the asymmetry is different when comparing the Co/IrMn and FeNi/IrMn systems. For the Co/IrMn bilayers,

larger M_{\perp} values and rounded M_{\parallel} transitions are always found in the descending branch of the hysteresis loop (see upper graphs of Fig.1). For the FeNi/IrMn bilayers, these features can be found in both descending and ascending branches, depending on the sign of the angle between the applied magnetic field and the easy axis (see bottom graphs of Fig.1). Additionally, when the field is applied along the easy direction, i.e., at 0° , M_{\perp} is negligible during the whole loop for the Co case, which indicates nucleation of domains parallel to the field orientation during the irreversible transition of M_{\parallel} . However, for the FeNi case a clear hysteresis is found, indicating that the domains are not parallel to the easy axis of magnetization.

All these features are well reproduced with a Stoner-Wohlfarth model by considering collinear anisotropies for Co/IrMn and, surprisingly, non collinear anisotropies for FeNi/IrMn. The origin of this non-collinearity is given with a model which combines a three-dimensional lattice of spins and spin disorder (generated by a random interface roughness) to elucidate the spin configuration of the FM/AFM bilayer as a function of the anisotropy. The anisotropy balance and the interfacial spin frustration, leading to a rotation of the FM axis for small FM anisotropies, are the keys which control the asymmetry of the magnetization reversal in FM/AFM systems. [2].

Asymmetric magnetization reversal behavior in exchange-biased multilayers in different antiferromagnetic thickness ranges.

D. Spenato, V. Castel, S. P. Pogossian, C. Le Graët, D. T. Dekadjevi, J. Ben Youssef
Laboratoire de Magnétisme de Bretagne, CNRS/FRE 2997, Université de Bretagne Occidentale, Brest, France

Exchange coupling between a ferromagnet and an antiferromagnet, called exchange bias, has been extensively studied due to its key role in applications such as giant magnetoresistive heads for high density recording. Among all the properties observed in exchange-bias systems, the asymmetry in the magnetization reversal is intriguing, since most of magnetic materials reveal symmetric reversal. The origin of asymmetry reversal is still controversial and may be attributed, depending on the nature of the bilayers, to different magnetization processes. Moreover, the asymmetry depends on the angle between the external field and the exchange bias direction [1-3]. A method to probe the magnetization reversal processes is to use experimental techniques that provide information on the vectorial character of the magnetization. In such experiments, the existence of transverse magnetization is interpreted as coherent magnetization rotation [2, 3] while the flatness of the transverse magnetization indicates that there are no net rotation of the F moments in the direction perpendicular to the applied field during the magnetization reversal (i.e. incoherent rotation or domain wall propagation).

In this digest, we study the magnetization reversal processes in NiFe/MnPt bilayers by tuning the ratio between the anisotropy (H_K) and exchange (H_E) fields especially on either side of a critical value $H_K = 2H_E$ where a strong change in the hysteretic behavior is observed. Earlier works focus the effect of the competition between anisotropies on the magnetization reversal in F/AF bilayers with $H_K < 2H_E$ [2] or in lithography-induced high shape anisotropy in order to obtain $H_K > 2H_E$ [4]. We now extend these measurements to non-patterned thin films with intrinsic anisotropies $H_K < 2H_E$ and $H_K > 2H_E$. The static measurement is based upon vectorial vibrating sample magnetometry (VSM). Both longitudinal magnetization (M_L), the component parallel to H and transverse magnetization (M_T), the component in the film plane but perpendicular to H have been measured with four detection coils. The samples are polycrystalline NiFe/MnPt bilayers of 35 nm NiFe thickness and different MnPt thicknesses grown on Corning Glass substrate by conventional RF diode Sputtering. The MnPt thickness dependence of both the exchange field (H_E) and the coercivity (H_c) is shown in Fig.1. The shift of the hysteresis loop appears at a critical AF thickness t_{crit} of 7.5 nm. The inset in Fig.1 represents typical $M_T(H)$ and $M_L(H)$ loops for 10 nm MnPt measured for an applied magnetic field at 15 degrees with respect to the depositing field direction.

Since H_E depends on the AF thickness, changing MnPt thickness should result in different $H_K/2H_E$ ratios. In this study we have carried out a systematic study of the angular dependance of the magnetization reversal to probe the contribution of the coherent rotation to this reversal for two NiFe/MnPt samples, one with 10 nm MnPt thickness ($H_K > 2H_E$, Fig.2 (a)) and for 40 nm MnPt thickness ($H_K < 2H_E$, Fig.2 (b)). The results are presented on Fig 3. Depending on the balance between these two anisotropies the magnetization reverses either in the opposite or the same semi-circles during the ascending and descending branches of the hysteresis loop. These results show an experimental evidence that, the balance between the uniaxial and unidirectional anisotropies in NiFe/MnPt bilayers rules the asymmetric magnetization reversal [5]. We have compared our experimental data with numerical calculations based on a Stoner-Wohlfarth type model (solid line Fig.2). As one can observe on this figure, this model provides a relevant description of the behavior of

the hysteresis loops in these bilayers. We are extending at the moment our study to NiFe/MnPt/NiFe trilayers, and the experimental results will be discussed.

The dynamic response of magnetoelectronic devices in the GHz regime relies on the dynamical response of the magnetization. The two key parameters which control the response of soft magnetic thin films are the magnetic anisotropy that determines the precessional frequency f_{res} , and the effective damping parameter α_{eff} . One way to tailor the dynamic magnetic properties is to dope ferromagnetic thin films with rare earth elements. On the other hand it has been shown that exchange biased ferromagnetic/antiferromagnetic (F/AF) systems exhibit an increase α_{eff} due to an inhomogeneous magnetization distribution within the AF layer and to a two-magnon scattering contribution. Here we demonstrate, how ultra-thin IrMn layers can be used to alter f_{res} and α_{eff} of $\text{Ni}_{81}\text{Fe}_{19}$ layers in a controlled manner and over a wide range.

The influence of an AF layer thickness t_{IrMn} as part of a $\text{Ni}_{81}\text{Fe}_{19}$ (10 nm)/IrMn/ $\text{Ni}_{81}\text{Fe}_{19}$ (10 nm) structure on the static magnetic properties is displayed in Fig. 1. For the given system, adding a thin IrMn layer, the effective uniaxial anisotropy field $H_{k,\text{AF}}$ can be increased by an order of magnitude. The overall dependence of the static unidirectional and uniaxial anisotropy field H_{eb} with t_{IrMn} is shown in Fig. 2(a). The change of f_{res} and α_{eff} is displayed in Fig. 2(b). By adding a layer of IrMn, α_{eff} of the surrounding $\text{Ni}_{81}\text{Fe}_{19}$ layers can be significantly increased from 0,008 to 0,054. Congruently, the gain in f_{res} is by a factor of 4 from 0,8 GHz to 3 GHz, which corresponds to an increase of the effective field by a factor of 16. One selected example showing how the dynamic magnetic properties vary with the ferromagnetic film thickness t_{NiFe} is displayed in Fig. 3. Comparing the shown data from the sandwich structures and data from additionally prepared F/AF multilayers we were able to derive simple general expressions for a constant AF layer thickness below the onset of exchange bias:

$$(i) f_{\text{res}} \sim (K_{u,\text{F}} + J_{u,\text{AF}} \cdot (1/t_{\text{F}}))^{0.5}$$

$$(ii) \alpha_{\text{eff}} \sim \alpha_{\text{F}} + \alpha_{\text{AF}} \cdot (1/t_{\text{F}})$$

In (i) (a modified form of Kittel's equation) the precessional frequency depends on the F film's uniaxial anisotropy constant $K_{u,\text{F}}$ and AF induced uniaxial coupling constant $J_{u,\text{AF}}$. α_{eff} can be described by the F layer's damping parameter α_{F} together with a AF induced coupling damping parameter α_{AF} .

Using Eq. (i) and (ii) for a given system, the essential dynamic magnetic properties can be adjusted easily by more than an order of magnitude. The use of thin AF layers allows for controlled tuning of effective magnetic properties of exchange coupled F layers independent and without modifications of the F layer's intrinsic properties.

Introduction

Exchange-bias (EB) is known to originate from symmetry breaking at the interface between a ferromagnet (FM) and an antiferromagnet (AFM). Due to the presence of complex disordered structural and magnetic configurations at the FM/AFM interfaces, a clear description of this phenomenon is still missing. The role of structural and magnetic defects is expected to be considerably reduced at nanosizes when the single crystalline and single domain state is entered [1]. Thus, the present study focuses on the magnetization behaviour of arrays of Co/CoO dots ($120 \times 360 \text{ nm}^2$) observed by magnetic force (MFM) and Kerr microscopy at low temperatures, $T = 50 \text{ K}$, and an applied in-plane field. When imaged with MFM the dots behave as magnetic dipoles where the reversal occurs mainly in a single switching event, as known for a Stoner-Wohlfarth process in a small uniaxial element. Nevertheless, in some dots multidomain formation is observed. In order to clarify the difference between microscopic and macroscopic reversal mechanism these results are compared with Kerr microscopy measurements on a mesoscopic length scale.

Magnetization behaviour

Patterned Co/CoO samples were prepared by electron beam lithography with a subsequent lift-off technique and characterized by global magnetic measurements using SQUID magnetometry. Fig. 1 shows a square shaped hysteresis curve ($H_c = 95 \text{ mT}$ and $H_b = 17 \text{ mT}$) after cooling the sample through the Néel temperature in a positive field along the long axis of the rectangular elements. The first and second loop reversals (measured by SQUID) are very similar, revealing a rather small training effect. This could also be expected due to the small sized dots ($120 \times 360 \text{ nm}^2$).

Fig. 2 shows the AFM topography consisting of well structured rectangles as well as the MFM images at different applied fields. The sample was again cooled through the Néel temperature in a positive in-plane field. In zero field, the fully in-plane magnetized rectangles show up as rows of black and white contrast arising from the magnetic charges building up at the element edges. When negative fields are applied, the elements individually switch their magnetization direction which is observed as a sudden reversal of the MFM contrast. After applying a magnetic field of -130 mT a few dots have already switched and by increasing the field more and more dots switch until we have the exactly opposite state ($H = -175 \text{ mT}$) as in zero field. As a whole, the sample reverses magnetization in a rather small field range of $\Delta H = 75 \text{ mT}$ around -150 mT . Evaluating the total magnetization of the imaged area throughout a full cycle we can construct the hysteresis curve plotted in Fig. 1. There is a good agreement with the globally measured curve. Nevertheless, some deviations from the perfect dipolar switching can be found. Examples are elements with more than two poles, or dipoles which are tilted away from the long element axis (see encircled areas). The latter can be explained by coherent rotation processes before the switching occurs and the existence of several poles must be due to a multidomain configuration during switching event.

SQUID and MFM measurements are giving global as well as very local information about the structuring, e.g. defects, of the sample. Looking on a mesoscopic scale by Kerr measurements allows to differentiate between microscopic and macroscopic reversal. The reconstructed hysteresis curve (Fig. 3) shows a shoulder at negative magnetic fields compared to the curves in Fig. 1. These deviations dependent on sample homogeneity and the quality of the structuring and their study and control is of great importance for future applications.

Previous studies have shown that a (111) texture of IrMn parallel to the interface is important to give a large exchange bias eg.[1]. Other studies have found that optimising seed layer, composition, and the ordering of the IrMn leads to an enhanced exchange bias effect eg.[2]. NiFe seed layers have been shown to induce a (111) texture when used to seed IrMn growth leading to an enhancement of the blocking temperature, T_B [3]. We report on the origin of the increase in the average blocking temperature $\langle T_B \rangle$ by varying the crystal structure of the IrMn/CoFe system using seed layers. We find that a (111) texture of the IrMn leads to an enhancement of the anisotropy constant of the antiferromagnet (AFM), thereby increasing $\langle T_B \rangle$.

Samples with structure Si $\langle 100 \rangle$ / Seed (5nm)/Ir₂₃Mn₇₇ (10nm)/CoFe (3nm)/ Ta (10nm) were prepared by DC sputtering using a HiTUS sputtering system. The seed layers used were Cu, Ru, and Ni₆₀Cr₄₀. The samples were deposited at $\sim 120^\circ\text{C}$ and then annealed for 30 minutes at 225°C in a 3kOe field. Structural characterisation of the samples was carried out by X-ray diffraction (XRD) using $\theta/2\theta$ and grazing incidence (GIXRD) scans. Thermal activation measurements were performed with a temperature controlled VSM to determine the blocking temperature distribution, using our well established measurement protocols [5]. The grain size distributions were determined from TEM images measuring 600 grains per sample.

Figure 1 shows a $\theta/2\theta$ scan for a sample with NiCr seed layer showing that the IrMn(111) peak is dominant. This indicates that the IrMn (111) planes in this sample are highly orientated parallel to the interface. GIXRD scans (not shown) confirmed this texture with the absence of the (111) peak for the NiCr seed sample. Thermal activation measurements are shown in figure 2 indicating a large increase in $\langle T_B \rangle$ for the NiCr sample (see table 1). The grain size analyses for the three samples are shown in figure 3. The distributions are log-normal with the NiCr showing the smallest grain size, and Cu the largest. The anisotropy of the AFM, K_{AF} , was then calculated using $K_{AF}V = k_B T_B \ln(\tau f_0)$, where V is the grain volume, τ the activation time, f_0 the attempt frequency ($f_0 = 10^9 \text{ s}^{-1}$), and k_B is the Boltzmann constant [6]. From this equation the high T_B and small median grain size (D_m) for the NiCr sample indicates that the K_{AF} has increased due to the texture of the IrMn.

Despite the experimental and theoretical investigations, the exchange bias phenomenon (EB) in nanostructured systems remains poorly understood [1]. We used focused ion beam (FIB) lithography to prepare a series of samples of antidots of the same size and different distances in x-y directions. All of the fabrication has been performed on bilayered samples prepared by electron beam evaporation and consisted of antiferromagnetic (AF) FeF₂ (70nm), ferromagnetic (FM) Ni (50nm) and Al (4nm) as a protective layer. The square antidots with antidot size of 200 nm and x and/or y distance of 120-900 nm have been fabricated using an ion current of 30 pA (Fig.1). It is well known that magnetoresistance (MR) measurements can be used to determine exchange bias in thin films and nanostructures. MR was measured with the standard four terminal dc techniques in a He4 flow cryostat equipped with a superconducting solenoid. All measurements were carried out with the field applied parallel to the easy axis of the AFM and transport data were taken with the current in plane and perpendicular to the field. The resistivity was measured at 4.2 K in various field cooling conditions. The measuring field was applied along the same axis as the cooling field.

We observed three different types of behaviour (Fig.2): for small cooling fields, MR displays a shift towards negative field values (negative EB), while for large cooling fields the shift is positive (positive EB). In the intermediate case, we observed two MR peaks with different height and area. In the first and second case (small and large cooling fields) the reversal is sharper in the opposite field direction to the resulting shift of MR data. It is worth stressing that the switching from positive to negative EB depends on the density and/or relative x/y distances among antidots. The positions of the MR peaks are mostly independent of the cooling field, which suggest the AF domain size is comparable to or larger than the FM domain size and that each FM domain couples only to one AF domain with a particular direction of the EB [2]. For small/large cooling fields we have only one EB direction while two appear for the intermediate cooling cases.

Exchange coupled IrMn/CoFe networks on mesoporous alumina.

N. N. Shams, M. Rahman, C. Lai

Materials Science and Engineering, National Tsing-Hua University, Hsinchu, Taiwan

Introduction

Some theoretical models dealing with exchange bias (EB) attribute such effects to the formation of domain and pinning of domain wall either in the ferromagnetic (FM) or in antiferromagnetic (AFM) layer. Therefore, the size of magnetic domain in both FM and AFM are crucial to the EB. Recently the EB nanostructure is widely studied for their technological importance in spintronics or other application as well as for an additional tunable source of anisotropy to stabilize the magnetization[1]. But fabrication of such structure is quite challenging. In this study, a mesoporous anodized aluminum oxide (AAO) is used as a prepatterned substrate to deposit IrMn/CoFe film. The EB is increased by 2 times on AAO compared to that of the continuous film due to pinning of the pores.

Experimental procedure

At first, 50 nm Al film deposited on a Si wafer by sputtering, is anodized to get AAO with a pore density of $\sim 1 \times 10^{11} \text{ cm}^{-2}$. The pore diameter and the interpore distance is 10-12 nm and ~ 40 nm, respectively. Then Ta(3nm)/Ni₈₀Fe₂₀(8nm)/Ir₂₀Mn₈₀(12nm)/Co₉₀Fe₁₀(10-20nm)/Ta(3nm) films are deposited on both Si/AAO and SiO₂ substrate by sputtering at room temperature. A Ta/NiFe seed layer is used to promote IrMn(111) texture and Ta overcoat is resists surface oxidation. Finally, the films are annealed at 210°C for 30 min in a magnetic field of 1.5kOe to promote EB. The morphological characteristic is observed by SEM and magnetic properties are measured by a VSM.

Result and discussion

The plane-view SEM image (Fig.1) of Si/AAO/Ta/NiFe/IrMn/CoFe film reveals that the magnetic material is deposited mainly on top of the AAO network [2]. The M-H loops of AAO/Ta/NiFe/IrMn/CoFe network structure and continuous SiO₂/Ta/NiFe/IrMn/CoFe film are shown in Fig. 2(a) and 2(b) respectively. The exchange field, H_{ex} and the coercivity, H_c of network structure exhibit larger magnitude than those of continuous film irrespective to the thickness, t_{CoFe} of CoFe; i.e. the H_{ex} of network nanostructure is 275Oe, while it is 137 Oe in continuous film for a thickness of $t_{\text{CoFe}}=10$ nm. The anisotropy field also increases 2.4 times in the network IrMn/CoFe film. The kink in the M-H loop for $t_{\text{CoFe}}=10$ nm, is due to the presence of NiFe seed layer. The value of H_{ex} for NiFe/IrMn is 295 Oe and 145 Oe in network and continuous film respectively. The H_c of CoFe is 3 times larger in network structure ($H_c = 47$ Oe) than that of continuous ($H_c = 13.5$ Oe) film. Fig.3 shows the angular dependence of the EB nanostructure measured as described [3]. Both H_{ex} and H_c exhibited the expected unidirectional and uniaxial symmetry respectively. The increase of EB and H_c can be attributed to the pinning of domains caused by the AAO pores. The FM domain size is determined by the competition between the random field due to the interfacial AFM-FM interaction and FM-FM exchange interaction [1,4]. Therefore reducing the FM-FM interaction or decreasing the AFM domain size, EB can be increased. In our study, the presence of pores in network IrMn/CoFe may reduce the FM-FM interactions, or may favor the formation of smaller AFM domains, leading to a larger H_{ex} . The increase of both EB and H_c is presumably related to the network. So the H_{ex} of network EB structure may be tuned by controlling the pores of the mesoporous AAO template.

Conclusion

A feasible and convenient method is demonstrated to tune EB by pinning the domains of AFM/FM nanostructure. This kind of structure may be very useful in different applications and in addition, it provides a useful template to study different EB-related phenomena.

Effects of nonmagnetic additives in metallic antiferromagnets on exchange bias.

The phenomenon known as exchange bias (EB) refers to the shift of the hysteresis loop along the magnetic field axis originating from the interfacial exchange coupling between a ferromagnet (FM) and an antiferromagnet (AFM). Many aspects of exchange bias are not yet fully understood. This refers also to the role of nonmagnetic additives (dilution) in metallic AFMs with respect to the strength of the shift field or EB field (H_{EB}).

In insulating AFMs it has been shown both experimentally [1] and by Monte Carlo simulations [2] that it is possible to enhance H_{EB} by replacing magnetic atoms in the AFM by nonmagnetic ones not at the interface but rather throughout the volume part of the AFM. The enhancement of H_{EB} in exchange-biased insulating CoO was attributed to uncompensated AFM magnetic moments using a domain state (DS) model [1,2].

Here we analyze the effect of substitutional nonmagnetic defects in *metallic* exchange-biased AFMs on EB. As a model system we have chosen Cu as nonmagnetic dilution in the metallic intermediate-anisotropy AFM IrMn exchange biased to CoFe [3]. Atomic-force microscopy scans of samples with different Cu dilutions showed that the average grain size in the AFM IrMn decreases significantly with increasing Cu dilution in IrMn.

Magnetic characterizations were performed by SQUID magnetometry. Dilution by Cu atoms throughout the volume of the AFM IrMn gives rise to an enhanced H_{EB} of the $\text{CoFe}/(\text{IrMn})_{1-x}\text{Cu}_x$ bilayers for $5 \text{ K} \leq T \leq 350 \text{ K}$. Samples containing sole AFM layers with different Cu dilutions in IrMn showed also an enhancement of their thermoremanent magnetization (M_{TRM}) with Cu dilution. An evident resemblance in the behavior of M_{TRM} and H_{EB} with increasing dilution was observed. Also the temperature dependence of H_{EB} (of FM/AFM bilayers) shows a strikingly good qualitative agreement with that of M_{TRM} (of sole AFM) [3]. We conclude that the dilution and temperature dependence of H_{EB} has its origin in the M_{TRM} of the AFM itself [3,4].

Monte Carlo (MC) simulations based on a Heisenberg model were performed for FM/AFM bilayers [3,4] as well as for sole AFM layers [4] using the DS model for EB. A DS throughout the volume of the AFM is stabilized when the diluted AFM is cooled below the Néel temperature in an external magnetic field. In this context, the DS magnetization (M_{DS}) is related to the M_{TRM} measured for the sole AFM samples. For a realistic simulation of the $\text{CoFe}/(\text{IrMn})_{1-x}\text{Cu}_x$ bilayers we considered their granular structure and assumed temperature dependent uncompensated moments of the AFM grains through an Arrhenius-Néel law. In the simulations we used a time-quantified MC algorithm which is based on a Heisenberg model and thus capable of describing the three-dimensional rotation of the spin moments. Figure 1 shows the simulated normalized EB field ($h_{eb} = \mu H_{eb}/|J_{AFM}|$) of an FM/AFM bilayer for different dilutions in the AFM as a function of temperature normalized by $|J_{AFM}|$. The experimental temperature dependence of H_{EB} of $\text{CoFe}/(\text{IrMn})_{1-x}\text{Cu}_x$ bilayers is shown for some selected dilutions in the inset of Fig. 1. The experimental temperature and dilution dependence of H_{EB} is well confirmed by our MC simulations.

Moreover, our MC simulations clearly corroborate that the simulated temperature and dilution dependence of M_{TRM} [4] determines the corresponding dependence of H_{EB} . Our work demonstrates the extension of the adapted DS model to metallic intermediate-anisotropy exchange-biased AFMs.

Negative and positive exchange bias in polycrystalline Ni/FeF₂ thin films.

R. Morales^{1,2}, J. Alameda¹, I. Schuller²

The exchange bias (EB) phenomenon appears in ferromagnetic/antiferromagnetic (FM/AF) thin films after cooling through the Néel temperature of the AF in an external magnetic cooling field (H_{FC}). The main feature of EB is the shift of the hysteresis loop along the magnetic field axis. The magnitude of this shift is known as exchange bias field H_{EB} .

The sign of EB, negative or positive, is defined by the relative sign of H_{EB} respect to the H_{FC} direction. If the loop is shifted in the direction opposite to H_{FC} , then EB is negative. Otherwise, EB is positive if the loop is shifted in the same H_{FC} direction.

All EB systems exhibit negative EB, but only few of them show the positive case. In this work we investigate the transition from negative to positive EB in polycrystalline Ni/FeF₂ bilayers as a function of H_{FC} and AF thickness. Fig. 1 shows the data for a Ni (50 nm)/FeF₂ (400 nm) bilayer. Three main features can be extracted from these data.

First, the transition from negative to positive EB occurs by gradual shift of the hysteresis loop from negative to positive values. This result is in contrast to the transition found in epitaxial FeF₂ [1] where double hysteresis loops were observed, and can be explained in the averaging regime of EB [2].

Second, the magnitude of positive EB is larger than the negative one. Previous works on epitaxial FeF₂ always obtained the same absolute value of H_{EB} for both positive and negative case [1,3]. Unlike epitaxial AF, high H_{FC} can increase the density of pinned uncompensated moments in polycrystalline FeF₂ yielding larger positive EB.

Third, the magnitude of H_{EB} is very low for thick FeF₂. The AF thickness dependence of EB demonstrates that the density of pinned uncompensated moments in polycrystalline FeF₂ is very sensitive to the AF thickness, proving the important role of the AF bulk on this EB system.

INTRODUCTION/EXPERIMENT

Exchange bias systems are of interest due to their applications to pin one layer of spin-valves and magnetic tunnel junctions in read heads and MRAM devices. Thermal annealing processes for MgO based MTJs decrease the exchange field due to interlayer interdiffusion. Also the reduction of stack thicknesses to give higher areal densities reduces the thermal stability of the exchange biased system and its blocking temperature. Hence it is necessary to use high anisotropy AFs, such as $\text{Li}_2\text{-IrMn}_3$ [1], and grain size control to improve thermal stability and the blocking temperature, (T_B). In this paper we report on probably the largest value of exchange field measured with a low H_C of <5%(H_{EX}) in IrMn/CoFe multilayers at room temperature.

The samples, were sputtered onto a range of seed layers with the structure: Si/Seed layer/ IrMn (t_{AF})/CoFe(t_F)/Ta(50) Å, with $t_{AF} = 85$ and 70 Å, and $t_F = 25$ and 10 Å. Measurements were made using an ADE Model 10 VSM, with a noise resolution of 1×10^{-6} emu. H_{EX} can be controlled by thermal activation [3]. In order to obtain uniform and reproducible data it is essential that measurements are made at a temperature (T_{NA}) where thermal activation of the AF does not affect the measurement. The samples studied are stable at RT and $T_{NA} = 20^\circ\text{C}$. Prior to each measurement the AF must be set by heating to a temperature (T_{SET}) for a fixed period of time with the ferromagnet saturated by a setting field, (H_{SET}). $T_{SET} = 225^\circ\text{C}$ was found to be optimum, as it was the highest temperature at which no degradation of H_{EX} was observed.

RESULTS

Above T_{NA} thermal activation produces changes in the AF that increase with time according to a series expansion of $\ln(t)$ on an order that depends on the distribution of energy barriers to reversal within the AF [4-6]. The dependence on time of the setting process has been measured and proved to be linear with $\ln(t)$, indicating that there is a wide distribution of energy barriers within the AF [6].

The distribution of blocking temperatures was studied following the measurement procedure described in [3] and measured at T_{NA} . In this process the effect of thermal activation with a negative activation field (H_{ACT}), produces the shift of H_{EX} to positive values, progressively reversing the order in the AF, see fig.1. At the mean blocking temperature, T_B , half of the AF order has been reversed. This procedure allows for the assessment of the stability of the AF at different temperatures, and particularly at the working temperature of the MTJs.

The dependence of the H_{EX} on the magnitude of the setting field, H_{SET} , is shown in fig.2 for each of the samples studied. Table 1 shows the percentage difference in the measured value of H_{EX} for $H_{SET} = 20$ kOe relative to that for $H_{SET} = 4$ kOe. The interfacial spins are aligned at small fields less than 0.5 kOe. The application of higher H_{SET} increases H_{EX} due to an improved interfacial spin alignment at the interface. Alignment at both interfaces H_{EX} increases up to 37% when H_{SET} is increased from 4 kOe to 20 kOe. The H_C values are less than 10% of the value of H_{EX} , see table 1, which is indicative of the good quality of the interface. The variation of H_C with H_{SET} is very small compared to the error in H_C of 1%, this is consistent with data published elsewhere [2].

Observation of Metastable Remanence States in Pinned Antiferromagnetically Coupled Ferromagnetic Layers.

K. Srinivasan, S. Wong, S. N. Piramanayagam, R. Sbiaa

Spintronics, Media and Interface Division, Data Storage Institute, A*STAR, Singapore, Singapore

Soft magnetic layers of films that are synthetically antiferromagnetically coupled through Ru layers have applications in read sensors as well as perpendicular recording media. In read sensors, one of the soft magnetic layers is also pinned by an antiferromagnetic layer, such as MnPt, IrMn, or IrMnCr. Hysteresis loops and magnetoresistance properties of such soft magnetic layers have been reported by several researchers in the past. However, there have been few in-depth studies on the magnetization reversal characteristics of such structures. It was observed from our experiments that the minor hysteresis loops of such pinned and antiferromagnetically coupled structures exhibit systematic properties that point towards a unique magnetization reversal behaviour. This report discusses the interesting observations and a model to describe the behaviour.

<p>

Soft magnetic layers of the type FeCo(30 nm)/Ru(0.8 nm)/FeCo(x nm, x=30, 40) were deposited by sputtering on AlMg substrates used in hard disk media. Prior to the deposition of the sandwich, a sequence of underlayers such as Ta(5 nm)/Ru(10 nm) and an antiferromagnetic IrMn(5 nm) layer were deposited. All the layers were deposited at room temperature and there was no post-deposition annealing or intentional magnetic field to induce bias direction for the IrMn layer. However, it is likely that there is a magnetic field from the magnetron during the deposition. The films were characterized by vibrating sample magnetometer (VSM), and alternating gradient magnetometer (AGM).

<p>

Figure 1 shows selected minor hysteresis loops superposed on the major or full loop of the IrMn/FeCo(30)/Ru/FeCo(30) sandwich. For the minor loops which begin from a positive saturated state, it can be noticed that the structure along the return path shows a systematic dependence on the return field point. In addition, the minor loops carried out from the positive and negative saturation (not shown here) looked different, suggesting that the remanence states, although having M_r of almost zero, are different. In order to verify if this is true, the second sandwich IrMn/FeCo(30)/Ru/FeCo(40) was investigated. Figure 2 shows the full loop and selected minor loops. It can be noticed from the full loop that not only are the two remanence states different, but also the remanence is negative after positive saturation and vice versa.

<p>

In order to understand this interesting behaviour, a phenomenological model was developed. Figure 3 shows the full loop, a minor loop, and a schematic description of the magnetization states at various stages of reversal. It was assumed that the antiferromagnetic IrMn layer has random in-plane easy directions, half of which point to the right and the other half to the left, when projected on to a one-dimensional line. The model suggests that the top (free) FeCo layer always flips ahead of the bottom (pinned) FeCo layer, leading to the numerous and distinguishable remanence states. Despite this, based on the competition or co-operation of the pinning (induced by IrMn layer) and RKKY type coupling (Ru layer), only one of the remanence states has the lowest energy. While fundamentally interesting, such a sandwich has to be avoided for application as soft underlayer in perpendicular magnetic recording media in order to reduce the noise from the soft underlayers.

Effect of hot and cold rolling on grain size and texture in FeSi strips with a Si-content larger than 2 wt%.

P. R. Calvillo¹, H. Hermann², J. Verstraete¹, J. Schneider^{1,2}, Y. Houbaert¹

1. Metallurgy and Materials Science, Universiteit Gent, Gent-Zwijnaarde, Belgium; 2. Institut für Metallformung, Technische Universität Bergakademie Freiberg, Freiberg, Germany

The magnetic properties of electrical steel such as magnetization behaviour and specific magnetic losses are related to the microstructure and texture of the steel. The micro structural parameters having a strong influence on the magnetic properties are: grain size, inclusions, internal stresses and surface defects. They depend sensitively on the conditions during hot and cold rolling as well as on the final annealing treatment. Low values of the magnetic losses demand for large grain sizes and a large intensity of the cube texture is favourable for improved magnetization behaviour.

While the development of grain size and texture in conventional steels is already well understood, the knowledge for FeSi-alloys is far-off from complete. The interest in the case of FeSi-alloys is different from the case of conventional steels, where a high intensity of the $\{111\}$ fibre and a small grain size is desired. In this paper we present and discuss some results of our recent studies on FeSi-alloys without phase transformation. Hot rolled samples of FeSi_{2.4} with a thickness of 2mm were fabricated using the four stand high speed hot rolling mill in Freiberg. The width of the hot rolled material is 80mm and the thickness is 2mm. The finishing temperature TF at hot rolling and the conditions for the following cooling down to 200°C have been varied in a wide range: 600 °C < TF < 1100°C; rapid cooling down to 400°C < T < 750°C followed by slower cooling down to 200°C. The samples have been cold rolled to a final thickness of 0.50mm. Finally a thermal annealing comparable with the continuous annealing was used in a specially designed laboratory furnace. The maximum temperature was 950°C.

In addition to metallographic investigations, the EBSD-technique is used for micro structural and texture characterization. The resulting grain structure and the relevant magnetic texture components for non-grain oriented electrical steels: eta-, theta-, zeta- and Cube-fibres before and after cold rolling as well as after annealing were analyzed. According to the shape of the grains these were classified as equiaxed, pancake or bands in the deformed states. The homogeneity of the grain size and texture across the thickness, which is favoured to reach optimum magnetic properties, is also analyzed in the different states.

The resulting grain structure and texture was found to be rather inhomogeneous across the thickness for all realized and quite different hot rolling conditions. The re-crystallization takes place heterogeneously through the thickness. The intensity of the magnetically relevant textures, especially of cube and rotated cube texture in the hot strips can be increased by a slower cooling after hot rolling. Cold rolling does not destroy the obtained favourable magnetic texture components in the hot strips. Nevertheless, cold rolling results in a general, but moderate decrease of the relevant magnetic textures and in an increase of the alpha-fibre. Rapid cooling after finishing the hot rolling down to about 400°C gives bands in the material, only at the surface re-crystallization takes place. The intensities of the relevant magnetic texture components depend sensitively on the hot rolling conditions. Preliminary studies indicate that there is a large impact of the (Si,Al)-content and of the realized deformation in the different passes at hot rolling on the grain size and its distribution as well as on the resulting magnetic texture.

Finally present models for the development of texture after cold rolling and thermal annealing in steels are regarded with respect to their relevance for the FeSi alloys. It is pointed out that the under-

Magnetization processes of Fe(Si,Al)-steels with homogeneous and inhomogeneous distribution of (Si,Al).

J. Schneider, J. Verstraete, K. Verbeken, Y. Houbaert

Metallurgy and Materials Science, Universiteit Gent, Gent-Zwijnaarde, Belgium

Recently there has been a lot of activity trying to produce steel with an increased concentration of Si and/or Al (over 3-wt%). Materials with homogeneous as well as inhomogeneous spatial distribution of (Si,Al) have been obtained. We will discuss in the paper aspects of the magnetization processes in these new types of materials. We will compare the resulting structure properties and magnetization behavior for samples with homogeneous and inhomogeneous distribution of (Si,Al) across the width of the strips.

A concentration increase of (Si and/or Al) may be obtained by surface deposition of Si and/or Al by hot dipping followed by a diffusion annealing, whereby homogeneous or inhomogeneous distributions of (Si,Al) across the width of the strips like for CVD followed by diffusion annealing are obtained. Normally the substrate is an Fe(Si-Al)-alloy without phase transformation. It was demonstrated by us that these techniques may also be applied to substrates with low, medium and high (Si-Al)-content to obtain materials with higher (Si,Al) content and homogeneous or inhomogeneous distributions of (Si,Al) across the width. It was found that the material after dipping may be cold rolled to get the desired final thickness, especially thin electrical steels with thickness smaller than 0.35mm.

In the following the structure and the magnetization behaviour of dipped and diffusion annealed samples using FeSi-substrates without phase transformation will be regarded. To discuss the magnetization processes in these materials with homogeneous or inhomogeneous (Si,Al) distribution across the width we have to take into account that there are spatial fluctuations of the value of the fundamental parameters exchange energy (exchange constant A), anisotropy energy (anisotropy constant K), and magnetostriction (magnetostriction constant λ). This will affect the domain wall energy ($ED \approx AK$) and the domain wall width ($dW \approx A/K$). In addition, the roughness of these samples is relatively large, which gives additional local demagnetizing fields in the surface region. These facts are reflected in the shape of the hysteresis loops for the same samples and in the unintegrated hysteresis loops, which indicate the distribution of the critical fields for domain wall motion at lower fields and domain wall rotation processes at higher values of the applied external field, respectively.

The B vs. H loops at low frequencies indicate low values of the remanence, that means a more or less isotropic behaviour, and a broad range of the field for the approach to saturation. The broad range of critical fields for domain processes appears in the samples with homogeneous as well as inhomogeneous (Si,Al) distribution across the width. The behaviour of the investigated samples is similar to that of amorphous samples. The unintegrated hysteresis loops for homogeneous as well as inhomogeneous samples are rather similar, which point to similar magnetization processes in samples with homogeneous as well as inhomogeneous distribution of (Si,Al) across the thickness. There appears no double peak in the distribution of the critical fields for domain processes of the samples with quite different (Si,Al)-content in the surface region and in the middle of the samples, which would indicate a superposition of two magnetically different materials.

The frequency dependence of the coercive force may be used to characterize the dynamic magnetic behaviour. Regarding the domain wall spacing L the dynamic coercive force H_{ac} is proportional to $L^{1/2}$ and to the frequency $f^{1/2}$. If L is a function of frequency, deviations from the fact that H_{ac} is proportional to the square root of f may be observed. The observed behaviour for the investigat-

ed samples indicates a variation of L with f , which means a variation of the number of moving walls with f .

With respect to the magnetic properties in the range up to 1000Hz it was found that the magnetization behaviour B vs. H as well as the magnetic losses P vs. B are practically the same for samples with homogeneous and inhomogeneous distribution of (Si,Al). The permeability exhibits the typical dependence as a function of the applied magnetic field and frequency. At much higher frequencies of 10kHz or higher the permeability is small and may be regarded as a constant like in the classic formulae for the skin depth. In this case the values of the permeability are finally determined mainly by the magnitude of order of the electrical resistivity, which is increased by increasing the (Si,Al) content, and the thickness of the material.

This brief discussion may indicate that the magnetization behaviour of the dipped and diffusion annealed samples may be well understood on the basis of the known relations between the parameters for the magnetization behaviour and the fundamental magnetic parameters A , K , and λ as well as the structure sensitive properties L (domain spacing), dW (domain wall width), and surface roughness. There appears no difference in the behaviour of samples with homogeneous or inhomogeneous (Si,Al) distribution across the width of the strips. The spatial fluctuations of the (Si,Al) content seem to be not remarkably relevant for the magnetization behaviour.

Effects of Si content on the magnetic properties of Fe-Si alloy powder cores.

P. Jang¹, B. Lee¹, I. Jeong²

1. Div. of Applied Science, Cheongju University, Cheongju, South Korea; 2. R&D Center, Changsung Corp., Incheon, South Korea

1. Introduction

Despite of the excellent magnetic properties of the famous Fe-6.5% Si alloys, Si content in Fe-Si alloys has been mostly limited below 3 % because workability of the Fe-Si alloys decreases drastically beyond 3 % Si. Powder compressed cores can partly overcome the poor workability of the Fe-Si alloys. Even in the powder cores, however, poor workability of the Fe-Si alloys can decrease compaction ratio and density of core, leading lower permeability and higher core loss. In this study effect of Si content on the properties of Fe-Si alloy powder cores were investigated with an emphasis on optimum Si content.

2. Experimental procedure

Gas-atomized Fe-3%, 4.5% and 6.8%Si powders were annealed at 1000°C in vacuum, and then cooled to room temperature. The annealed powders were re-annealed at 900°C. The final powders with mean particle diameters of 49-56 μm and a similar size distribution were mixed with 0.5% insulation agent and then compressed into toroid, the inner and outer diameters of which were 7.6 and 12.7 mm, respectively. The compressed cores were annealed at 800°C for 1 hr in 99.999% N₂. The above annealing procedure is a condition for lowest total core loss in Fe-6.5%Si powder cores [1,2]. To reduce an experimental uncertainty five cores were fabricated at a time.

3. Results and discussion

Figure 1 shows a variation of total loss (P_{total}), hysteresis loss (P_h) and eddy current loss (P_e) of the Fe-Si cores as a function of Si content under a condition of 0.1 T and 50 kHz. P_h is larger than P_e in all cores. P_e decreases with increasing Si content while P_h slightly increases with increasing Si content. With increasing Si content workability decreases while resistivity increases as shown in Fig. 2. Resistivity of the cores increases with Si content. Compaction ratio(=density of core/density of bulk) decreases with Si content due to poor workability. As a result, 4.2%Si powders can have a moderate resistivity and workability. P_{total} shows a minimum value of 744 mW/cm³ in 4.2% cores. In Fe-Si alloys an abrupt decrease of ductility is due to the formation of FeSi(B2) and Fe₃Si(DO₃) ordered phases which appear as Si increases beyond around 5%. Lower compaction ratio of 6.8% cores in Fig. 2 is due to ordered phases as shown in Fig. 3. In Fig. 3, there is no trace of ordered phases in 3% and 4.2% cores. However, in 6.8% cores, the (111) and (200) characteristic lines of DO₃ and (B2+DO₃) phases are clearly seen. In Fig. 3, all indices of the diffraction lines are referred to the DO₃ unit cell. AC permeabilities of 3%, 4.2% and 6.8 %Si cores at 50 kHz are 84, 96 and 87, respectively. Shapes of DC hysteresis loops of 3% Si and 4.2% Si cores are very similar when loops were measured under a maximum field of 400 Oe as shown in Fig. 4. High AC permeability and high magnetization loop of 4.2% cores are due to both relatively good workability and higher resistivity. In conclusion, lowest core loss could be obtained in Fe-4.2%Si alloy powder compressed cores when resistivity and magnetic properties are compromised with workability.

An In-depth Study of the Barkhausen Emission Signal Properties of the Plastically Deformed Fe-2%Si Alloy.

L. Piotrowski¹, B. Augustyniak¹, M. Chmielewski¹, F. J. Landgraf²

1. Dept. of Appl. Phys. and Math., Gdansk University of Technology, Gdansk, Poland; 2. Dept. of Met. Eng., University of Sao Paulo, Sao Paulo, Brazil

The digest presents the results of the in-depth study of the Barkhausen effect signal properties for the plastically deformed Fe-2%Si samples. The set of 10 samples having deformation levels up to $\epsilon = 8\%$ has been investigated. The previous studies have shown that the rms-like signal envelope steadily increases with the increasing deformation level. However one can not tell whether the Barkhausen noise pulses are grater in number or rather their amplitude is higher. Being so we have undertaken the task of the time domain resolved pulse and frequency analysis of the Barkhausen noise signals. In Fig 1 the results of the time domain resolved FFT analysis for the non-deformed sample are presented. One can observe two, clearly separated maxima practically for all the frequency components of the signal – up to about 270 kHz. In order to facilitate the comparison of the results the contour maps obtained for all the samples have been intersected at various frequencies, the results of such intersection for the frequency $f = 10$ kHz are shown in Fig. 2. As can be seen the two maxima observed for the non-deformed sample disappear for the intermediately deformed sample ($\epsilon = 2\%$) and then an additional maximum appears for the highly deformed samples ($\epsilon = 8\%$). The intersection at the higher frequency ($f = 250$ kHz) gives different results (not shown). For all the investigated samples the two maxima envelope is present, though the observed minimum is somewhat less pronounced for the more deformed samples. In both cases the overall signal intensity is higher for the deformed samples but the difference is bigger for the lower frequency.

The complementary study consisted of the time resolved pulse count analysis as well as total pulse count. It turned out that the overall pulse number increases for the deformed samples, yet for the lower threshold levels the difference between deformed and non-deformed samples is not very important and the different deformation levels are practically non-discernible. The important difference is that for the non-deformed sample two clearly separated (in time domain) maxima are visible whereas for the deformed ones the maxima are weakly marked. Much bigger difference can be observed for the higher threshold levels (see Fig 3). Now two deformation stages (namely $\epsilon = 2$ and 8%) are easily discernible and the difference between the deformed and non-deformed samples is more pronounced. The difference in the dynamic of the pulse count change for various threshold levels suggests usefulness of the pulse height distribution calculation. Such calculations have been performed for varying both the threshold level and time duration of the pulses. In order to show clearly the difference between the samples, the difference between the distributions obtained for the deformed samples and the one obtained for the non-deformed one has been calculated. The result of such calculation for the most deformed sample ($\epsilon = 8\%$) have shown that the most useful region for comparison of the samples is the region of the relatively high threshold level (approx. about 1V), and pulse duration up to 10ms. For the higher pulses the total number of counts steadily decreases for all the samples and even though the rate of change of the relative pulse count as a function of deformation may be quite high the results become less certain.

Concluding one can say that the observed changes in results of both the time resolved FFT analysis and pulse distribution suggest that the increase in the Barkhausen noise signal as a function of deformation level is mainly due to the increase in the number of bigger pulses.

Correlation between core loss and microstructure for Fe-Si powder cores.

S. Takemoto, T. Saito
R&D Center, Daido Steel, Nagoya, Japan

[Introduction]

Soft magnetic powder cores are widely used for choke coils and reactors of switching regulators and DC-DC converters as power supplies. They demand magnetic cores with high magnetic performance and miniaturization as well as with the ability to fabricate in various geometries. Recently powder cores have been used replacing the conventional soft ferrite for smoothing and boost choke coils of these power supplies in high frequency 50kHz to 1MHz.

In previous report [1][2][3], we have studied eddy current loss for Fe-Si powder cores and suggested that magnetic domain configuration should contribute to eddy current loss.

In this study we have examined the eddy current losses by decomposing into classical eddy current loss and excess loss. The correlation between excess loss and both magnetic domain configuration and crystal grain size was discussed.

[Experimental procedure]

Fe-3mass%Si powders were made by atomizing process. Powders were sieved to make various particle distributions. After annealing at 1223K in H₂ atmosphere, silicone resin of 0.5mass% was added for the purpose of insulation between particles. Ring shaped specimens with outer diameter of 28mm and inner diameter of 20mm were press formed under 1.96GPa. The cores were heat treated between 1023K and 1273K in Ar atmosphere.

Core loss, P_c , was measured up to 100kHz at fixed magnetic flux density of 0.1T, and separated into hysteresis loss, P_h , classical eddy current loss, P_{cl} , and excess loss, P_{ex} .

[Results and discussions]

Figure1 shows the losses at 0.1T 100kHz decomposed into hysteresis loss, classical eddy current loss and excess loss. When particle size is large, main loss is classical eddy current loss, which is determined only by particle size. On the other hand, when particle size is small in terms of reduction of core loss, excess loss and hysteresis loss are significantly large. These losses are considered to have strong connection with microstructure.

Figure2 presents the dependencies of crystal grain size on hysteresis loss and excess loss. It is considered that both hysteresis loss and excess loss have an explicit dependency of crystal grain size for various particle sizes. As crystal grain size becomes larger, hysteresis loss decreases.

To discuss excess loss mechanism, paying a lot of attention to the magnetic domain configuration is of importance in terms of considering magnetising process for soft magnetic materials. We observed domain configuration in the Fe-3mass% Si powder core by means of Kerr effect microscope. The averaged crystal grain size and the averaged domain width were measured and the correlation between them was investigated. To compare the data with theoretical ones, calculation of domain width was carried out using following equation [4].

$$L = (8 \gamma_r \mu_0 / N_d I_s^2)^{0.5}$$

L : domain width, γ_r : domain wall energy, r : crystal grain size, N_d : demagnetising factor

Figure3 represents the averaged domain width from experiment along with the data calculated by the equation. The averaged domain width and crystal grain are 8 μ m and 33 μ m. The experiment data shows the increase in domain width as the crystal grain size increases.

It is concluded that wider domain with larger crystal grain makes excess loss larger.

These results is consistent with the data discussed for grain- oriented steels.[5]

More over we calculated excess loss for Fe-3Si powder core using equation described as follows [6]. Average particle size is 54 μ m.

$$P_{ex} = 8(G S V_0 / \rho)^{0.5} (B f)^{1.5}$$

B : excited magnetization, f : frequency, G : dimensionless geometrical factor 0.1356,

S : cross-sectional area, V_0 : phenomenological parameter, ρ : electrical resistivity of material.

Figure4 shows that calculated excess loss has a good agreement with measured data.

Effect of surface magnetic domain structure on iron loss of thin-gauged 3% si-fe sheets.

H. Jung¹, J. Kim¹, S. Kim²

1. Metallurgy and Material Science, Hanyang University, Ansan, South Korea; 2. Machinery and Materials Group, Korea Electric Power Research Institute, Taejeon, South Korea

Introduction

Fe-3% Si grain-oriented silicon steel with $\{110\}<001>$ Goss texture has been widely used for transformer cores. Currently, reducing the iron loss of the silicon steel is one of the most important industrial issues because of high oil price. Up to now, many methods regarding the reduction of iron loss have been developed including improvement in $\{110\}<001>$ Goss alignment, reduction of sheet thickness and refinement of magnetic domain wall spacing. [1,2] In particular, thin-gauged 3% Si-Fe sheets with excellent Goss texture were recently developed through a tertiary recrystallization method, which was induced by the surface energy difference between (110) and other grains.[3] Through this recrystallization process, the thickness of the thin-gauged sheets was down to 0.1 mm, which effectively reduced the eddy current loss. However, few researches have been conducted on domain structures related to iron loss in the thin-gauged sheets. In this paper, we investigated the effects of domain structure on the iron loss of thin-gauged 3% Si-Fe sheets using a MOKE microscope and Bitter patterns.

Experimental Procedures

Thin-gauged 3% Si-Fe sheets with a thickness of 150 μm were prepared by hot and multistage cold rolling process including an intermediate annealing followed by conventional vacuum induction melting. The detailed procedure was in other literature. [3] After fabricating the thin-gauged sheets, the orientation of each grain was identified by an etch-pit method. Magnetic induction under an external magnetic field strength of 800 A/m, which was referred to as B10(T), was measured using a DC flux meter and an open-circuit method. Iron loss was measured by an H-coil method. In this H-coil method, the maximum magnetic-flux density, Bm, was 1.7 Tesla and the frequency of AC field was 50Hz. The domain patterns was observed by a Bitter method and the dynamic domain behaviors were observed by a MOKE microscope. For domain observation, the surfaces of the thin-gauged sheets were prepared by electrical polishing at 1 A in mixed perchloric and acetic acid (3:1). In order to observe Bitter patterns, magnetite (Fe_3O_4) particles with a size of 20 nm were prepared by a sol-gel process and an optical microscope was used. An observation of domain patterns using MOKE microscopy was performed after applying an AC field of the 8 kA/m along the rolling direction of the thin-gauged sheet.

Results and Discussions

Table 1 shows magnetic induction and iron loss values of four different thin-gauged 3% Si-Fe sheets. As indicated in the table, the magnetic induction values of four sheets are closed to a theoretical value of 2.05 Tesla. This indicates that Goss texture is well developed in all sheets. Despite of these analogous magnetic induction values, four sheets show the very different iron loss values. Figure 1 shows the schematic diagrams of microstructures and corresponding magnetic domain images of four sheets. In all samples, 180o strip domains are well developed and lancet domains are also formed inside the strip domains. The presence of the lancet domains indicates that the sheet normal direction, $<110>$, is tilted to $<001>$ direction. Compared with Table 1, the domain images clearly show that the formation of tilted 180o strip domains result in high iron loss. Although several small disoriented grains to Goss texture are developed and have closure and spike domains, the iron loss of Sample 3 is very small, which results from low Eddy current loss. These results suggest the desirable microstructure of the thin gauged sheets for low iron loss.

Specific total loss components under axial magnetization in electrical steel sheets with different degree of Goss texture.

W. Pluta

Electrical Engineering Faculty, Czestochowa University of Technology, Czestochowa, Poland

1. Introduction

The efficiency of electrical machines is improved in between by the improve of electrical steel sheets quality [1]. Several years ago the specific total loss was measured at peak flux density equal to 1.0 T, later at 1.5 T and presently more and more the value 1.7 T is used for classification. This increase from 1.0 to 1.7 T also confirms both material and instrumentation improvements, particularly specific total loss decrease in electrical steel sheets.

The aim of the paper is to provide a contribution to the better understanding of specific total power loss in electrical steel sheets with different degree of Goss texture.

2. Measurement procedure

The experiment was carried out on grain-oriented (GO) and non-oriented (NO) electrical steel sheets with different texture degree κ . The texture degree was defined as a ratio of the volume of (110) [001] oriented crystals to the total volume of the sample and determined by using the anisometric method [2, 3].

The measurements of specific total power loss were carried out in a standard Epstein frame on samples magnetized along RD at 20, 50 and 150 Hz to allow separation of the specific total power loss into three components by the use of Bertotti's model [4].

3. Experimental data

The specific power loss P_s for GO (grades M140-27S, M150-30S and M165-35S) do not significantly differ – from scientific point of view – from each other. GO sheets possess degree of Goss texture 96%, 85% and 59%, respectively. The NO electrical steel sheets (grades: M300-35A and M470-50A) with lower Goss texture (15% and 10%) possess significantly higher specific total loss. The specific total loss of electrical steel consists of three components: hysteresis loss component and both classical and additional eddy current loss components. It was found that all three components are dependent on anisotropy i.e. degree of Goss texture and the dependencies show different trends as the magnetic flux density increases. The sum of eddy current losses increase nearly linear above 1.1 T as the maximum permeability was reached. The dependency of the additional loss on flux density shows also that the electrical resistivity has smaller influence on loss than the thickness of the sheets. This is also shows the nature of additional loss on which higher influence has the domain structure.

The relative additional loss factor η describes the ratio of the sum of classical and additional eddy current loss components to the value of classical eddy current loss component. The additional loss factor η for non-oriented electrical steel M470-50A is changing slightly with flux density but together with increase of grain orientation the dependence of the factor η on flux density become more non-linear. The non-linearity is higher at low flux densities and for GO steel.

Often in electrical machines design is used the loss separation factor Γ , which is the ratio between hysteresis and eddy current losses (considered together: classical and additional components). According to the practical knowledge, the loss separation factor $\Gamma = (20 : 80)\%$ in GO electrical steel and $\Gamma = (60 : 40)\%$ in NO electrical steel sheets [5]. The values of the additional loss factors η and ratio Γ are not commonly presented in literature and the assumption of constants ratio Γ for non and grain-oriented steel sheets is practically to simple.

The ratio Γ changes significantly from grade of electrical steel sheets according to texture degree κ and value of flux density. As the texture increases the ratio Γ increases faster, the hysteresis loss become less important and the eddy current loss opposite. In GO steel the ratio Γ changes significantly with high flux density opposite to the NO sheets. as the domain structure is reduced importance of eddy current loss components decreases and the hysteresis loss become more significant. In low texture degree κ steels hysteresis loss is dominant and the ratio Γ do not change significantly with flux density in comparison to grain-oriented sheets.

5. Conclusion

The specific power loss separation was performed by means of Epstein frame measurement at three frequencies. The specific total power loss components in electrical sheets (with orientation 10, 15, 59, 85 and 96 percent) are strongly dependent on texture degree. In NO electrical steel sheets the hysteresis loss is the main component of specific total loss and in GO steel the eddy current loss components are more significant. The the additional loss factor η is strongly dependent on both flux density and the texture degree. The loss separation factor Γ differs significantly from the values most often mention in literature. Factor Γ depends on the texture degree and flux density and it could be about 50% to 50% in steel with grain orientation about 50 %. The changes of factor Γ with flux density is wider range in GO steel.

Three Dimensional Polycrystal Magnetic Field Analysis of Electrical Steel.

K. Fujisaki

1. Technical Development Bureau, Nippon Steel Corporation, Futtsu-city, Japan; 2. Graduate School of Environmental Studies, Tohoku University, Sendai, Japan

Introduction

Electrical thin steel plate is used for electrical equipment such as a motor core or transformer [1], since it has a high permeability. Usually, electrical steel is selected by its magnetic property so as to obtain the high performance of the electrical equipment. Then the magnetic property is important for the electrical steel design as well as the electrical equipment design. To estimate the magnetic property, numerical calculation method is useful for the evaluation. Though micromagnetics calculation method based on Landau-Lifshitz-Gilbert equation is researched in magnetic domain [2], only a single crystal grain or a few numbers of crystal grains are possible to calculate. However, since the electrical steel consists of a lot of numbers of crystal grains, the micromagnetic calculation method is impossible to be applied to. To obtain the magnetic characteristics of polycrystal steel, three dimensional polycrystal magnetic field analysis is proposed and applied to the GO steel in this paper.

3D Polycrystal Magnetic Field Analysis

The polycrystal steel consists of a lot of numbers of crystal grains which are separated in crystal grain boundaries. In the proposed 3D polycrystal magnetic field analysis, it is assumed that each crystal grain has the same magnetized characteristics as the magnetized characteristics of a single crystal grain, which are given by the measurement of a single crystal or the calculation of micromagnetics. The crystal grains have their own different crystal orientations from each other. Therefore, each crystal grain is considered to have its own orthogonal local coordinates which is based on the crystal orientation and the polycrystal steel is considered to have its own total coordinates as shown in Fig.1. Then the coordinate transformation from the local coordinates to the total coordinates is introduced as equation (1) in this case.

Equation (1) : $[T] = [R_z(\alpha)][R_y(\beta)][R_x(\gamma)]$.

Here, α , β , γ are an angle around Z-direction (normal axis), Y-direction (hard axis), X-direction (easy axis) respectively from the total coordinates. By the coordinate transformation, the magnetic flux density from a point of view of the local coordinates is related to the one of the total coordinates. In the local coordinates, the magnetic flux density is decided in the given single crystal magnetic characteristics and the crystal orientation. Then the Maxwell equations are introduced from a point of view of the total coordinates. By solving the Maxwell equations in finite element method, the magnetic flux density distribution in the polycrystal steel is obtained in the condition that the total electromagnet energy is minimized.

Calculation results

Fig.2 and 3 are calculation results of the GO (Grain Oriented steel) materials with 56 crystals in 80mm square obtained by the proposed calculation method. The GO materials has the strong crystal orientation near (110)[001] [3]. Each crystal has its own crystal angle of α , β , γ as shown in Fig. 2 and 3. The α angle distribution of the GO materials shows that magnetic flux density gathers in the #4 crystal grain, since the α angle of #1 crystal grain is almost zero and the one of #2 crystal grain is plus and the one of #3 crystal grain is minus. The calculated magnetic flux density distribution shows that the #4 crystal grain has large magnetic flux density as shown in Fig.2. In supplying external magnetic field in easy axis direction, the angle difference of the magnetic flux den-

sity is expected to be the same as the α angle of each crystal grain. They are in good agreement as shown in Fig.3.

Improvement of the Bertotti's formula for energy loss in soft magnetic materials.

K. Sokalski, J. Szczygłowski
TU Częstochowa, Częstochowa, Poland

The paper presents the application of the scaling theory to the description of energy loss in soft magnetic materials. The postulated generalized description of energy loss has the form of series, dependent only on two exponents α and β . On the basis of measurement data it has been proved, that only two first terms of the series are relevant. For a wide class of soft magnetic materials, a universal linear dependence between α and β was obtained. The data collapse of energy loss, which confirms definitively the scaling hypothesis in the analyzed phenomenon, was also revealed. The Bertotti's formula of energy loss has been criticized in the light of the scaling theory.

The contemporary approach to energy loss phenomenon in soft magnetic materials assumes that the total loss P_{tot} is the sum of described above contributions [1,2,3]

$$P_{\text{tot}} = C_1 f B_m^\gamma + C_2 (f B_m)^2 + C_3 (f B_m)^{3/2} \quad (1)$$

where: C_1, C_2, C_3 are constants.

The approach to energy loss, which assumes their additive character, allows for their separation and consequently for the independent analysis of the obtained components in different scales. However the results obtained in the case of the modern materials of amorphous and microcrystalline structure reveal discrepancies between the theoretical and experimental values [4,5]. In the seventies of the past century the aforementioned approach to energy loss was criticized as being oversimplified. It was pointed out, that the energy loss phenomenon ought to be considered as a total [4]. In order to find whether the discrepancy and the separation are correlated one should reconsider *ab initio* the source of separation in

(1). Following this line we focused our attention on the formula for the total density current $\mathbf{j}(\mathbf{r}, t)$ being a result of the Barkhausen jumps at different random points \mathbf{r}_i and at different random times t_i , presented in [1]

$$\mathbf{j}(\mathbf{r}, t) = \sum_{i=1}^N \mathbf{j}(\mathbf{r}, t, \mathbf{r}_i, t_i),$$

where $\mathbf{j}(\mathbf{r}, t; \mathbf{r}_i, t_i)$

is the contribution to $\mathbf{j}(\mathbf{r}, t)$ resulting from the Barkhausen jump at (\mathbf{r}_i, t_i) . This formula is a too rough approximation, because it does not correlate the events at (\mathbf{r}, t) and (\mathbf{r}_i, t_i) . In order to improve (2) one should write down the following expression

instead of the aforegiven one

$$\mathbf{j}(\mathbf{r}, t) = \sum_{t_i < t} \mathbf{j}(\mathbf{r}, t; \mathbf{r}_i, t_i) \delta((\mathbf{r} - \mathbf{r}_i)^2 - c_m^2 (t - t_i)^2),$$

where c_m is the electromagnetic wave velocity in the considered material. The relationship (3) disables the derivation of the separation formula, whereas (2) leads to (1), which in general case for any given γ is not a homogeneous function, even though all its terms are homogeneous.

This contradiction results from the fact that all energy terms of this formula were derived independently of the others and next "artificially" summarized. This approach does not take into consideration the influence of these terms each other. We suspect that this contradiction in the Bertot-

ti's formula is a reason of often observed discrepancy between the experiment and theory. Recently, an attempt to the application of the scaling theory in phenomenological description of energy loss in soft magnetic materials was made [6]. The obtained results pointed out on the validity of the assumptions and usefulness of the proposed formula in practical applications, as well.

A heuristic argument has been developed into a coherent approach to understanding the ubiquity of scale invariance in a wider range of considered systems. By the scale invariance we mean a hierarchical organization that results as the homogeneity in generalized sense of functions describing properties of the considered complex system.

On the basis of the scale invariance of the considered system, it can be assumed, that the total energy loss in soft magnetic materials $P_{\text{tot}} = F(f, B_m)$

is given by a generalized homogenous function, where

P_{tot} - total energy loss, B_m - maximum magnetic induction, f - frequency of magnetizing field. This assumption leads to the following formula for energy loss [6]

$$P_{\text{tot}} \approx B_m^\beta (\Gamma^{(1)} f/B_m^\alpha + \Gamma^{(2)} (f/B_m^\alpha)^2) \quad (4)$$

where α , β , $\Gamma^{(1)}$ and $\Gamma^{(2)}$ are free parameters to be determined from the experiment. Measurement values of total energy loss for chosen magnetic materials and values of energy loss obtained from the scaling theory have been compared. The measurement and theoretical data agree well, which confirms the expected improvement of the Bertotti formula.

On the basis of measurement data for all analyzed materials a relationship between the exponents α and β

was obtained in the following form

$$\beta = 1.35 \alpha + 1.75. \quad (5)$$

On the basis of presented results it could be stated, that the abovegiven relationship (5) is universal, whereas the exponents are not. The exponent values are dependent on the chemical composition of the material and the sample geometry.

Influence of improving efficiency using Fe-P-B-Nb type ultra low loss glassy metal dust core on inductor for large-current.

H. Matsumoto, Y. Yamada, A. Urata

RESEARCH AND DEVELOPMENT UNIT, NEC TOKIN, Sendai, Japan

Introduction

As a result of the evident advancement of ubiquitous technology, information equipment applications, including those for notebook PCs are making significant progress and their power consumptions are increasing more and more. Following this trend, the supply of a high-speed, high-quality energy and the control of power consumption become big problems along with it in CPU. The achievement of a high level of power efficiency in the power supply circuit has become a high-priority issue. We observed the loss characteristic of metal inductors as well as their high-current compatibility and have developed Fe-P-B-Nb type soft magnetic material which is a new low-loss metallic glass composite material that can compactly achieve high-efficiency inductors for low-voltages and high-current power supplies. Fe-P-B-Nb type soft magnetic material is a metallic glass dust powder that features both a high saturated magnetic flux density ($B_s=1.3\text{T}$) that is proper to metallic materials and a stable amorphous structure proper to metal glass composite materials. There is no magnetic saturation under a high-current supply and it can therefore significantly reduce magnetic loss resulting from the effect of the core material. This paper reports the effect when applying to the loss characteristic and the inductor of Fe-P-B-Nb ultra low loss glassy metal dust core.

Experiments

Metallic glass powder that made Fe-based composition element was made by the water atomization method. The obtained metallic glass powder was observed particle shape by SEM, analyzed amorphous condition by XRD and metallic glass condition by DSC. Next, the made Fe-P-B-Nb metallic glass powder was mixed with the resin binder, and after granulation, the pressurizing molding was done to a constant particle size. The molding body of ring core ($\phi 13\text{mm} \times \phi 8\text{mm} \times 6.5\text{mm}$) and the SMD choke coil ($10\text{mm} \times 4\text{mm}$ and inductance $0.56\text{ }\mu\text{H}$) was made. Permeability (1mA , 100kHz) and core loss (50mT , 300kHz) were measured in the made ring core.

Moreover, the SMD choke coil was mounted on voltage step down DC/DC converter evaluation board (MAXIM 1717 Evolution Kit), and power load efficiency was evaluated. Additionally, the rise in heat of the inductor according to the change of the current by the SMD shape was simulated based on the loss characteristic in the core.

Results and discussion

Fig.1 shows the results of a loss comparison between Fe-P-B-Nb type glassy metal and Fe-type amorphous dust material. It shows that the loss of Fe-P-B-Nb type glassy metal is 1/2 compared with iron powder, is 1/3 and a very low loss compared with Fe-type amorphous material. Fig.2 shows the improvement of the power load efficiency confirmed by the use of Fe-P-B-Nb glassy metal for the core of SMD choke coil. The graph shows that the use of Fe-P-B-Nb glassy metal has improved the effective efficiency all over the load current range from 0.1A to 10A . In particular, in the low-current range below 5A where the hysteresis loss has occupied an important share, the efficiency has been improved by more than 1.5% .

Fig.3 shows the results of the simulation of change of inductor surface temperature in SMD choke coil that used glassy metal and iron powder. The graph shows the possibility that generation of heat of the inductor can be controlled compared with iron powder by using Fe-P-B-Nb glassy metal.

Conclusion

We succeeded in the decrease of the loss of the core material by using Fe-P-B-Nb glassy metal, and the improvement of the inductor loss. Additionally, the possibility that it becomes easier to design the temperature in the power supply circuit was confirmed by generated heat about the inductor being suppressed.

Introduction

Since 1974, (Fe, Co)-Si-B, (Fe, Co, Ni)-(Cr, Mo, W)-C, (Fe, Co, Ni)-(Zr, Hf) and (Fe, Co, Ni)-(Zr, Nb, Hf)-B amorphous alloy systems were developed and they exhibited superior soft magnetic properties¹. These have been widely used in the transformer cores that were wound from ribbons with the thickness around 30 μm^2 . Subsequently, Fe-based alloys with nano-crystalline structure were developed, such as FINEMET and NANOPERM, which exhibited much superior soft-magnetic properties their amorphous counterparts.

Recently, amorphous ribbons with thickness up to 220 μm exhibiting low core loss and good soft magnetic properties was developed in Fe-Al-Ga-P-C-B-Si³. This remarks a great improvement in developing “thicker” amorphous ribbon. In this study we intended to develop nano-crystalline thick ribbons from compositions modified from ternary Fe-B-Y BMG compositions by substituting Y with Ta and Ag. Our target was to obtain thick ribbons at thickness up to at least 100 μm , in which Ta was to replace the highly oxidative Y while Ag served as the nucleation agent to induce nano-crystalline structure. Structural, thermal and magnetic properties of the nano-crystalline thick ribbons were investigated and are disclosed in the article.

Experimental

$\text{Fe}_{71}\text{B}_{22}\text{Ta}_x\text{Y}_{6-x}\text{Ag}_1$ ($x = 1 \sim 5$) ribbons with different thickness were prepared by the melt-spinning technique under Ar atmosphere. The ribbons were then post annealed at a temperature upon which proper crystallization occurred. The properties of ribbons were analyzed by XRD, DTA, VSM, and TEM.

Results and Discussion

DTA result of $\text{Fe}_{71}\text{B}_{22}\text{Ta}_x\text{Y}_{6-x}\text{Ag}_1$ amorphous ribbon showed glass-transition temperature (T_g) and crystallization temperature (T_x) are 565 °C and 605 °C, respectively. Fe_{23}B_6 becomes the main crystalline phase as the annealing temperature is increased as shown in Fig. 1. According to the Scherrer equation, the grain sizes of the bcc-Fe and Fe_{23}B_6 can be calculated from the FWHM and found to vary from 20 - 36 nm and 16 - 24 nm in properly annealed samples, respectively. From TEM observation of the ribbon annealed at 615 °C, the structure consists of nano-crystalline mixture of bcc α -Fe and Fe_{23}B_6 phases. The average crystallite size of α -Fe and fcc Fe_{23}B_6 is around 19 nm, being typically the same for the two nano-crystalline phases. At higher annealing temperatures, the major crystalline phase becomes Fe_{23}B_6 . In Fig. 2, the ribbons show good soft magnetic properties that saturation magnetization and coercivity are around 1.44 T (152 emu/g) and 35 A/m, respectively. By annealing for a longer time, the crystallite consists of the major Fe_{23}B_6 phase, however the ribbons still show good soft magnetic properties such as high saturation magnetization ~ 140 emu/g (1.31 T) and low coercivity ~ 46 A/m, respectively. Table 1 indicates a comparison in soft magnetic properties of our thick ribbons with some other ribbons. The effective permeability of our thick ribbon is superior. It is concluded that a new nano-crystalline thick ribbons have been developed in Fe-B-Ta-Y-Ag system with good thermal stability, glass forming ability and sound soft magnetic properties. These thick Fe-B-Ta-Y-Ag nano-crystalline ribbons show great potential in future applications.

Gas flow effects to the magnetic properties of current annealed Vitroperm samples.

V. de Manuel¹, R. Pérez del Real²

1. Space Programs and Space Sciences, INTA, Torrejón de Ardoz, Spain; 2. Space Programs and Space Sciences, INTA, Torrejón de Ardoz, Spain

Current annealing of Finemet-like samples has many advantages compared with furnace annealing: it is a faster technique [1] and samples show smaller grains [2-4] together with better mechanical properties [5].

Other interesting results have been found when current-annealed samples were 'over-annealed', that is, when harder phases (FeB and big FeSi crystals) appear at temperatures over 650 C. After this kind of annealing the hysteresis loops reported were sometimes constrained (making them useful for fabricating magnetic labels [6]). These exotic results come from the fact that this technique is very sensitive to environmental conditions. In this work, it is presented how the effect of gas flow during current annealing can critically affect the magnetic properties of the sample.

Three Vitroperm[®] ($\text{Fe}_{73}\text{Si}_{16}\text{B}_7\text{Nb}_3\text{Cu}_1$) samples ($100 \times 8.3 \times 0.023 \text{ mm}^3$) were annealed during 60 s with a computer-controlled Agilent[®] 3634 power source. The current density was $J = 36.67 \times 10^6 \text{ A/m}^2 \text{ DC}$.

All samples were placed in a sealed chamber during annealing with a controlled overpressure of Ar. A valve at the inlet of the system, a manometer and a second valve at the outflow were used to control the flow of Ar escaping the chamber. The pressure inside the chamber, with the outflow valve completely opened, was set to 4 mbar (A), 10 mbar (B) and to 20 mbar (C) (initial pressure P_0) controlling the opening of the inlet valve, which connected the Ar bottle with the system. Once set, the outflow valve was closed until reaching a value of 40 mbar. Thus, the Ar flow inside could be indirectly controlled during the annealing process, being proportional to P_0 . The pressure during annealing was kept constant at 40 mbar in order to keep all annealing conditions of every sample constant except for the Ar flow.

The hysteresis loops are shown in figure 1.

Sample A had the lowest flow, and almost no heat exchange between the sample and the surrounding gas occurred. That is why the temperature of the sample was very homogeneous and the heat was enough to create FeB and big FeSi crystals showing the typical hard loop.

Sample C had the highest flow and therefore the heat exchange during annealing was enough to create only FeSi nanocrystals distributed homogeneously over the sample surface showing a soft hysteresis loop.

Sample B had enough gas flow to create such a temperature gradient that the sample got nanocrystallized creating FeSi nanograins (which corresponds to the softer phase) at the borders and crystallized creating FeB and big FeSi crystals at the center (which corresponds to the harder phase). For this reason it shows a constrained loop.

In order to prove this hypothesis, two pieces of sample B were taken: one from the center (sample B1) and the other from one edge (sample B2). Both hysteresis loops were measured with a VSM, obtaining the results in figure 2. A hard hysteresis loop for sample B1 with a coercive field of 14.97 Oe and a soft loop for sample B2 with a coercive field of 0.05 Oe are obtained demonstrating that a gradient existed during the annealing. As a conclusion, the magnetic properties of the samples can be tailored just by changing the gas flow during annealing.

Routes to Create Ultrathin Co Films with Perpendicular Magnetic Easy Axis.

S. Gallego, C. Muñoz

Inst. Ciencia Materiales Madrid, Madrid, Spain

The characteristic length scales governing the processes of magnetic reorientation and exchange in Co [1] make Co nanostructures specially appealing. Recently we have proved the existence of a double magnetic reorientation transition (MRO) in ultrathin Co films of 1-3 monolayers (ML) thickness grown on Ru(0001) substrates [2]. The uniqueness of such MRO is based on the correlation between magnetic orientation and ML completion, and on the ultrathin thickness of the film. Our ab-initio calculations of the magnetic anisotropy energy (MAE) demonstrate the fundamental role of the structural distortions on the MRO: there exists a 8% mismatch between the in-plane lattice parameters of Ru and Co, and it is the tendency of both elements to recover their own atomic volume which lies at the origin of the MRO.

The apparent simplicity of the Co/Ru(0001) ultrathin films hides in fact a complicated structure. Stacking faults at the Co/Ru interface altering the perfect hcp sequence have been observed [3]. The effect of stacking faults on the MAE has never been analyzed previously. In a pioneering work, we have investigated the MAE of the ultrathin Co films considering the existence of the experimentally observed stacking faults, both in the very low thickness regime (1-3 ML) and for larger thicknesses up to 7 ML. A different behaviour appears for both regimes, as evidenced in figure 1. In the lower thickness limit, the existence of a stacking fault altering a perfect hcp (AB/AB) or fcc (ABC/ABC) sequence doubles the MAE, improving the low values obtained in [1] where the stacking faults were not included. For thicker films, the magnetic easy axis varies depending on the global fcc or hcp structure of the Co film, with almost no influence of the stacking fault at the Co/Ru interface. While the magnetization lies in the surface plane at the fcc films, a perpendicular magnetization can be obtained for hcp structures.

The stabilization of Co films with perpendicular (to the surface plane) magnetic easy axis is of technological interest. Our investigations show that the key ingredient to obtain such structures is to stabilize hcp structures with an expanded in-plane lattice parameter (figure 2). The usage of Ru(0001) substrates achieves this goal for 2 ML thick films. However, the tendency of the Co film to distort towards a Co lattice upon increasing thickness makes necessary the search of additional routes to maintain the expanded two-dimensional (2D) Co lattice. A promising mechanism is the use of capping layers. On one side, a capping layer enhances the MAE of the Co film, expanding the range of thicknesses for which the MRO occurs (see figure 3 and ref. [4]). On the other, the adequate choice of the capping element helps to stabilize the expanded Co structure, thus favouring the perpendicular magnetic easy axis.

In this talk we will show all these results with detail, justifying the microscopic origin of the obtained MAE and quantifying the interplay between strain, stacking and hybridization effects which allow to tune the magnetic properties of ultrathin Co films and, in particular, their magnetic anisotropy.

Perpendicular magnetic anisotropy at Co/Oxide interfaces.

Y. Dahmane, S. Auffret, U. Ebels, B. Rodmacq, B. Dieny
CEA Grenoble, Grenoble, France

For many spintronics applications, it is of increasing interest to use magnetic materials with perpendicular magnetization. We are currently developing new materials with exceptionally large perpendicular magnetic anisotropy (PMA) for various applications such as magnetic electrodes of tunnel junctions (MTJ) or perpendicular polarizers for RF oscillators [1].

Most of MTJ based on Al or Mg oxides require relatively high temperature annealing treatments (up to 350°C for magnesium oxide) in order to reach the largest possible TMR ratio. For such high temperatures, classical (Co/Pt) multilayers can no longer be used since, due to intermixing, PMA properties rapidly degrade with increasing annealing temperature and vanish for temperatures as low as 200 to 250°C. A similar problem due to recrystallization takes place with rare earth transition alloys.

Following previous investigations on oxygen-induced PMA in Pt/Co/oxide trilayers [2], we present here a study of the evolution of PMA in similar structures as a function of both Co thickness and thermal treatments.

Samples of the form substrate/Ta3/Pt20/Cot/AlOx/Cu2/Pt2 (in nm) were prepared by conventional dc-sputtering at room temperature. The oxide layer was obtained by natural oxidation (10 min, 170 mbar oxygen pressure) of a metallic aluminium layer. Annealing treatments were performed in a vacuum furnace at increasing temperatures from 150 to 350°C. Magnetic measurements were performed after annealing using Hall Effect, the magnetic field being applied either perpendicular to the plane, or in-plane for anisotropy field measurements.

Figure 1 shows, for the complete structure given above, with Al thickness of 0.5 nm, the hysteresis loop obtained in the as-deposited state for a Co thickness of 0.4 nm, the magnetic field being applied in the perpendicular direction. We obtain a square loop with 100% remanence, characteristic of a single domain perpendicular magnetization. The perpendicular magnetic anisotropy is quite large for this sample, since an in-plane field of 20 kOe is necessary to saturate the magnetization in plane.

The effective anisotropy per unit volume of Co film was derived from the saturation field measured with field applied in-plane for samples with out-of plane anisotropy and with field applied out-of-plane for samples with in plane anisotropy ($K_{eff} = M_s H_{sat}/2$). Figure 2 shows the Co thickness (t_{Co}) dependence of $K_{eff} \cdot t_{Co}$ for the as-deposited and 350°C annealed samples. Bulk and interfacial anisotropy can be separated by writing $K_{eff} \cdot t_{Co} = K_v \cdot t_{Co} + K_s Co/Pt + K_s Co/AlO$. Fig 2 shows that whereas the bulk anisotropy almost does not vary with annealing temperature, the interfacial anisotropy dramatically increases upon annealing. Since it is well known that the interfacial anisotropy at the Pt/Co interface decreases with annealing and vanishes after annealing at 200°C, this implies that the very large anisotropy observed at 350°C is entirely due to the Co/AlOx interface. Interfacial anisotropy as large as 1.6 erg/cm² has been observed (Fig.2). This is larger than all interfacial anisotropy ever reported in polycrystalline or epitaxial (Pt/Co) multilayers in as-deposited state and a fortiori after annealing [3].

As a consequence of this very large interfacial anisotropy, the reorientation transition between out-of-plane and in-plane anisotropy now occurs for a Co thickness of 2.7 nm which is exceptionally large in such structure.

Giant magnetic anisotropy of Fe₃Pt alloy thin films with various crystallographical orientations.

H. Yamamoto, T. Suzuki

Information Storage Materials Laboratory, Toyota Technological Institute, Nagoya, Japan

It was reported that the “quasi” L1₂ ordered phase of Fe₃Pt alloy thin films deposited onto MgO single crystal substrates exhibits huge magnetic anisotropy constants ($K_1 = -4 \times 10^6$, $K_2 = 2 \times 10^7$ erg/cc)[1]. Theoretical calculation also predicted that Fe₃Pt alloy thin films could possess a large in-plane magnetic anisotropy in deforming fcc to fct or m-DO₁₉[2]. However, the origin of this giant magnetic anisotropy of Fe₃Pt alloy thin films is still open to question. Therefore, the purpose of this study is to elucidate the origin of such a giant magnetic anisotropy.

Alloy thin films of Fe₃Pt were fabricated by electron beam evaporation onto MgO(100), (111) and (110) substrates held at various deposition temperatures, T_s . The film thickness for all the samples was about 500 Å. The structural analyses were carried out by a XRD (Cu-K α). Magnetization, M_s were measured by using a VSM. K_1 and K_2 were evaluated by torque magnetometer. K_1 , K_2 and M_s of Fe₃Pt alloy thin films were investigated as a function of temperature, T for various crystallographical orientations.

From both the high angle and low angle X-ray diffraction analyses, the Fe₃Pt alloy thin films grown onto MgO substrates are found to be single crystalline films. Fig.1-(a) shows K_1 and K_2 of Fe₃Pt alloy thin films fabricated at various T_s . The maximum K_1 and K_2 values of the Fe₃Pt alloy thin films fabricated onto MgO(110) are 3×10^7 and -6×10^7 erg/cc, respectively. These values of K_1 and K_2 are larger than the values of the Fe₃Pt alloy thin films fabricated onto MgO(100) and MgO(111) (K_1 and K_2 are -4×10^6 and 2×10^7 erg/cc, respectively). Furthermore, the signs of K_1 and K_2 are opposite to those of the Fe₃Pt alloy thin films on MgO(100) and MgO(111). Fig.1-(b) shows the degree of ordering, S of Fe₃Pt alloy thin films. The Fe₃Pt films start to be ordered at about $T_s = 200$ °C, increasing with T_s . Fig.1-(c) shows lattice constant ratio, c/a which changes with T_s . This variation of K_1 and K_2 with S suggests that there exists a strong relationship between the magnetic anisotropy and S .

The L1₂ phase and the m-DO₁₉ phase are shown in Fig.2. In the bulk phase, l of the Fe₃Pt alloy is 2.64 Å. It is predicted that an 2% expansion of l reduces the energy difference between the L1₂ phase and the m-DO₁₉ phase by theoretical calculation[3]. Fig.3 shows K_1 and K_2 increase with l . Furthermore, the maximum expansion of l is 1.8%. This result might suggest that the m-DO₁₉ phase stabilized by the expansion of l is responsible for the giant magnetic anisotropy of the Fe₃Pt alloy thin films.

Fig.4 shows the relation between K_1 , K_2 and $[M_s(T)/M_s(R.T.)]^2$. It is observed that the temperature dependences of K_1 and K_2 are very close to the curve of $[M_s(T)/M_s(R.T.)]^{1.8}$. The dependence for Fe₃Pt is, within the accuracy of experiment, consistent with the theoretical prediction of M^2 for the two-ion model put forward by O.N.Mryasov et al. for the case of Fe₅₀Pt₅₀[4].

The potential for semiconductor applications utilizing charge and spin of the conducting electrons has spurred significant interest in ferromagnetic MnAs layers grown epitaxially on GaAs. Recently, our group has explained transport measurements on epitaxial MnAs/GaAs/MnAs tunnel junctions by a resonant tunneling model through a band of localized states (played by As antisites) in GaAs.¹ Potential applications include the technologically important areas of spin injection into GaAs-based devices, non-volatile memory devices, and optical control of ferromagnetism in semiconductor devices. It is well-known that MnAs bulk samples exhibit a first order phase transition at about 40°C from the ferromagnetic hexagonal α -phase to the paramagnetic β -phase. A more complex magnetic ordering has been found for MnAs epitaxially grown on GaAs substrates which exhibits a temperature region with coexistence¹⁻⁴ of the α -phase and β -phase. Well ordered stripes alternating the two crystallographic phases are observed for MnAs/GaAs(001) (see STM image in figure 1) over a rather wide temperature range ($\sim 10^\circ\text{C}$ to 40°C). Structural and magnetic properties of this transition phase have been studied extensively by, among others, AFM/MFM,^{1,3} XRD,² and PEEM.⁵

When capping MnAs/GaAs(001) with a ferromagnet like Fe a complex coupling between the two magnetic systems is expected in the temperature range of the α - β -phase coexistence due to the stripe formation. We have recently confirmed this expectation by recording element selective hysteresis curves, which were obtained by resonant x-ray magnetic scattering at the Fe and Mn L3 absorption edge at three representative temperatures below (0°C , MnAs in the ferromagnetic α -phase), within the α - β -phase coexistence regime (22°C , stripe formation) and above the phase transition (70°C , paramagnetic β -phase). The temperature dependence of the dichroic signals⁶ (see figure 2) suggest that the formation and disappearance of the stripes is accompanied by a reorientation from parallel to antiparallel and then back to parallel coupling of the magnetization directions. This indicates a complex magnetization behavior in the coexistence of the α and β phase. Recently, we have confirmed this finding by X-ray PhotoEmission Electron Microscopy (X-PEEM at SLS Synchrotron), which allows imaging of the magnetic domain structure of the ferromagnetic Fe film and of the surface of the underlying MnAs film. The comparison of these images reveals unambiguously the coupling between the two magnetic domain patterns.

We note that typically an antiferromagnetic coupling between two ferromagnetic materials requires the presence of a non-magnetic spacerlayer, whose structural thickness actually defines the coupling. For the system studied here, on the contrary, we find a relative coupling between two layers in direct contact, which in addition can be reversed by temperature variation. Potentially, this makes it a technologically attractive system for which we intend to measure magneto-resistance and other macroscopic properties.

CAPTIONS.

Figure 1. Room temperature STM image of the MnAs/GaAs(001) template, prior to Fe deposition. Stripes form parallel to the c-axis of MnAs (y direction in the figure), alternating α (bright) and β (dark) phases. Shorter period troughs are visible normal to the stripes. X-ray scattering measurements give an average period of 924nm and 115nm for stripes and troughs, respectively.

FIGURE 2. (a) Specular reflectivity vs. temperature, measured at remanence after a magnetic pulse of 600 Oe. Top: asymmetry ratio. Bottom: magnetization averaged reflectivity. Open and solid symbols refer to cooling down and warming up, respectively. (b) Specular reflectivity vs. applied magnetic field at $T = 22^\circ\text{C}$ (α - β phase coexistence). Photon energy is tuned to the Mn 2p resonance (640 eV, bottom) and to the Fe 2p resonance (707 eV, top). Vertical dotted lines locate the coercive field for the Mn curve ($H_c \sim 75$ Oe).

Magnetic anisotropy control by ion irradiation.

The chemical ordering of thin FePt layers using light ion irradiation was analyzed in regards of their magnetic properties. Thin FePt(001) films grown layer by layer by Molecular Beam Epitaxy exhibit unique features of interest. First, a huge magnetocrystalline anisotropy can be obtained through uniaxial chemical ordering of the alloy within the L_{10} structure. Second, it was shown in thicker FePd films [1] that the combination of He ion irradiation and thermal mobility may control the transformation from the fcc chemically disordered phase to the tetragonal chemically ordered L_{10} one.

Films of thickness ranging from 2 to 30 nm were investigated and next irradiated at a temperature $T=300^\circ\text{C}$ with 30 keV He^+ ions at doses, starting from 2×10^{13} ions/cm².

For the thinnest films, the initial chemical order within the layer was revealed by a combination of Kerr magnetometry and microscopy experiments. In a 5 nm FePt film, 2 magnetic contributions were evidenced by comparing the polar in-field and remnant hysteresis loops. The usual polar in-field hysteresis loop (Fig. 1a) shows a lower remanence than the remnant hysteresis one (Fig. 1b), obtained from Kerr microscopy. In the latter, after saturating the sample, magnetic field pulses were applied to trigger the magnetization reversal but cancelled to perform imaging. The remnant hysteresis loop was obtained from the magneto-optic intensity after switching off the magnetic field for each value. States of the reversal process frozen by the field cancellation can be observed and a fully remnant out-of-plane magnetic contribution accounts for the polar signal (Fig. 1b). A magnetic contribution with no significant perpendicular remanence at zero field must enter the in-field hysteresis loop (Fig. 1a). To confirm the existence of both contributions, we relied on polar Kerr magnetometry but applying the magnetic field at angle α of the sample plane. Like in anisotropy experiments, the magnetization is dragged towards the sample plane, requiring a larger applied field range. The loops and their angular dependence (Fig. 2a) confirm the existence of 2 magnetic contributions. Those are i) an out-of-plane component M_1 fully remnant and ii) a component M_2 without remanence. The M_2 behavior is assumed as being that of systems exhibiting stripes domains, well known from chemically disordered alloys. In each field configuration, signatures of M_1 and M_2 were simulated. A combination of the two contributions can reproduce the experimental loops (Fig. 1c and Fig. 2b). So, in thin FePt films, magneto-optical techniques appear as a unique tool to characterize and evidence the coexistence of magnetic components corresponding to local inhomogeneities between ordered or disordered phases.

Finally, as a clear signature of the L_{10} phase growth after irradiation, the usual polar Kerr hysteresis loops of films of increasing thicknesses are reported Fig. 3. The thinnest films that were initially partly disordered exhibit now a fully remnant loop. So, the combined use of ion irradiation with moderate heating could possibly lead to the L_{10} structure within nanometric size particles, without particle sintering. We are now exploring this opportunity.

Study of magnetic structures on the nanoscale: a multiscale approach based on first principles calculations.

L. Szunyogh¹, L. Udvardi¹, A. Antal¹, B. Lazarovits^{2,1}, B. Újfalussy²

1. Department of Theoretical Physics, Budapest University of Technology and Economics, Budapest, Hungary; 2. Research Institute of Solid State Physics and Optics, Hungarian Academy of Sciences, Budapest, Hungary

During the last two decades, investigations of magnetic properties in confined geometries such as multilayers and clusters have led to discoveries of exciting new magnetic properties like giant magneto-resistance (GMR), exchange biasing and spin-dependent tunneling which have attracted much attention because of their importance in magnetic storage technologies. The development of nanoscale devices based on electron spin requires both a fundamental understanding of magnetic interactions and practical solutions to a variety of challenges.

In this contribution we present a multiscale study of the formation of magnetic patterns in various thin film systems. We derive the parameters of an extended classical Heisenberg Hamiltonian consisting of tensorial exchange interactions and on-site anisotropy terms derived from relativistic spin-polarized first principles calculations [1]. By using these parameters we then perform Monte Carlo simulations to explore the low-temperature (ground-state) spin structures.

The interplay of the different anisotropic exchange interactions and the on-site anisotropy can influence the formation of domain walls and lead to nanometer sized magnetic patterns. It is well-known that thin films may exhibit a large magnetic anisotropy, while it has also been recently shown [2] that the Dzyaloshinskii-Moriya (DM) interactions, $\mathbf{D}_{ij} \cdot (\mathbf{S}_i \times \mathbf{S}_j)$ [3], can be especially strong at magnetic surfaces.

In case of an Mn monolayer deposited on a W(110) surface the DM interactions give rise to a formation of a cycloidal spin-spiral pattern modulating the underlying antiferromagnetic structure [3,4]. This is clearly seen in figure 1 that shows the spin-structure from our multiscale approach. We obtained a length of about 7.6 nm for the period of the spin-spiral that nicely compares the measured period of 12 nm [3].

Moreover, we present an extensive study for several ultrathin systems such as Mn, Cr and Fe monolayers deposited on W(001) and W(110) surfaces. In figure 2 displayed is the calculated ground-state spin-structure of a ferromagnetic Fe bilayer on W(110). It should be stressed that the domain wall formation here is the consequence of strong DM interactions, too, as switching them off the simulations result in a normal-to-plane ferromagnetic ground state.

We also investigate magnetic nanoparticles deposited on surfaces. In general, the form of the on-site anisotropy term can not be deduced from symmetry constraints, therefore, we invented a new strategy of the parametrization of the spin-Hamiltonia in terms of a least-square fit of the calculated (total) energies. It turned out that for the case of Cr trimers on Au(111) fourth-order spin-spin interactions play a crucial role. In order to find the ground-state spin-structure we solved the corresponding Landau-Lifshitz-Gilbert equations. Figure 3 shows two configurations with different (± 1) chirality that are degenerate in the absence of DM interactions. DM interactions, however, lift this degeneracy and state a) becomes the ground state. We confirmed this result in terms of ab-initio spin-dynamics simulations. We shall present new results on Cr trimers in equilateral and isosceles triangle as well as in linear chain geometries.

Spin-states with different chirality of a Cr trimer forming an equilateral triangle on Au(111) being degenerate in the absence of DM interactions. The DM interactions lift this degeneracy and state a) becomes the ground state.

Magneto-optic sensing using ultrathin ferromagnetic films.

E. Liskova, S. Visnovsky

Institute of Physics, Charles University, Prague, Czech Republic

Magneto-optic (MO) reflection in ultrathin ferromagnetic films can be enhanced by embedding the films into multilayer systems. The effect can be exploited in sensors of magnetic fluxes. The media sandwiching ferromagnetic film must be chosen in a way which ensures the system chemical stability and favorable magnetic properties in addition to its optimal optical performance. The growth of ultrathin ferromagnetic films the thickness of which is typically ten nm requires the use of substrate with extremely flat surface. Often additional buffer layers are deposited on the substrate to achieve good interface quality. For an *ex situ* use, high purity Fe, Ni, and Co, as well as ferromagnetic alloys require the protection against oxidation which is best provided by Au capping layers. With the restriction to the normal light incidence and the magnetization perpendicular to interfaces, the optical characteristics of the system may be expressed in terms of the Jones 2x2 matrix, $\begin{Bmatrix} r_{xx} & -r_{yx} \\ -r_{yx} & r_{xx} \end{Bmatrix}$. This relates the incident and reflected electric field x and y components of the monochromatic plane wave. The propagation vector of the wave and the magnetization are set parallel to the z axis. There is an approximate upper limit for $|r_{yx}|$, $|r_{yx}|_{\max} = |\kappa_{xy}/\text{Im}[2\kappa_{xx}]|$ where κ_{xx} and κ_{xy} are the diagonal and off-diagonal elements of the relative permittivity tensor in a ferromagnetic metal [1]. An optimal situation corresponds to a complete conversion of the incident x polarized wave to a MO reflected y polarized wave where $|r_{yx}|$ reaches its maximum value and $r_{xx} \rightarrow 0$. Any additional absorbing layers in the system reduce the value of $|r_{yx}|$. The optimum conditions are therefore approached by embedding the magnetic film into a Fabry-Perot like resonator made of dielectric layers. To avoid oxidation at inner interfaces of ferromagnetic films, oxygen free dielectrics, e.g., FeF_2 or AlN, are preferred. Nevertheless, these are also vulnerable to oxidation and may require capping with a noble metal (e.g., Au or Pt) layer. We are therefore led to study a layer sequence $\text{Au}(d^{(\text{Au})})/\text{AlN}(d^{(\text{AlN1})})/\text{Fe}(d^{(\text{Fe})})/\text{AlN}(d^{(\text{AlN2})})/\text{Au}$. Here $d^{(X)}$, $X=\text{Au1, AlN1, AlN2, Fe}$, denotes the thickness of a layer. Then, the thicknesses, $d^{(X)}$, represent the variables in the design of a sensor with optimum MO performance. The relevant material parameters correspond to the radiation wavelength of 632.8 nm: $\kappa^{(\text{Fe})}_{xx} = -0.8845 - 17.938j$ and $\kappa^{(\text{Fe})}_{xy} = -0.6676 - 0.08988j$ for Fe layer, $\kappa^{(\text{Au})} = -13.29 - 1.27j$ for Au and the AlN real index of refraction, $n^{(\text{AlN})} = 2$. Here, we focus on a single aspect of the sensor design. Figure 1 illustrates the effect of the Au capping on $|r_{yx}|$ and $|r_{xx}|$ as a function of $d^{(\text{Fe})}$ for $d^{(\text{Au})} = 0, 5$, and 9 nm. Despite the absorbing Au capping, there is a significant MO enhancement with respect to that on an air – Fe interface (marked by a dotted horizontal line) or in a Fe film on Au where AlN is absent. In the region of the $|r_{xx}|$ minimum, $\arg[r_{xx}]$ displays a steep change. The addition of the Au capping changes the conditions for the maximal $|r_{yx}|$ as well as those for the maximal amplitude of the ellipsometric parameter, $|r_{yx}/r_{xx}|$, and requires the readjustment of $d^{(\text{AlN1})}$, $d^{(\text{Fe})}$, and $d^{(\text{AlN2})}$. Figure 2 shows the Au capping effect on $|r_{yx}/r_{xx}|$ as a function of $d^{(\text{Fe})}$ for $d^{(\text{Au})} = 0, 5$, and 9 nm. Surprisingly, the thickest Au (9 nm) gives the strongest $|r_{yx}/r_{xx}|$. Fig1. Effect of Au capping on $|r_{yx}|$ in multilayers $\text{Au}(d^{(\text{Au})})/\text{AlN}/\text{Fe}(d^{(\text{Fe})})/\text{AlN}/\text{Au}$ for $d^{(\text{Au})} = 0, 5$ and 9 nm as a function of Fe layer thickness. The figure shows curves for $|r_{yx}|$ and $|r_{xx}|$ for structures (1) $\text{AlN}(58.9\text{nm})/\text{Fe}(d^{(\text{Fe})})/\text{AlN}(30.4\text{nm})/\text{Au}(\text{substrate})$ (2) $\text{Au}(5\text{nm})/\text{AlN}(62)/\text{Fe}(d^{(\text{Fe})})/\text{AlN}(24.7\text{nm})/\text{Au}(\text{substrate})$ (3) $\text{Au}(9\text{nm})/\text{AlN}(86\text{nm})/\text{Fe}(d^{(\text{Fe})})/\text{AlN}(154\text{nm})/\text{Au}(\text{substrate})$. Horizontal dotted line indicates $|r_{yx}| = 0.00641$ at vacuum/Fe interface and dashed line is showing $|r_{yx}|$ in structure vacuum/Fe($d^{(\text{Fe})}$)/Au.

Fig2. Effect of Au capping on $|r_{yx}/r_{xx}|$ in multilayers $\text{Au}(d^{(\text{Au})})/\text{AlN}/\text{Fe}/\text{AlN}/\text{Au}$ for $d^{(\text{Au})} = 0, 5$ and 9 nm as a function of Fe layer thickness. The composition of multilayers are the same as in Figure 1.

Nonuniform RKKY magnetism in nanosized films, wires and spheres.

E. Meilikhov, R. Farzetdinova
Kurchatov Institute, Moscow, Russian Federation

Indirect magnetic impurities' interaction of Ruderman-Kittel-Kasuya-Yosida (RKKY) type is considered as one of the basic mechanisms of the magnetic ordering in systems with free carriers of high concentration (e.g., degenerate semiconductors with magnetic impurities). Because every potentially interesting electronic device is characterized by nanosizes it is actual to consider how magnetic features of the relevant systems depend on their finite size [1,2]. The typical instances are thin films and wires of the thickness on the order of tens lattice constants a .

● Under considering the processes of ordering interacting magnetic moments in small systems one should take account of some new (as compared to "large" systems) circumstances associated with the surface and quantum-size effects. Firstly, with indirect interaction (of RKKY type) putting into effect with the aid of free charge carriers it is necessary to take into account the modification of the carrier energy spectrum connected with the system finiteness. Secondly, the non-uniformity of the effective field describing the spin interaction comes to be essential as those fields in the bulk and near the surface are differing. There are three parameters of the length dimension: the system size L by itself, the carrier de-Broglie wavelength $\lambda=2\pi/k_F$ defined by their concentration, and the characteristic interaction length l , coinciding, in the simplest case, with the carrier free path. Depending on the relation between those parameters, the following effects are possible and essential: (i) increasing the surface contribution - becomes apparent at $L<l$, (ii) the Fermi energy rise associated with the level quantization - appreciable at $L<\lambda$, (iii) shifting the lower boundary of the carrier wave number interval connected with the level quantization, as well, - comes to be essential at $L^2<l\lambda$.

● To obtain concrete results we use the mean-field theory extended over the case of the non-uniform effective magnetic field. The local effective field is defined by the relation $\mu H_{\text{RKKY}}(r)=n_\mu \int J(r-r')j(r')d^3r'$, where the integration is spread over the volume occupied by impurities, μ and n_μ are their moment and concentration, $J(r)$ is the energy of RKKY interaction between magnetic moments spaced at the distance r , and $0<j<1$ is the reduced magnetization in the point r' . Contrary to the infinite system, the value of that integral depends on the specific geometry of the system and the position of the considered point.

● The corresponding mean-field integral equation reads $j(h)=\tanh[(1/\tau)\int K(z,h)j(z) dz]$, where $\tau=kT/I_0$ is the reduced temperature (I_0 is the exchange energy), and the kernel $K(z,h)$ could be easily specified for films, wires and spheres. This nonlinear integral equation determines the spatial distribution of the magnetization in the system. To solve it we have used the method of successive approximations which turns to be rapidly convergent and stable.

● Calculations show that the magnetization of the considered objects is highly non-uniform. Results of calculating the spatial distribution $j(h)$ of the longitudinal magnetization in the wire of the diameter $2R=10a$ with the impurity concentration for which $4\pi n_\mu a^3=1$, and at the finite interaction length ($l=3a$) are represented in the Figure (insert, h is the distance from the wire axis): only the paraxial section of the wire has a significant magnetization, while its periphery is practically non-magnetic. Temperature dependencies of the average wire magnetization $\langle j \rangle$ at $l=3a$ and $l=\infty$ are also shown in the Figure. The distinguishing feature of the dependence corresponding to the finite interaction length is its negative curvature.

● In conclusion, we have considered the mean-field continual model of the RKKY magnetism of thin films, wires, and small spheres under the condition of their essential non-uniformity. We suc-

ceeded in discovering the spatial magnetization distribution described with the nonlinear integral equation using some iterative procedure of rapid convergence. At temperatures close to the Curie temperature, the mentioned integral equation comes to be linear, the Curie temperature by itself is determined as the eigenvalue of the equation kernel, and the magnetization distribution over the film thickness is close to the parabolic one. As for the wire, its magnetization profile is much more nonuniform if the interaction length is comparable with the wire radius, and at temperatures close to the Curie temperature that distribution is near Gaussian. Magnetic properties of the sphere are more like those for the film than for the wire. The dependence of the Curie temperature on the film thickness has been found, along with the temperature dependencies of the average film, wire, and sphere magnetization. Results could be used for describing properties of nanosized system based on the diluted magnetic semiconductors.

Spin Dynamics of Ge:Mn Thin Films.

O. Kazakova¹, R. Morgunov², M. Farle³, L. Ottaviano⁴

1. NPL, Teddington, United Kingdom; 2. IPCP, Chernogolovka, Russian Federation; 3. Universitat Duisburg-Essen, Duisburg, Germany; 4. Università dell'Aquila, Coppito L'Aquila, Italy

Modern electronics vastly relies on semiconductor heterostructures and rapidly develops towards high-speed digital circuits and use of diluted magnetic semiconductors (DMS) as a novel material solution¹. To satisfy growing industrial needs, DMS should have high Curie temperature and be compatible with conventional silicon technology². One of the most promising material solutions is to use germanium, which has higher electron mobility than silicon and, hence, is much more suitable for ultra-high-speed electronics. Magnetically doped germanium is also a particularly appealing candidate for spintronic applications.

We report a study of resonant and non-resonant microwave absorption in Ge thin films ($t = 120$ nm) implanted with manganese to a concentration of $x = 2-8$ at. %. The germanium matrix contains Mn_5Ge_3 ferromagnetic nanoclusters (Fig. 1 inset) and diluted Mn ions³. These two systems have considerably different Curie temperatures: T_{C1} (diluted Mn ions) ≈ 15 K, and $T_{C3}(\text{Mn}_5\text{Ge}_3) = 290-295$ K as revealed by SQUID magnetometry measurements. An additional transitional temperature, $T_{C2} = 60$ K, was found in Mn-implanted Ge samples and attributed to an additional type of clusters, for example, a fraction of amorphous GeMn precipitates, which become ferromagnetic below 60 K.

The electron spin resonant (ESR) spectra of Ge:Mn films exhibit a strong temperature dependence. Three main temperature intervals can be distinguished: low ($T = 4-60$ K), intermediate ($T = 60-220$ K) and high ($T = 220-300$ K) temperatures (Fig. 2). From the analysis of orientation and temperature dependencies of the resonances, we demonstrate that high-temperature resonant peaks correspond to the ESR in spatially separated ferromagnetic Mn_5Ge_3 clusters. On the other hand, low-temperature resonances can be interpreted as arising from spin wave excitations and obeying the dispersion law⁴, $H_{\text{res}} \approx n^{2/3}$ (Fig. 2 inset). The appearance of spin-wave resonances at low temperatures indicates the presence of a cooperative magnetic response originating from long range spin ordering in the whole system.

We show that a strong non-resonant background observed at intermediate and high temperatures has a magnetoresistive origin and contains two components: a positive classic Lorentzian magnetoresistance and negative one arising from the Zeeman splitting. The orientation dependences of both components are explained by a superposition of the isotropic part of the magnetoresistance due to Zeeman splitting of the charge carriers' states and its anisotropic part caused by dimensional limitations in the thin film. Following the approach developed in Ref. 5, we show that the field-dependent magnetoresistance has a minimum at some characteristic magnetic field, H_ϕ , where phase coherence of carriers is destroyed. This field is related to the phase relaxation length of charge carriers, L_ϕ , as $H_\phi = hc/8\pi e L_\phi^2$. Based on this, we calculate L_ϕ , which is varied in the range 70-350 nm as the temperature decreases from 300 to 4 K (Fig. 1). Since this length exceeds significantly the cluster size, all observed features of the magnetoresistance are 'cluster-independent' and can be attributed to charge carriers in the Ge matrix.

In overall, we demonstrate a very good correlation between the ESR and SQUID magnetometry results. Combination of these techniques allow us to elucidate a complex magnetic structure of the

Ge:Mn films, elucidate the different physical nature of resonances at high and low temperatures and distinguish contributions from several types of magnetically ordered clusters and diluted ions.

Magnetoelastic coupling in epitaxial monolayers: The role of lattice strain.

D. Sander, Z. Tian, J. Kirschner
Max Planck Institute, Halle, Germany

Magnetoelastic (ME) coupling has been identified as a decisive contribution to the magnetic anisotropy of strained films [1]. However, experimental results [1] and theoretical work [2] of recent years clearly indicate that bulk magnetoelastic coupling coefficients do not apply to strained epitaxial monolayers. Rather, lattice strain induces a change of the effective magnetoelastic coupling, which can affect both magnitude and sign of the corresponding magnetoelastic coupling coefficient. Thus, bulk magnetoelastic properties are not suitable for the description of the impact of lattice strain on the magnetic anisotropy, and experimental and theoretical data on magnetoelastic coupling are required.

We compile in this contributions our recent results on the non-bulklike magnetoelastic coupling of Fe, Ni, and Co monolayers on Ir(100). We apply the crystal curvature technique [1] to measure both film stress during film growth and magnetoelastic stress during a reorientation of film magnetization. Whereas the former stress amounts typically to some GPa in epitaxially strained films, the latter is three orders of magnitude smaller of order MPa. Nevertheless, the resulting minute curvature changes are reliably detected, and allow direct measurements of the effective magnetoelastic coupling coefficients in films as thin as five monolayers. The in situ combination of both measurements on lattice-misfit induced stress and magnetization-induced stress is exploited to investigate the correlation between film stress, lattice strain, and magnetoelastic coupling coefficients for a film thickness from monolayers up to 10 nm.

We demonstrate how stress measurements are analyzed in conjunction with in situ low energy electron diffraction experiments to derive lattice strain and to detect structural transition in the growing film. Thus, subsequent in situ measurements of the magnetoelastic coupling coefficients are reliably correlated with the respective film strain. The epitaxial films are under large stress of the order GPa due to the mismatch between film and substrate in the percent range. For bcc Fe on Ir(100) we find a compressive strain ranging from -4.9% for pseudomorphic growth (2–10 layers), which relaxes to -2.4% at higher film thickness. Ni and Co grow as fcc films under tensile strain on Ir(100). We measure the difference of magnetoelastic stress along different crystalline axes by switching the external magnetic field along the length and width of the sample. ME coupling coefficients B1 and B2 are obtained according to the geometry of the sample and the magnetic field orientation.

Our results indicate that the ME coupling coefficients B1 and B2 of Fe, Co and Ni deviate from the bulk value. We show that lattice strain is an important factor which drives the deviation of the magnetoelastic coupling coefficients from the respective bulk values. The experimental results can be fitted with an effective strain-dependent ME coupling coefficient B_{eff} with $B_{eff} = B_i + D_{eff}$. Our analysis shows that the nonlinear coefficient D_{eff} is much larger than the first order coupling term B_i . We obtain for Fe: $B_1 = -3.6$ MJ/m³ and $D_{eff} = 155$ MJ/m³ (bcc Fe: B_1 bulk: -3.4 MJ/m³), for Co: $B_1 = 3.5$ MJ/m³ and $D_{eff} = -842$ MJ/m³ (fcc Co: B_1 bulk: -9.2 MJ/m³), and for Ni: $B_1 = 1.3$ MJ/m³ and $D_{eff} = 273$ MJ/m³ (fcc Ni: B_1 bulk: 9.4 MJ/m³). These results indicate that already a strain in the sub-percent range changes the ME coupling significantly [2].

The magnetic anisotropy of Fe, Co and Ni films on Ir(100) is well described by our experimental values of the ME coupling coefficients in calculating the ME anisotropy. We find an easy in-plane magnetization direction for Fe and Co. For Ni films on Ir(100) the easy axis is out-of-plane from 7 ML to 15 ML. With increasing film thickness a spin reorientation transition (SRT) is observed

around 16 ML, and the easy axis turns back to in-plane. The thickness of 16 ML where this SRT is observed is well reproduced by our data on the strain dependence of B1 of Ni. The bulk value of B1 would favor a SRT back to in-plane at a much higher thickness in excess of 60 ML, in contrast to the experimental result.

The control of the magnetic anisotropy in thin films is a topic of both applied and basic research. In particular it is of interest to achieve materials with perpendicular magnetic anisotropy. The anisotropy energy responsible for this effect arises from a delicate balance between competing effects, and it is influenced by the strain in the film, as well as the substrate and capping overlayer material. Although usually there is a single transition from perpendicular orientation to an in-plane magnetic easy axis as the magnetic film thickness is increased, the presence of successive easy-axis reorientation transitions in thin films have also been observed. In this case, the easy-axis is in-plane up to a critical thickness, then it turns to an perpendicular orientation, and back again to an in-plane orientation at a larger thickness, due to a complex interplay of magnetism and strain. It is uncommon to find magnetic materials where the easy axis changes orientation abruptly at consecutive atomic layers. Two systems which present consecutive spin-reorientation transitions at consecutive atomic layer thicknesses are Fe/W(110)[1] and Co/Ru(0001)[2]. In both systems the double spin reorientation transition takes place in films (or islands) one, two, and three atomic layers thick.

One crucial element to understand the behavior of such thin films is to have available a local determination of the magnetic properties as well as a simultaneous local characterization of the structure. The effect of roughness can be reduced or eliminated altogether if microscopic techniques allow to study the film on a single terrace or island. One technique that allows this level of detail in specific systems is spin-polarized low energy electron microscopy. The use of a source of spin-polarized electrons allows the determination of the 3-dimensional sample magnetization on a nm scale, even during the growth of the films themselves. Such a technique together with the growth of Co films in large substrate terraces in a perfect layer-by-layer mode for up to 10 monolayers[2] has been used successfully to understand the Co/Ru system[3].

Given that ultra-thin films of transition magnetic metals oxidize readily in air, capping the films with non-magnetic material such as gold or copper has become standard practice for measuring the magnetic properties ex-situ. This raises the issue of the possible effect of the capping layer on the magnetic properties of the magnetic film. Specially, capping layers have been observed to influence the magnetic anisotropy. Interface effects, a broad term that includes from the modification of the electronic structure of the magnetic material in direct contact with the capping layer to changes in the strain of the magnetic film, have been frequently detected. In particular it has been reported that the deposition of copper on cobalt films on W(110) produces an increase in the perpendicular magnetic anisotropy at around one monolayer [4]. But no consecutive complete reorientations of the magnetization, such as observed as a function of the thickness of the magnetic film itself [2] have been reported, to the best of our knowledge.

We report on SPLEEM observations of the easy-axis of magnetization of Co thin films on Ru(0001) during the growth of capping overlayers of coinage metals (Cu, Ag, Au), together with local area diffraction of selected combinations of materials. The different coinage metals present extremes in terms of lattice mismatch with the Co film, from a nearly lattice match for Cu/Co to a large mismatch that is accommodated by dislocations in Ag and Au/Co. For most of the capping layer and magnetic film thicknesses, there is no change in the easy-axis of the magnetization of the

Co film although the Curie temperature may change. But for selected combinations of overlayer and magnetic film (1-2 ML Cu/ 3,4 ML Co/Ru, 1-2 ML Ag/ 3 ML Co/Ru, 1-3 ML Au/5,6 ML Co/Ru) we observe consecutive spin reorientation transitions by changing the capping -non-magnetic metal- overlayer thickness (from an in-plane easy-axis in bare films to perpendicular easy axis upon capping the film with a monoatomic capping layer, and to an in-plane orientation again for additional capping layers).

Magnetic Properties of Single-Crystalline FeRh Alloy Thin Films.

S. Inoue, Y. Y. Hnin, N. T. Nguyen, T. Suzuki

Information Storage Materials Laboratory, Toyota Technological Institute, Nagoya, Japan

Introduction

Thin films and nano-particles[1] of FeRh have drawn much attention from a basic point of view and also for possible applications, such as a HAMR. The CsCl type FeRh (bulk) exhibits the first-order magnetic phase transition.[2-3] However, the magnetic phase transition mechanism in films is quite complicated and is not well understood. In the present work, the effect of external magnetic field on AF-FM transition process in single crystalline Fe₁₀₀-XRhX ($26 \leq X \leq 56$) films has been systematically investigated.

Experimental

Thin films of Fe₁₀₀-XRhX were fabricated onto MgO(100) substrates by an electron beam co-evaporation. The substrates were kept at around 400deg. during deposition. As-deposited films were annealed at 700deg. for 4 hrs. Measurements of magnetic properties were carried out using a VSM. Magneto-optical properties were examined by a polar magneto-optical Kerr effect system

Results and Discussions

Figure 1 shows X-ray diffraction spectra ($\theta/2\theta$ and ϕ) at $26 \leq X \leq 63$. All the films are grown with FeRh(100) planes parallel to the substrate, and furthermore the ϕ -scan patterns confirms that the films exhibit the four-fold symmetry in the film-plane, indicating that the films are single crystalline films of the CsCl-structure. Figure 2 shows the temperature dependence of magnetization for different compositions. For $26 \leq X \leq 45$ and $X=63$, the films do not undergo any transformation, behaving as ferromagnetic. However for $51 \leq X \leq 60$, the films exhibit the AF-FM phase transition. A magnetic phase diagram for the films and bulk is shown in Fig.3 (a). It is found that the transition temperatures for films are higher than that of bulk, and the range for composition of which film exhibits the transition is expanded. Figure 3 (b) shows the composition dependence of total entropy change ΔS at the transition, together with the ones for bulk reported by Kouvel et al.[3] It is of great interest to note that ΔS decreases with increasing X. And it is found that $\Delta S=13.7$ mJ/(deg g) in heating process and $\Delta S=14.3$ mJ/(deg g) in cooling process at $X=51$, respectively, which are in reasonable agreement with the bulk value, $\Delta S=14.0$ mJ/(deg g).[3] Magneto-optical polar Kerr spectra of the films under consideration are shown in Fig.4. The polar Kerr rotation for the AFM is nearly zero for the entire photon energy. However, upon the appearance of the FM phase, the polar Kerr effect becomes enhanced, showing a broad maximum at around 4 eV. The result of the polar Kerr effect upon heating and cooling is consistent with that for the magnetization behavior of the films.

Controlling the microstructure in Ni-Mn-Ga alloys.

M. Pötschke, F. Thoss, U. Gaitzsch, C. Hürlich, S. Roth, B. Rellinghaus, L. Schultz
Institute for Metallic Materials, IFW Dresden, Dresden, Germany

Magnetic shape memory alloys show large strain when subjected to an applied magnetic field. This is due to the motion of twin boundaries in the martensitic phase. The effect was discovered in 1996 by Ullakko et al. [1]. Single crystalline samples of the off-stoichiometric Ni_2MnGa composition have recently been shown to produce strains of up to 10% [2]. Most of the investigations of magnetic field induced strain via twin boundary motion (MFIS) have been performed on single crystals, which show the largest MFIS effect.

However, the preparation of single crystals is a time and cost consuming process and there can be compositional changes along the axis of the crystal and segregations [3]. That is why from a technological point of view, polycrystals are of great interest. They are easier to produce. Unfortunately they usually exhibit lower strains because of the different orientations of the separate crystals and the presence of grain boundaries, which act as pinning centers and impede the twin boundary motion. A possible approach to improve the polycrystalline material is to have a coarse-grained and highly textured sample, because then it is nearest to a single crystal.

The attempt to achieve texture in polycrystalline Ni-Mn-Ga is by free directional solidification. The principle of the experimental set up is displayed in Fig. 1 (left). A hot mold is mounted on a cooling plate. To avoid heating of the cooling plate by the hot mold, an insulation ring is placed between the mold and the plate. When the melt is cast into the mold, a temperature gradient and thereby a heat flow through the melt towards the bottom is generated, which causes a directional solidification in opposite direction.

The texture of the sample was analyzed using EBSD. Fig. 1 (right) shows a typical EBSD-picture of one of the samples with an area of elongated grains at the bottom of the sample. The [100] direction seems to grow preferred in the direction of heat flow. In order to study the effect of various preparation conditions on the texture development, we have chosen the composition $\text{Ni}_{48}\text{Mn}_{30}\text{Ga}_{22}$, which is austenitic at room temperature and therefore easy to investigate via EBSD. For magneto-mechanical measurements we chose the compositions $\text{Ni}_{50}\text{Mn}_{30}\text{Ga}_{20}$ and $\text{Ni}_{50}\text{Mn}_{29}\text{Ga}_{21}$, which are martensitic (7M and 5M [4]) at room-temperature and therefore suitable for applications.

The casting process was performed in an Indurett S investment cast machine. The as-cast samples were subjected to a thermal annealing at 1000°C for 48 h in an Ar / 5 % H_2 atmosphere. Variations in composition were ruled out by measuring the Austenite-Martensite transformation temperatures with a Perkin Elmer DSC. Since the transformation temperature depends strongly on the composition (50 K/ at. %) [5], variations of composition of less than 0.1 at. % can be resolved. All cuts of the samples were made electro-erosively to avoid mechanical impact and structural changes [6]. For visualization of the microstructure metallography by means of optical microscopy was used.

The mold temperature has a strong influence on the as-cast microstructure. The length of the zone of elongated grains depends on the casting parameters, especially the mold temperature. With increasing mold temperature the area of elongated grains grows. To increase the textured length an additional heater, which is wound around the hot mould, is used.

To study composition variations along the axis of the ingot samples were taken from different parts within the annealed ingot and DSC curves measured for these samples. DSC reveals chemical homogeneity along the sample of better than 0.1 at. %.

The annealing step (48 h, 1000°C, Ar/ H_2 atmosphere) causes a coarsening of grains, homogenization, stress relaxation, possible ordering during cooling and affects the texture. By cutting off

the bottom grains of the sample the orientation of the as-cast state can be retained also after annealing.

The influence of different annealing parameters and a mechanical load on the texture development during annealing is investigated.

The superelastic behavior of textured austenitic samples with the composition $\text{Ni}_{48}\text{Mn}_{30}\text{Ga}_{22}$ is studied and compared to randomly oriented samples and theoretical values.

After a thermal treatment to adjust the right crystal structure and a mechanical training to decrease the stress, which is necessary for twin boundary motion, textured samples showed a magnetic field induced strain of 1%.

1. Electromagnetics, INRiM, Torino, Italy; 2. Physics, Politecnico di Torino, Turin, Italy

Magnetic materials presenting field induced first-order structural phase transitions are attracting considerable interest due to their magnetocaloric, magnetoelastic or magnetoresistive properties [1-6]. In these systems temperature, stress and magnetic field can drive the transition and influence its hysteretic properties: a proper control of external parameters is then fundamental in the development of novel applications taking advantage of the multifunctional behavior of these materials.

In the present case we have investigated the combined effects of temperature-mechanical stress and magnetic field-mechanical stress on the martensitic phase transition occurring in the Heusler alloy with composition $\text{Ni}_{55}\text{Mn}_{20}\text{Ga}_{25}$. This composition presents a sharp first-order magneto-structural phase transition from a ferromagnetic-martensite phase to paramagnetic-austenite [7].

During heating the martensite-to-austenite (M-A) phase transition occurs in the temperature range $A_s = 306 \text{ K} \leq T \leq A_f = 320 \text{ K}$ whereas the inverse transition (A-M) occurs in the temperature range $M_f = 294 \text{ K} \leq T \leq M_s = 305 \text{ K}$. At high temperature, $T > A_p$, the austenite presents a cubic symmetry lattice whereas the full symmetry is reduced in the martensite phase which presents a tetragonal unit cell with a 'c' axis contracted by 6% [8,9].

The purely mechanical characteristics were studied performing stress-strain measurements on an oriented single crystal with {100} faces at different temperatures. (See fig.1) At temperatures above $A_f = 320 \text{ K}$ superelastic curves can be observed with large reversible strain. At temperatures around 315 K, a stress of the order of 32 MPa can induce the A-M phase transition. Decreasing the test temperature closer to $M_s = 305 \text{ K}$ we observe a decreasing of the stress necessary to activate the martensite growth. This reduction of the yielding stress is associated to a change of the A-M transition temperature under a compressive load. We observe that the M_s temperature is linearly reduced with a slope $dM_s/d\sigma \approx -0.34 \text{ K MPa}^{-1}$. On the other hand, at temperatures below $M_f = 294 \text{ K}$ stress strain-curves become superplastic, and a permanent 6% strain is retained after stress is released.

The effects of magnetic field and stress on the A-M phase transition were investigated using an electromagnet with one movable pole embedded in a two columns dynamometer. The movable pole was attached to the dynamometer crossbar and used to apply both a unidirectional compressive stress and a magnetic field up to 360 kA/m. In fig. 2, the stress-strain curves under applied field are presented. The applied field collaborates with the mechanical compressive stress promoting the growth of the martensite (the ferromagnetic phase) and hence we observe a general reduction of the yielding stress. When the material is already in the martensite phase the applied field has a smaller impact on the stress-strain curves whereas, at temperatures in the interval $M_f \leq T \leq M_s$, we have that the reversibility of the stress induced phase transition at zero field (superelastic behavior) is even cancelled, upon stress releasing, by the martensite stabilization due to the field. The reduction of the yielding stress at $T = 316 \text{ K}$ allows to estimate that the magnetic field is equivalent to a corresponding stress of almost 10 MPa/T.

Stress-strain curves performed at different temperatures show either the 'superelastic' or the 'superplastic' behavior as temperature is decreased. Above M_s , the stress plateau after the yielding stress represents the stress induced A-M phase transition.

'Superelastic' and 'superplastic' curves measured under different applied magnetic fields.

Effect of annealing conditions on the structure formation in NiMnGa shape memory alloys.

R. Wroblewski, M. Leonowicz

Faculty of Materials Science and Engineering, Warsaw University of Technology, Warsaw, Poland

Ferromagnetic shape memory alloys (FSMA) attract substantial scientific and technological attention due to a giant magnetic-field-induced strain (up to 10%) arising from rearrangement of martensitic variants. This effect was first reported for the Ni_2MnGa Heusler alloys [1]. The NiMnGa alloys undergo a martensitic transformation from parent, cubic $L2_1$ phase to martensite phase. The martensite phase may have different modulated or non-modulated structures, depending on the composition, represented by the electronic concentration (e/a) [2] and atomic order.

In this work we studied the effect of annealing temperature, chosen respectively below and above the ordering temperature, on the structure and transition temperatures for the $\text{Ni}_{50}\text{Mn}_{29}\text{Ga}_{21}$ polycrystalline alloy.

The alloy was induction melted and cast into an alumina die. Afterwards the alloy was homogenized at 1173 K for 72 hours and cooled with a furnace. The 25 mm diameter ingot was cut into 3 mm thick slices which were annealed at 873 K and 1073 K for 12 hours and subsequently either cooled slowly with a furnace or quenched in ice water. The X-ray diffraction analysis on bulk samples was done using Philips PW 1830 diffractometer, Cu $K\alpha$ radiation. Magnetic measurements were done using LakeShore 7410 Vibrating Sample Magnetometer equipped with a cryostat.

The transformation temperatures, A_s (martensite-to-austenite transformation start temperature), A_f (martensite-to-austenite transformation finish temperature) and T_c Curie temperature, for the specimens annealed at various conditions are shown in Table 1 and Figure 1. One can conclude from these data that the A_s temperature, 330 K, for the homogenized and for the annealed specimens is independent on the annealing and cooling conditions. However, different magnetization values, A_f and T_c temperatures suggest differences in the magnetic anisotropy and structure of the specimens having various thermal history. Especially changes of the magnetization in the austenitic region, upon heating, for the specimen quenched from 1073 K, evidence structural inhomogeneities. The magnetization in the austenite region grows from 340 K up to 365 K. This suggests continuous evolution of the parent phase structure. These suggestions were confirmed by X-ray phase analysis (XRD), shown in Fig. 2. It is evident from this data that the homogenized specimen has a structure of non-modulated (NM) martensite. Both the specimens, slowly cooled and quenched from 873 K, exhibit broadly the same structure, characteristic of 5M modulated martensite. However, substantial differences are shown for the specimens slowly cooled and quenched from 1073 K, respectively. For the former 7M modulated martensitic structure was obtained, whereas for the later multiphase structure, showing reflections characteristic of both 5M and $L2_1$ phases is evident. It is clear from these studies that the order-disorder transformation in the austenite plays an important role in the formation of martensitic structure. Annealing at 873 K, irrespective of cooling rate, does not make any special change to the microstructure. However, quenching from 1073 K partially “freezes” the disordered B2 phase and consequently, at room temperature, a mixture of martensite and the parent phase is present. When slow cooling from 1073 K is applied the diffusion in the austenite enables ordering of Ga and Mn atoms and in consequence full transition from the B2 to $L2_1$ phase and formation of the martensitic phase. It is not clear in this stage why upon slow cooling from 1073 K the 7M modulated martensitic structure, very convenient for practical application, was formed.

Magnetic-field induced strain in 5M polycrystalline alloy.

U. Gaitzsch, C. Huerrich, M. Pötschke, S. Roth, L. Schultz
Inst metal mater, IFW Dresden, Dresden, Germany

Magnetic shape memory alloys show a unique coupling of magnetic and mechanical properties [Han00]. If twin boundaries move in the martensite phase, both the magnetisation and the shape changes. Therefore the magnetisation can be changed by application of an external stress (sensor mode) and the shape can be changed by an external magnetic field (actuation mode). If a sample shall be driven in the actuation mode, the twinning stress has to be smaller than the stress which is originated by an external magnetic field. The latter is defined by the crystal structure of the martensite phase. For the 5M structure the maximum stress is 2.6 MPa. This stress is reached in ideally oriented samples at the anisotropy field. If the external magnetic field exceeds the anisotropy field, the stress acting on a twin boundary stays constant. In contrast to that the twinning stress is a defect controlled property which is controlled by the microstructure of the martensite phase and can vary from sample to sample.

In single crystals, magnetic field induced strain of maximum 6 % can be seen in the 5M structure [Soz01]. The objective of this work is to achieve magnetic field induced strain in polycrystals. Investment casting is used in order to obtain directional solidification, which results in a [100] fiber texture [Poe07]. Once the samples are cast they have to be annealed for homogenization (1000 °C, 48 h) and stress relaxation (600 °C, 14 h) [Gai07a]. From these ingots cubic samples are cut for thermo-mechanical training. The first training step is cooling under load, which shall cause a variant selection during the martensitic transformation. However, by cooling under load the phase transformation is accompanied by a small strain only. Therefore additional compression cycles have to be performed to decrease the twinning stress and to increase the strain. These compression cycles have to be done along all three axis of the samples to activate all possible twinning systems, as it has been shown for 7M samples [Gai07b]. In contrast to that, a two axes compression can be applied, if the sample is properly oriented and trained before to decrease the twinning stress further. But, if the misorientation of the twin system is too large, a two axes compression will only lead to an accumulation of strain in the third, not compressed axis. Additionally the applied stresses must not be too large in the training process in order to avoid crack initiation or even brittle fracture in the samples. During the mechanical training the twin microstructure adopts to the deformation by simplification of the variant hierarchy and proper alignment of the twin boundaries. However, the exact mechanism is still under investigation. Therefore magnetic measurements are used as well as in-situ deformation in an SEM. Due to orientation contrast, twin variants can be observed in the BSE mode. Additionally, magnetic domains can be imaged by SEM [Ge07].

In a well-trained polycrystalline sample the magnetic field induced strain has been measured by relaxation in an external magnetic field after compression. This was done as well as the training experiments in an Instron mechanical testing machine, which is equipped with an home-made electromagnet. The whole setup can be operated in a temperature range of -25 °C to 100 °C. By changing the temperature the twinning stress can be lowered, which causes an increase of magnetic field induced strain to 1.5 %. But this strain has to be corrected for viscoelastic strain, which is caused by relaxation of the previously compressed sample. Therefore only 1.0 % can be related to the applied magnetic field. In fig.1 the relaxation curves with and without field are displayed.

1. Institute for Metallic Materials, IFW Dresden, Dresden, Germany; 2. Laboratory of Materials Science, Helsinki University of Technology, Helsinki, Finland

Magnetic shape memory effect (MSME) is due to the redistribution of martensite twin variants in the magnetic field resulting in microstructure reorientation and giant strain [1]. The redistribution is driven by the difference of magnetic energy in differently oriented martensite variants. According to the simple model [1-3] the MSME occurs, when the difference of magnetic energy ΔE_{mag} exceeds elastic energy needed for twin boundary motion.

$$\Delta E_{\text{mag}} \geq \sigma_{\text{tw}} \varepsilon_0 \quad (1)$$

where σ_{tw} is twinning stress, and $\varepsilon_0 = 1 - c/a$ is tetragonal distortion of the lattice. The twinning stress describes the mobility of the martensitic twin boundaries. The magnitude of the twinning stress depends on the structure and the character of the obstacles in the material about which is known very little. Experimentally $\sigma_{\text{tw}}(\varepsilon)$, where ε is macroscopic strain, can be obtained from the stress-strain curve, i.e. from mechanical testing. This simple model describes reasonably well the observed MSM behavior in a single crystal with $\langle 100 \rangle$ orientation, i.e. in the orientation when magnetic field (or stress) is oriented along the a-axis of the crystal. In tetragonal 5M martensite, this axis is hard magnetic axis. In magnetic saturation in $\langle 100 \rangle$ orientation the difference of magnetic energy equals to $K_u \geq \sigma_{\text{tw}} \varepsilon_0$, where K_u is the magnetic anisotropy constant of tetragonal martensite. This value sets the largest difference and for other crystal orientations in the field the difference is smaller and thus it is expected that the MSME occurs in higher field. Although it is intuitively clear that the effect depends on crystal orientation in the magnetic field, the angular dependence of the MSM effect has not been studied rigorously. Here we calculate the difference of magnetic energy as a function of the angle between magnetic field and crystal axis and compare it with the experiment. The angular dependence is important for an application e.g. for the estimation of MSM effect in randomly oriented polycrystal.

The experiment was performed on single crystal close to stoichiometric Ni_2MnGa with Mn excess having 5M martensitic structure and exhibiting MSME at room temperature. The martensite-to-austenite transformation temperatures was 314 K. The MSME was evaluated from the magnetization curves measured in different angles to $\langle 100 \rangle$ crystal axis. The sharp magnetization change in the magnetization curve (Fig. 1) is a sign of the structural reorientation or MSME.

The model calculation was performed for idealized two variants microstructure assuming that the variants behave independently in the field, i.e. any mutual interaction is neglected. Additionally ideal uniaxial anisotropy behavior is assumed for each variant. Fig. 2 shows calculated difference as a function of the angle between magnetic field and $\langle 100 \rangle$ axis.

The angular dependence of MSME is measured and observed behavior is compared with the prediction made from equation (1). However the prediction cannot be very precise as the angular dependence of the twinning stress is not yet known.

Ferromagnetic shape memory alloys (FSMA) are characterized by the occurrence of large magnetic-field-induced strains as a result of the re-orientation of martensitic variants under applied magnetic field [1]. In particular, large magnetic field induced strains of around 10 % has been observed in Ni₂MnGa single crystals [2]. However, the analysis of production methods to obtain FSMA alloys to be applied as MicroElectroMechanical Systems (MEMS) elements constitutes one of the most interesting topics regarding the application of these new magnetostrictive alloys.

In this work, the magnetic properties of Ni-Mn-Ga FSMA in wire form is reported. Wires, with nominal composition Ni_{2.10}Mn_{0.98}Ga_{0.92} and mean diameter 170 μm , were obtained by the rotating water bath melt spinning technique. Pieces of wire were annealed under vacuum at 400°C, 600°C and 800°C during 15 min.

The Scanning Electron Microscopy images show (see fig.1) that the as-cast wire displays a typical dendrite-like (cellular) structure of rapidly solidified alloys. The martensitic transformation, monitored through Differential Scanning Calorimetry, is mainly determined by the compositional heterogeneity associated to such cellular structures. The main effect of the low temperature annealings (annealing temperatures, $T_a \leq 600^\circ\text{C}$) is to shift the broad martensitic transformation towards higher measuring temperatures as a consequence of the increase in the atomic order (i.e. atomic rearrangements associated to the annihilation of quenched-in vacancies and relaxation of quenched-in stresses). Once that the cellular structure disappears through thermal treatments leading to the recrystallization of the sample ($T_a = 800^\circ\text{C}$), the martensitic transformation does not significantly differ from the transformation in the bulk sample.

With respect to the magnetic behavior of the alloy, a SQUID magnetometer was employed in the magnetic characterization of the samples. A remarkable decrease in the saturation magnetization is detected in the as-cast sample and correlated to the Mn-Mn antiferromagnetic interactions associated to structural defects (mainly antiphase boundaries, APBs). The recovery effect (mainly elimination of APBs) for low temperature annealings ($T_a \leq 600^\circ\text{C}$), leads to an increase in the mean magnetization of the sample (see fig. 2), reaching similar values than those reported for the tetragonal phase (saturation value, $M_s \approx 81 \text{ emu/g}$). The results indicate that a high temperature annealing (i.e. recrystallization of the sample) is required to optimise both the martensitic transformation and the magnetic characteristics of these rapidly quenched NiMnGa wires.

Comparative study of structural and magnetic properties of bulk and powder Ni₅₂Fe₁₇Ga₂₇Co₄ magnetic shape memory alloy.

J. Liu, N. Scheerbaum, D. Hinz, O. Gutfleisch
Institute for Metallic Materials, IFW Dresden, Dresden, Germany

Magnetic shape memory (MSM) alloys have attracted considerable attention within the last decade, owing to their capability to produce large magnetic-field-induced strain [1]. Ni-Fe-Ga-Co has been proposed as a new MSM system due to its wide martensitic and magnetic transformation temperature range [2]. We have shown recently that the martensitic transformation temperature T_m and the Curie temperature T_c can be tailored in a wide range by changing composition and heat treatment, $T_m \sim 170$ to 370 K and $T_c \sim 280$ to 400 K [3]. In particular, the alloy composition Ni₅₂Fe₁₇Ga₂₇Co₄ is more interesting for practical application due to its relatively high martensitic and magnetic transformation temperature ($T_m = 363$ K, $T_c = 360$ K).

Here, martensitic transformation, phase structure and magnetic properties of Ni₅₂Fe₁₇Ga₂₇Co₄ alloys in form of bulk and powder were studied. Bulk samples were prepared by arc-melting followed by annealing at 1473 K for 4 h, while powder samples were made from the bulk by filing and annealing at 673 K for different times ($0 \sim 15$ h). The martensitic transformation temperatures were determined using a differential scanning calorimeter (DSC, Perkin Elmer Pyris 1). The crystal structures were determined by X-ray diffraction at room temperature (XRD, Philip X'Pert, cobalt $K\alpha$ radiation). Magnetic properties were analyzed using a high-temperature a.c. susceptometer (6 kHz), a SQUID magnetometer (Quantum Design MPMS-5S) and a vibrating sample magnetometer (VSM).

The peaks related to the martensitic transformation of the bulk sample, which are detected by DSC (Fig. 1), totally disappeared after powderisation. The Curie temperature of the powder sample is about 100 K lower than that of the bulk one (Fig. 2). The temperature hysteresis of magnetisation for the bulk sample is ascribed to a coupling of martensitic and magnetic transformations. Additionally, the saturation magnetisation ($M_{sat} = 54$ emu/g) of the bulk sample is reduced significantly down to 35 emu/g by powderization, but increased again with increasing annealing time (Fig. 3). After the powders were annealed for 15 h, the M_{sat} is up to 64 emu/g. This value is even above that of the bulk sample. However, after annealing, the martensitic transformation of the powder samples is still absent in both DSC and SQUID measurements. From XRD patterns (Fig. 4), it is found that the bct martensite in the bulk sample is completely transformed to a disordered fcc phase by filing, and then gradually changed into a bcc austenite phase during the subsequent annealing. The change of magnetic properties, e.g. T_c and M_{sat} , of powdered samples is discussed in relation to the structural evolution.

Near room-temperature magnetic refrigeration based on the magnetocaloric effect (MCE) is becoming a promising technology to replace the conventional gas-compression/expansion technique. Recently, several materials with a so-called giant MCE have been discovered, such as $\text{Gd}_5\text{Si}_2\text{Ge}_2$, $\text{MnAs}_{1-x}\text{Sb}_x$, $(\text{Mn,Fe})_2(\text{P,As})$ - and $\text{La}(\text{Fe,Si})_{13}$ -type [1]. A first-order magnetic phase transition is common for all these materials that gives rise to an abrupt change of the magnetisation near the transition point. The large MCE in Ni-Mn-based Heusler compounds with compositions close to the stoichiometric Ni_2MnX ($X = \text{Ga, Sn, In, Sb}$) follows from a coupling between the martensitic transition and the magnetic order [2]. The magnetic properties of these alloys are sensitive to the distance between neighbouring Mn atoms and various types of magnetic behaviour are observed for various X elements [3,4].

In this work, we report the effect of hydrostatic pressure on the martensitic transformation and MCE in $\text{Ni}_{50}\text{Mn}_{34}\text{In}_{16}$ and $\text{Ni}_{49.5}\text{Mn}_{35.5}\text{In}_{15}$ alloys prepared by arc melting and subsequent heat treatment at 1073 K/2 h.

According to the Rietveld refinement of x-ray data (Cu $K\alpha$ radiation, temperature range 40 - 350 K, ambient pressure), the high temperature austenite phase has the cubic L2_1 structure. The transformation to the martensite starts at about 240 K. At low temperatures, the modulated martensite structure is observed, presumably of 14M-type.

Figure 1 shows the temperature dependence of the magnetisation at a low magnetic field at selected applied pressures for $\text{Ni}_{50}\text{Mn}_{34}\text{In}_{16}$. The measurements have been performed using a SQUID magnetometer in a zero-field-cooled (ZFC), field-cooled (FC), and field-heated (FH) sequence. On cooling, the cubic L2_1 phase orders ferromagnetically at $T_c \approx 310$ K which causes a sharp increase of the magnetisation. At a lower temperature M_s , the sample transforms to the martensitic phase, and there is a sharp drop of the magnetisation. Upon further cooling the Curie temperature of the martensite is reached and the magnetisation rises again. The hysteresis in the FC and FH curves is a consequence of the first order character of the martensitic transition, while the splitting between the ZFC and FH curves is apparently associated with the presence of low temperature anisotropy. Whereas the magnetisation of the austenite and martensite phases is essentially unchanged on applying the pressure, all the characteristic temperatures associated with the martensitic transition shift to higher values as the pressure is increased (Fig. 1). The shift is also consistent with differential thermal analysis measurements under pressure [5]. It is observed that the transition temperature shift dT/dp varies with In concentration.

The magnetic entropy change ΔS_M has been calculated from the magnetisation versus field curves using the Maxwell relation [1]. Figure 2 shows ΔS_M for a field change of $\Delta H = (0 - 2)$ T for $\text{Ni}_{50}\text{Mn}_{34}\text{In}_{16}$. The sign of ΔS_M is positive in the temperature range near the martensitic transition, whereas negative ΔS_M values are observed near the Curie temperature of the austenite. As pressure increases, the positive $\Delta S_M(T)$ peak shifts to higher temperatures and the maximum entropy change

ΔS_{max} increases from 225 to 265 kJ/m^3 . However, the relative cooling power (RCP), integrated area under the $\Delta S_M(T)$ peak, remains essentially unchanged and is equal to 1.0(1) MJ/m^3 . The analysis of the influence of pressure and magnetic field on the MCE and martensite transformation in the Ni-Mn-In alloys will be discussed in detail.

Magnetic domain reorganization and twin boundary dynamics in magnetic shape memory alloys.

J. McCord

Institute for Metallic Materials, IFW Dresden, Dresden, Germany

Magnetic shape memory alloys (MSMAs) attract considerable research focus due to the exhibited magnetic field induced strain (MFIS, up to 10% for NiMnGa) for potential applications in e.g. actuators. Under an external magnetic field, the twin variants with the easy axis parallel to the field grow by twin boundary motion. Investigating the performance during (fast) reorientation process provides vital information for the optimization of the properties for future devices. Using a unique dynamic actuation experimental set-up, the congruent magnetic field induced reorientation of crystallographic and magnetic domains could be imaged directly for the first time up to frequencies approaching the dynamic limit of MSMAs.

From static magnetic surface domain imaging, using a magneto-optical indicator film technique (MOIF), a clear picture of the volume domains of NiMnGa MSMA single crystals is derived. One example of domain images obtained separately from four different surfaces of the same crystal in the same state of magnetization is displayed in Fig. 1. With the occurrence of a twin boundary, also a hidden surface inside the bulk material has to be considered. Starting from this analysis, it is demonstrated that a reorganization of the magnetic domains is not required for the occurrence of twin boundary motion (Fig. 2). With the abrupt nucleation of the second variant sections of magnetically highly charged head-on domain structures at the twin boundaries are formed. The absence of interaction between magnetic and structural domains is different from currently proposed models, which assume domain wall movement under an external field.

Based on these results, the actuation performance of different MSMAs single crystals at various frequencies is presented. Reversible twin boundary motion activated in the frequency range up to 600 Hz is observed (Fig. 3). Strain hysteresis curves measured at different frequencies show similar onset of fields of strain. An average twin boundary mobility up to $2 \cdot 10^5 \mu\text{m/s}$ is found. The maximum field-induced strain increases with actuation frequency. Twin boundary mobility enhancement by fast twin boundary motion is proposed to explain the increase in MFIS.

Additional experimental data from temperature dependent measurements, from other MSMA bulk materials, and from thin films will be presented for comparison. The results provide significant information of twin boundary performance during static and high frequency actuation, and give important guidance to the refinement of already existing models of twin boundary motion.

Funding through the DFG Priority Program SPP1239 is gratefully acknowledged.

Exchange bias in Ni-rich ferromagnetic shape memory alloys Ni-Mn-Sn.

V. Khovaylo¹, V. Koledov¹, V. Shavrov¹, A. Korolyov², M. Ohtsuka³, H. Miki⁴, T. Takagi⁴

1. Institute of Radioengineering and Electronics, Moscow, Russian Federation; 2. Institute of Metal Physics, Ekaterinburg, Russian Federation; 3. Institute of Multidisciplinary Research for Advanced Materials, Tohoku University, Sendai, Japan; 4. Institute of Fluid Science, Tohoku University, Sendai, Japan

Recently, it was found that for ferromagnetic Heusler alloys $\text{Ni}_{50}\text{Mn}_{25}\text{Sn}_{25}$, $\text{Ni}_{50}\text{Mn}_{25}\text{In}_{25}$, and $\text{Ni}_{50}\text{Mn}_{25}\text{Sb}_{25}$, deviation from the stoichiometry results in appearance of martensitic transformation [1]. For these systems, the martensitic transformation temperature decreases upon substitution of Mn for Sn, In or Sb; an especially drastic decrease was observed in the NiMnIn system.

The stoichiometric $\text{Ni}_{50}\text{Mn}_{25}\text{Sn}_{25}$ has a Curie temperature $T_C \sim 350$ K and a saturation magnetic moment $\sim 4.3 \mu_B$. Structural instability observed in $\text{Ni}_{50}\text{Mn}_{50-x}\text{Sn}_x$ has a considerable impact on magnetic properties of these compounds. The compositional dependence of the Curie temperature T_C of the austenitic phase was found to be small, while T_C of the martensitic phase strongly depends on the composition and drastically decreases with decreasing Sn content [1,2]. Magnetic properties of this system is quite interesting and has not been understood clearly yet. For example, it was reported [2] that different strength of exchange interactions in martensitic and austenitic phases of $\text{Ni}_{50}\text{Mn}_{37}\text{Sn}_{13}$ leads to an unusual sequence of magnetic transitions, namely, upon heating low-temperature ferromagnetic state transforms to a paramagnetic state at intermediate temperatures and then again to ferromagnetic state upon further heating. It has also been reported that in Co-substituted Ni(Co)-Mn-Sn highly magnetized austenite transforms to presumably antiferromagnetic martensite with negligible net magnetization [3]. Besides, very recently exchange bias behavior has been observed in $\text{Ni}_{50}\text{Mn}_{50-x}\text{Sn}_x$ alloys [4,5].

Motivated by the recent experimental results obtained for the Ni-Mn-Sn system, we studied low-temperature magnetic properties of Ni-Mn-Sn alloys with Ni excess by a SQUID magnetometer. Polycrystalline $\text{Ni}_{50+x}\text{Mn}_{37-x}\text{Sn}_{13}$ (A series) and $\text{Ni}_{50+y}\text{Mn}_{39-y}\text{Sn}_{11}$ (B series) ingots were prepared by a conventional arc-melting method. Since the weight loss during arc-melting was small ($<0.2\%$) we assume that the real composition corresponds to the nominal one. The ingots were annealed at 1273 K for 24 h and quenched in ice water.

Field dependencies of magnetization $M(H)$ of the samples studied measured at liquid helium temperature indicate that in low fields $M(H)$ has a complex character. Specifically, when a sample is cooled down in zero magnetic field, the virgin magnetization curve differs significantly from subsequent full $M(H)$ loop. An example of these measurements is shown in Fig. 1 for the case of $\text{Ni}_{53}\text{Mn}_{34}\text{Sn}_{13}$ composition.

Solid experimental evidence for the existence of antiferromagnetic interactions at low temperature in Ni-Mn-Sn alloys with Ni excess can be obtained in the case when $M(H)$ loop is measured after field-cooling protocol. The shift of the hysteresis loop due to the exchange anisotropy is attributed to the coexistence of antiferromagnetic and ferromagnetic exchange interactions in the studied alloys. An example of these measurements is shown in Fig. 2 for the case of $\text{Ni}_{53}\text{Mn}_{36}\text{Sn}_{11}$ composition.

Magnetic and shape memory properties of FeMnSi-based glass-coated microwires.

H. Chiriac¹, N. Lupu¹, C. M. Craciunescu², S. Corodeanu¹, M. Grigoras¹

1. *Magnetic Materials and Devices, National Institute of Research and Development for Technical Physics, Iasi, Romania;* 2. *"Politehnica" University, Timisoara, Romania*

Ferromagnetic shape memory alloys (FSMAs) belong to the class of smart materials whose physical properties depend on the interaction between thermal, magnetic and elastic energy. They are among the newest type of alloys that focused attention for use in actuators and transducers. The ferromagnetic Ni_2MnGa is the most well known and studied FSMA [1]. However, the occurrence of shape memory properties in Heusler-type alloys is limited to single crystal [1] and polycrystalline thin films and melt-spun ribbons [2,3]. More recently, it was reported the shape memory behavior in FeMnSi intermetallics [4]. In this work, we report the magnetic and shape memory properties of Fe-Mn-Si glass-coated microwires with additions of Ni and Cr, as an approach leading to new developments in the exploration of FSMAs prepared in different shapes.

(Fe,Ni)-Mn-(Si,Cr) glass-coated microwires have been prepared by glass-coated melt-spinning. The metallic nucleus of the microwires was ranging between 14 and 25 μm , whilst the glass coating varied between 15 and 40 μm . Mn has been substituted in the $\text{Fe}_{62}\text{Mn}_{33-x-y}\text{Si}_5$ master alloy with $x = 8$ -12 at.% of Cr and $y = 5$ at.% Ni. $\text{Fe}_{62}\text{Mn}_{32}\text{Si}_6$ microwires have been also prepared. The structural studies indicated the formation of martensite-type L2_1 phase along with small traces of α -Fe. No other superlattice reflections have been observed in the as-quenched glass-coated microwires. The EDS spectra of the microwires after glass removal proven that the composition is very close to the nominal one, with slight differences for Mn content. No oxygen intakes have been detected.

The magnetic behavior of the as-quenched glass-coated microwires depends strongly on the composition and the ratio between the diameter of the metallic core and the glass thickness (Fig. 1).

Usually, FSMAs are paramagnetic in the as-cast state, their ferromagnetic behavior being induced by proper annealing [3]. On the contrary, for Fe-Mn-Si glass-coated microwires the ferromagnetic behavior is induced during the preparation process for certain compositions or/and ratios metallic core/glass thickness, as shown in Figs. 1 and 2.

It is worth noting that the character of martensite-austenite transformation in Fe-Mn-Si FSMAs is dramatically changing as a function of composition. The glass-coated microwires with additions of Cr and Ni exhibit premartensitic transformations to intermediate phase while for Fe-Mn-Si only direct martensite-austenite transformation is observed. One should notice also that the martensitic temperature (T_m) is shifted to higher temperatures (above 500 K) compared with already known Ni_2MnGa FSMAs [1], indicating these novel materials suitable for different applications. All these aspects will be discussed in detail considering the electronic and the specific magnetic domains structure of Fe-Mn-Si-based glass-coated microwires.

Analytical computation and experimental verification of magnetic core loss of permanent magnet generator considering the wind turbine speed.

S. Jang¹, K. Ko¹, J. Choi¹, H. Cho²

1. Chungnam Nat'l Univ, Daejeon, South Korea; 2. Korea Institute of Machinery & Materials, Daejeon, South Korea

Nowadays more attention is paid to the developing high efficiency electrical machines for energy saving and protection of natural resources. [1] In general, the electromagnetic losses appearing in electrical machines are widely classified into copper loss, core loss and rotor loss. In permanent magnet (PM) synchronous machines, core losses form a larger portion of the total losses than in another machine. So, satisfactory prediction of core loss at the design or analysis stage of PM machines is essential to active high efficiency and high performance.

Core loss in a magnetic material occurs when the material is subjected to a time varying magnetic flux. Traditionally, core losses consist of two components. The first component of core losses is the hysteresis loss which is the rate of change of the energy used to effect magnetic domain wall motion as the domain grows and rotates under the influence of an externally applied magnetic field. Hysteresis losses vary as a function of the frequency of the applied field. The second component of core losses is eddy current losses which flow in closed paths within the magnetic material. The eddy current losses are proportional to the square of the frequency of flux. [1]

For electrical machine designers, core loss data are usually provided in the form of tables or curves of total loss versus flux density or frequency. So, engineers normally use loss data obtained from the Epstein test as a basis on which to predict the core loss of each part of a particular machine with corresponding assumed flux density there. This method has been proved to have good precision in predicting core loss in transformers where the alternating field is dominant. However, complex flux distribution, flux density harmonics, and the rotational field in rotating machines bring great difficulties for the evaluation of core loss. [2][3]

This paper deal with core loss estimation of PM generator for wind power application using modified Steinmetz equation considered anomalous loss. Moreover, using the nonlinear finite element analysis (FEA), we applied separated rotating and alternating magnetic field to core loss calculation. Figure 1 shows the detail calculating process of core loss by proposed method. As shown in figure, in Step-1, the core loss data provided by manufacture are rearranged and plotted as a function of P_{core}/f vs. B . In Step-2, the data of frequency vs. Core loss are plotted by curve fitting of P_{core}/f vs. B plot and nonlinear curve fitting functions for core loss coefficient are derived. In Step-3, using the nonlinear FEA, the rotating and alternating magnetic field are separated. In Step-4, core losses are calculated using the obtained core loss coefficients.

In order to verify the core loss results by proposed method, the experimental system has been implemented with 3-ph induction motor, power analyzer (PM3300-Voltech) and manufactured PM generator. Figure 2 shows the experimental setup for no-load core loss measurement. The core losses data are obtained by subtract output power without stator core from output power with stator core.

From the comparison of between analysis results calculated using the obtained core loss coefficients and the provided core loss data, the deducted core loss coefficients have been validated, as shown in figure 3 (a). And, as shown in figure 3 (b), the analysis results with wind turbine speed agree extremely well with those obtained by nonlinear FEA and measurement.

Stator core loss prediction in large synchronous machines.

A. Knight, S. Troitskaia, Y. Zhan
Electrical and Computer Eng, University of Alberta, Edmonton, AB, Canada

A comparison between numerical and analytical approaches to calculate the stator core loss of large synchronous machines is presented. The approaches are implemented on machines with ratings above 1 MVA and skewed stators. The proposed approach allows the investigation of skew and inter-bar currents in the amortisseur circuits. The numerical approach used is a multi-slice 2D FEA model.

A multi-slice time-stepped FEA model is used to numerically predict the stator core losses [1]. This method is impractical for design use, but is used to provide a baseline prediction to evaluate the analytical method, due to the fact that it is impossible to segregate stator core loss during the test of a multi-MW machine. The analytical method predicts air gap flux density as the product of mmf and permeance functions [2]. Both sets of functions may be described using harmonic series that vary with time, angular position and axial position. The inputs to the analytical model are known mmf functions for the field and armature windings, the machine geometry, plus results from 4 magnetostatic FEA simulations. The magnetostatic FEA provides data on saturation level, plus harmonics to describe rotor and stator slot permeance harmonics. Both numerical and harmonic methods apply a bar-iron contact resistance interbar model to predict the amortisseur circuit currents [3]. A discrete number of axial loops are used to describe the currents: in the FEA model, these correspond to the number of FEA slices; in the harmonic model 5 slices are used, with discrete currents and mmf functions converted back to harmonic series.

In the harmonic method, the stator core flux is calculated by integrating the total air gap flux density over the surface of each tooth for each packet of laminations (between radial ducts). In order to do this, a number of assumptions are made: (1) if the angular period of a harmonic is less than one tooth pitch, λ , the flux harmonic will not penetrate down the tooth, skin effect must be considered (2) if the period is greater than λ , the flux penetrates down the tooth (3) all flux over λ enters the face of the tooth (4) flux density is uniform in a given region of the tooth or back iron. Each tooth is divided into 5 regions, increasing in distance from the air gap. The flux in each region allows the flux density to be calculated. If the flux passing through each tooth into the back iron is known, the back iron flux density can be calculated.

Core losses are calculated using traditional formulae for eddy, hysteresis and anomalous (or excess eddy current) loss. In both models, the core loss calculations require reconstruction of the flux density waveforms in the region of interest. In FE, the waveforms are constructed directly from the elemental vector potentials. In the analytical model the flux density harmonic series in each region of interest is summed to produce a time-domain signal. The number of flux density harmonics is typically in the range 2-5000.

Table 1 presents the predicted stator core loss values for three machines, for both open (OC) and short circuit (SC) test conditions. As mentioned earlier, direct measurement of stator core loss is not possible, however, the predictions are within the range of expectations based on measured total loss. It can be seen that the SC agreement is better than OC. This may be expected, as the SC condition is unsaturated, while OC tests are at a high flux level. OC predictions with the analytical method are consistently below FEA. Again, this may be expected as the analytical method assumes uniform back iron flux density between slots. It is well known that saturation causes uneven flux distribution in the back iron. The proposed method is consistent relative to FEA and provides the capability

to rapidly analyze the impact of design changes. Future development of the method could involve adding a saturating reluctance network in the back iron.

Figure 1 illustrates the flexibility of the proposed method to analyze the impact of skew on SC stator core loss. It can be seen that total loss increases rapidly with increasing skew.

Design and analysis of ultra high-speed permanent magnet generator driven by gas turbine for micro scale power generation.

S. Jang¹, K. Ko¹, J. Choi¹, Y. Lee²

1. Chungnam Nat'l Univ, Daejeon, South Korea; 2. Korea Institute of Science of Technology, Seoul, South Korea

Recently more attention has been paid to the development of a high-speed permanent magnet synchronous generator (PMSG) driven by gas-turbine. Since the generating system applying to PMSG do not have mechanical coupling such as gearbox, they have outstanding performances such as high efficiency, high power density, small size, low weight, simple mechanical construction, easy maintenance and good reliability, etc.[1][2] Since PMSG used in the portable or emergency power supplies, power generation using renewable energy resources, electric vehicles, and main generator for aircraft, are almost demanded good reliability, the design and accurate electromagnetic analyses of high-speed PMSG are essential.[3] However, it is quite difficult to design the high-speed PMSG because both mechanical and electromagnetic aspects should be considered owing to high rotor speed and high frequency in a stator.

Therefore, this paper deals with the design of an 870,000rpm class high-speed PMSG applied to micro turbine system. As shown in Fig. 1(a) and (b), since space where the high-speed PMSG coupled with the micro turbine occupies in the system is strictly limited, the work described in this paper is motivated by the desire to make maximum output power of the generator considering rotor dynamics, rotor structures, winding methods and bearing system under restricted space. First, we determine an axial active length and outer diameter of the rotor considering rotor dynamics. In particular, using simple open-circuit field solution obtained from space-harmonic method, we also determine the proper rotor structure by investigating the air-gap flux density due to PMs according to material (or permeability) of the rotor shaft. And then, since simple stator structure and compact winding method are required for our system due to restricted small space, slotless stator structure with an air-foil bearing and ring-wound method are employed for our work. Finally, we design and manufacture the high-speed PMSG shown in Fig. 1(c). The design procedure is shown in figure 2. As shown in figure, from solution by open-circuit and armature reaction filed of the determined model, we estimated electrical parameters such as back EMF constant, resistance and inductance. And, using the estimated electrical parameter, output characteristics of PMSG is obtained. As shown in figure 3, analysis results are validated by comparison with nonlinear FEA and experimental results. More detailed experimental and analysis results, discussion and design procedures will be presented in the final paper.

Electromagnetic Performance Analysis and Vector Control of a Flux-Controllable Stator-PM Brushless Motor with Skewed Rotor.

M. Cheng¹, X. Zhu^{1,2}, W. Hua¹, H. Jia¹

Permanent magnet brushless (PMBL) motors are promising for electric vehicles (EVs)[1]. Among them, the stator-PMBL motor drive is most viable, since it inherently offers high efficiency, high power density and maintenance-free operation. Also, it takes the definite advantage that the PMs are located in the stator so that the thermal influence on the PMs becomes insignificant while the rotor becomes mechanically robust[2]. Recently, by incorporating both PMs and DC field windings, a flux-controllable stator-PMBL motor has been proposed, which not only remains the advantages of stator-PMBL motors, but also offers a unique field control capability [3]. However, similar to the switched reluctance (SR) motor, the flux-controllable stator-PMBL motor still suffers from severe torque ripples because of the nature of salient poles in both the stator and rotor. These torque ripples cause mechanical vibration and acoustic noise, which greatly affects its acceptability. To minimize the torque ripple, a current vector control strategy is applied to the proposed motor for the first time and the effectiveness is verified by both the simulation and experimental results in this paper.

Fig. 1 shows the structure and magnetic field distribution of the proposed flux-controllable stator-PMBL motor. It consists of two types of stator windings, namely the 3-phase concentrated armature winding and the DC field winding. The armature winding is the same as that of the doubly-salient PM motor[4], whereas the DC field winding is the key for airgap flux weakening above the base speed. Firstly, the electromagnetic performance of the motor with rotor skewing is obtained by 3D FEM. Fig.2 shows the measured three-phase back-EMF waveforms at 1500rpm. The total harmonic distortion (THD) of the waveforms is only 1.93% which are very close to sinusoidal waveform. Then, a mathematical model in rotor reference frame of the motor is built and the current vector control drive system is implemented by using Matlab/Simulink model. Thus, the feasibility of current vector control method is investigated. Furthermore, to verify the validity of the method, a 12/8-pole prototype is controlled with the current vector control strategy. The measured torque and current waveforms at different current control methods are shown in Fig.3. At the rated load, by comparing with torque ripple factor $K_r=39.4\%$ at the common rectangular current control method [5], the K_r is only 14.1% at current vector control. Finally, the capability of flux control is investigated. Due to the existence of the additional DC field windings, the motor has a special capability of flux control. Above the base speed, by tuning the DC field current on line, the speed range is significantly extended from 2700rpm to 3600rpm, which is shown in Fig.4.

In this paper, a new flux-controllable stator-PMBL motor drive has been designed and controlled with a current vector control strategy. Both computer simulation and experimental results have confirmed that the operating torque ripple at the rated load can be significantly reduced by about 25.3%. Moreover, the DC field windings provide an additional degree of freedom with respect to the flux weakening operation. Hence, the proposed motor drive can offer lower torque ripple, fast speed response and wide speed range which makes the motor an interesting candidate for traction drive systems especially for EV operation.

Permanent magnet optimization for reduction of cogging torque of BLDC motor using response surface methodology.

J. Lee, H. Shim, S. Wang

Mechatronics, Gwangju Institute of Science and Technology, Gwangju, South Korea

Abstract — This paper presents an optimization of permanent magnet (PM) in a brushless dc (BLDC) motor using the response surface methodology (RSM). Size and angle of the PM are optimized to minimize the cogging torque, while maintaining the magnitude of harmonic at a critical frequency and the operating torque. The optimized design is validated by carrying out nonlinear transient finite element analysis.

I. INTRODUCTION

Cogging torque is one of the main undesirable sources causing vibration and noise, which is magnetically induced in electric machines [1]. The cogging torque can be reduced by modifying the design of permanent magnet (PM). For a practical optimization technique, the response surface methodology (RSM) is used to minimize cogging torque. The design of experiment (DOE) is carried out on a basis of the nonlinear transient finite element analysis (FEA). For validation, in this paper, the optimized design is reanalyzed by the FEA to compare initial design.

II. INITIAL DESIGN AND VALIDATION OF ANALYSIS

A. BLDC motor

Fig. 1 shows a brushless dc (BLDC) motor with 6-poles, 9-slots, and 3-phases power sources. The 12 PMs and air holes next to the PMs are aligned in the rotor. The air holes are for reducing the cogging torque. The cogging torque of the initial design is 1.65×10^{-4} [Nm] and the operating torque is 4.43 [Nm] at 1200 [rpm]. A fundamental frequency of radial magnetic force is 60[Hz]. Dominant harmonic is 2nd one occurring at 120 [Hz] and the magnitude is 6.17 [Nm], which is an interesting frequency in this paper.

B. Validation of FEM analysis

It is required to validate the finite element model with experimental data to confirm analysis accuracy. Fig. 1(b) depicts the analysis result of the flux line and the flux density. The maximum cogging torque is 0.19 [Nm] from the FEA and 0.19 [Nm] from experiment. Thus, the FEA is in good agreement with the experiment.

III. OPTIMAL DESIGN USING RSM

A. Construction of RSM

The DOE, as the major part of the RSM, is to determine sampling points for efficient construction of the RS model with less experiment. D-optimal design is used in this paper. Initial design values of the PM are shown in Fig. 1(a). The initial angle depicted in Fig. 1(a) is considered as 0° . The area of the PM is 26.25 [mm²]. The number of sampling points is sixteen, which is determined by the D-optimal design with respect to design parameters. The nonlinear transient analysis is performed sixteen times in order to obtain the responses at each point. From a RS model equation the fitted second-order polynomials of three response functions are constructed, which will be revealed in a full paper.

B. Optimization

For optimization problem, an objective is to minimize the cogging torque. Constraint is three. The first constraint is that the PM area must be greater than 26.05 [mm²] and less than 26.45 . The second is that the operating torque is limited to maintain that of the initial design. The third is that the magnitude of 2nd harmonic is smaller than the initial design. From the purpose of minimizing the

cogging torque and maintaining constraints, the estimated optimal design values are 1.46° for rotation, 10.35 [mm] for length, and 2.56 [mm] for thickness of the PM.

C. Reanalysis of optimal design

It is necessary to validate the estimated optimal design due to the fact that the responses in the RS model have nonlinearity. Fig. 2 shows the optimized design in which size of the PM is modified in accordance with arrows and the PM is rotated in the directions of circled arrows. The operating torque is decreased by 0.9 [%], and the magnitude of harmonic is reduced by 0.49 [%] comparing with the initial design. However, it is noted that the cogging torque is much reduced by 14.55 [%] from the initial design, and the difference of the cogging torque performance between the initial and the optimized design is shown in Fig. 3.

Introduction

Recent study shows great demand for small-to-medium rating (up to 20kW) wind generators for stand-alone generation-battery systems in remote areas. The types of generator for this application is required to be compact and light so that the generators can be conveniently installed at the top of the towers and directly coupled to the wind turbines. A construction containing no gear box offers several advantages, namely higher overall efficiency and reliability, reduced weight and diminished need for maintenance. However, in order to produce a 60Hz frequency at such a low speed, a large number of poles required [1]. Potentially, the PMG displays uniqueness to meet requirements stated above.

Therefore, this paper deals with the design of a direct-coupled, small-scaled permanent magnet (PM) generator suitable for the wind power system shown in Fig. 1. With wind turbine characteristics presented in the Table I, the design of a wind turbine generator is performed as following steps: 1) Using the TRV method presented in [2], the outer diameter and axial length of the rotor is determined. 2) We derive the analytical open-circuit field solutions in terms of a magnetic vector potential and a two dimensional (2-d) polar coordinate system. On the basis of open-circuit field solutions and 2-d permeance function presented in [3], the analytical solution for the cogging torque is also derived. 3) Using the analytical solutions, the thickness and pole arc ratio of the PM and basic magnetic circuit of the stator are determined. 4) On the basis of initial design results, the detailed design satisfied with required specifications is achieved by non-linear finite element (FE) method.

Finally, the wind turbine generator based on final design results is manufactured, and we confirmed through non-linear FE calculations and measurements that its performance such as output power, node voltage, current are satisfied with required specifications under various load and speed conditions.

Design Results and Verification

Figure 2(a) shows the comparison of predictions with FE calculations for magnetic fields due to PMs considering slotting effect. Since the analytical results are shown in good agreement with FE results, we predict the proper magnet thickness using analytical field solutions, as shown in Fig. 2(b). Due to the design constraints that the starting torque should be smaller than 0.5Nm, we can select 0.77~0.8 for pole arc ratio which makes the cogging torque have the minimum value from the results of Fig. 2(c). Fig. 2(d) shows the schematic of the final design model with 8-pole parallel magnetized PM rotor and 3-phase, double-layer windings slotted stator. Design equations, more detailed design procedures and results used in this paper in order to obtain Fig. 2(d) will be given in the final full paper. Figure 3 (a) shows the actual manufactured PM generator for wind turbine. As shown in Fig. 3(b), experimental results for the performance of the manufactured PM generator are shown in good agreement with FE results under rated load and speed conditions. More detailed results and discussion for design verification will be made in the final full paper.

Introduction

Flywheel Energy Storage System (FESS) is environment-friendly energy storage equipment which can be supplying electrical energy when needed, after electrical energy is stored into mechanical rotational energy. Some applications such as bus and semiconductor production require high peak power output from the FESS to recover energy during regenerative braking and to protect the sensitive industrial process by momentary voltage sags or outages. Both these applications share the characteristic of high peak power requirements for only a short amount of time, so the total amount of energy required is small [1]. However, in the high power energy storage applications for distributed power source such as solar power or wind power, the important factor is to be continuously offering electrical energy from the mechanical rotation energy of flywheel for a long time. Thus, design of the high power FESS must be considered high power requirement for rotating the large and heavy flywheel in high speed and rotational loss reduction for supplying the electric energy for hours. Here, the rotational loss is defined as mechanical loss by mechanical friction including windage loss and iron loss by magnetic field parts including eddy current loss when flywheel is rotated.

In Fig. 1(a), a manufactured 5kWh-class FESS with the whole flywheel weights 215kg has the Active Magnetic Bearing (AMB) for elimination of mechanical friction and Floating Magnetic Bearing (FMB) for stable levitation of flywheel. And, the general PM Synchronous Motor/Generator (PMSM/G) with slotless iron-cored stator and 2-pole PM rotor is used for high power energy storage in dynamic range of flywheel speed 12000~18000rpm. These all parts are installed in vacuum chamber. As the experimental result for evaluation of the presented FESS, Fig.1 (b) shows the flywheel speed according to driving mode. In idling mode without generating load, the rotational loss of the FESS is mainly generated in the part of magnetic field such as AMB and PMSM/G. Also, the core loss of PM type motor/generator is much larger than that of AMB with zero power controllers. Therefore, to improve storage efficiency, the PM type motor/generator must be redesigned considering minimization of core loss in accordance with application object of the high power FESS.

Design and Evaluation of Invented PMSM/G

In our works for high power FESS, to design 30kW-class PM motor/generator without iron loss, we presents the invented PMSM/G with double-side PM rotor composed of Halbach magnetized array and coreless winding stator as shown in Fig. 2. Although the PM rotor with Halbach magnetized array has the disadvantage in complex analysis and fabrication, the Halbach array field has the excellent merits with non-saturation of rotor core by self-shielding property and with high flux density as well as the more sinusoidal waveform at the air gap as shown in Fig.2 (b) [2]. Also, the winding stator without core doesn't cause reduction of flywheel speed by the rotational loss in idling mode. For design approach of the invented PMSM/G, this paper offers analytical formulae and FEM verification for its magnetic field, force, inductance of the winding and back electromotive force in polar geometries [3]. And then, we have focus on design parameters estimation to satisfy the high power requirement according to PM size and winding turns. A manufactured PMSM/G

through design process is evaluated from the required power and the core loss in motoring mode and idling mode as shown in Fig.3.

Experimental method for determining magnetically nonlinear characteristics of electric machines with magnetically nonlinear and anisotropic iron core, damping windings and permanent magnets.

G. Stumberger^{1,2}, T. Marcic², B. Stumberger^{1,2}, D. Dolinar¹

1. Faculty of electrical engineering and computer science, University of Maribor, Maribor, Slovenia; 2. TECES, Maribor, Slovenia

This work focuses on experimental methods appropriate for determining magnetically nonlinear characteristics of electric machines that contain an iron core with magnetically nonlinear and anisotropic behavior, permanent magnets (PMs), damping windings in the form of a squirrel cage and a wye connected three-phase stator winding. The three stator currents are dependent due to the wye connection. Therefore, the magnetically nonlinear two-axis dynamic machine models with independent state variables are normally used to analyze dynamic behavior of such machines. However, before the analysis is performed, the magnetically nonlinear iron core characteristics, normally given in the form of current dependent characteristics of flux linkages, must be determined. A simple experimental method for determining magnetically nonlinear characteristics of iron core inductors and transformers by the DC excitation is proposed in [1]. Evaluation of different experimental methods appropriate for determining magnetically nonlinear characteristics of electromagnetic devices is given in [2], where each individual device coil is individually supplied by a current or voltage controlled source. However, in the case of machine discussed in this work the stator windings of individual phases are wye connected and cannot be supplied independently. An approach similar to that presented in [3], where the three-phase synchronous reluctance machine is supplied by a voltage source inverter (VSI) controlled in the d-q reference frame in order to determine magnetically nonlinear (machine's) iron core characteristics, could be applied. In this case, the current in one axis is closed-loop controlled in order to keep constant value, while the voltage in the other axis is changing in the stepwise manner. The characteristics of flux linkages are determined by numerical analysis of currents and voltages measured during the test. Unfortunately, in the case of machine discussed in this work, the aforementioned method gives incorrect results due to the currents induced in the squirrel cage. This problem can be effectively solved by applying a similar approach as that presented in [4], where it was used for determining mutual inductances of a three-phase squirrel cage induction machine. After the (voltage) change, the stator current reaches a steady-state value. If it stays in the steady state long enough, the squirrel cage currents die out. Thus, the squirrel cage currents influence the time response of the flux linkage calculated by numerical integration of current and voltage measured during the test, but they cannot influence final value of the flux linkage. If the test with closed-loop controlled current in one axis and with stepwise changing voltage in the orthogonal axis is performed with different amplitudes of applied values, the steady state values of the stator currents and flux linkages are different. This makes possible to determine current dependent characteristics of flux linkages of the machine discussed in this work.

In order to confirm the new, in this work proposed method for determining current dependent flux linkage characteristics, one stator and four different four-pole experimental rotors were manufactured. The rotor structures are shown in Fig. 1: a) reluctance rotor; b) reluctance rotor with squirrel cage; c) reluctance motor with inserted PMs; d) reluctance motor with inserted PMs and squirrel cage. The d-axis is defined with the direction of flux linkage vector due to the PMs (direction in which PMs are magnetized) while the q-axis is aligned with the direction of the lowest reluctance.

The flux linkage characteristics given in Fig. 1 show a very good agreement between characteristics determined for reluctance rotor with and without squirrel cage (curves a) and b)) as well as between characteristic determined for both aforementioned rotors with inserted PMs (curves c) and d)). In the last two curves the offset due to the flux linkage caused by the PMs is not present due to the integration, but it could be added in the form of integration constant. The results presented show that squirrel cage and damping windings do not influence the d-q axis flux linkage characteristics determined by the proposed method, thus confirming the method completely.

Detent force minimization of permanent magnet linear synchronous motor by means of two different methods.

Y. Zhu, Y. Cho

Electrical Engineering, Dong-A University, Busan, South Korea

Introduction

The thrust ripple in permanent magnet linear synchronous motor (PMLSM) is mainly generated by detent force, which is caused by the interaction between the permanent magnet (PM) and iron core without input current in armature winding. This paper proposes two different techniques to minimize the detent force in PMLSM. One is to choose an optimal constructive design; the other is the employ of a current compensator. In this paper, we investigate the performance of detent force minimization using both of them. The effectiveness is verified by both numerical and experimental results.

Analysis and Results

In this paper the structure of PMLSM model is shown in Fig. 1. The mover core of the prototype PMLSM is composed of the semi-closed slot iron core without auxiliary poles and the concentrated windings. The mover core is in a 9-slot/8-pole fractional-slot pitch structure [1], which is similar to the straightened rotary motor core being cut off on the middle point between two adjacent teeth. This structure not only reduces the back EMF harmonics, but also suppresses the detent force. The stator is the path with surface mounted permanent magnet.

The two-dimensional (2-D) FEM is used to calculate the detent force and the electromagnetic force. The results of the static force distribution with respect to the mover position are shown in Fig. 2. To minimize the detent force, we investigate the PMLSM system by two different techniques. The first technique is using to optimize the PMLSM structure. The detent force can be reduced to 6.9[N] by appropriately positioning the auxiliary poles shown in Fig. 1. The calculated and measured results with/without auxiliary poles are shown in Fig.3. They are in good agreement, which validates the 2-D FEM.

However, this remained detent force with auxiliary poles is still large for low velocity operation. The second technique is using current compensator to counteract the detent force [2]. The control block is shown in Fig.4. In this paper we test the PMLSM system on 0.1[m/s] using speed closed loop control based on general PID. The velocity and thrust responses are shown in Fig.5. We can see that the velocity and thrust responses are much better for involving the second technique, but the phase currents are distorted seriously and unbalance for only using the second technique shown in Fig. 6(a). The phase currents waveforms with the auxiliary poles and the current compensator are shown in Fig. 6(b), which is similar to sine wave. Therefore, the combination of these two techniques shows good performance of PMLSM.

A STUDY ON THE IRREVERSIBLE MAGNET DEMAGNETIZATION IN SINGLE-PHASE LINE-START PERMANENT MAGNET RELUCTANCE MOTOR.

J. Hong², H. Nam³, T. Kim¹

1. Electrical Engineering, Gyeongsang National University, Jinju, South Korea; 2. Hanyang University, Seoul, South Korea; 3. LG Electronics, Changwon, South Korea

I. Introduction

A single-phase line-start permanent magnet reluctance motor (LSPRM) is known to be capable of high efficiency and near unity power factor performance. These attributes make them an attractive choice for various high duty cycle applications. The LSPRM does not need a driving system such as an inverter, because of the asynchronous starting torque by means of conductor bars in the rotor [1]. However, the large currents at a starting or locked rotor condition can cause severe irreversible demagnetizing in the permanent magnet. This demagnetizing field deteriorates the performance of the LSPMM such as phase peak-to-peak variation. Therefore, the demagnetization of the permanent magnet should be considered in the design of the rotor shape of the LSPMM. In this paper, we introduce the phenomena of the irreversible magnet demagnetization and propose design techniques which are effective to avoid irreversible demagnetization. To analyze the irreversible magnet demagnetization, two-dimensional finite-element method (2D FEM) is used. The nonlinear characteristic of the permanent magnet is considered as well as that of a magnetic core on each B-H curve.

II. Analysis Model

Fig. 1 shows the constructed proto-type LSPRM with two-layer rare-earth permanent magnet. It has a 24-slot stator and 2-pole rotor. The permanent magnet material is sintered Nd-Fe-B. The air gap was designed to be 0.5 mm to obtain a reasonable permeance coefficient value.

III. Analysis Results and Discussion

Fig. 2(a) shows the procedure of demagnetization. When operating P1 moves P2 due to the external demagnetization field, the residual flux density B_r is decreased to B'_r , and irreversible magnet demagnetization occurs. As a result, the magnetization M of the magnet is also decreased. Fig. 3 shows the demagnetization phenomena according to the increase of the stator magnetomotive force (MMF). Firstly, the center part of the lower layer magnet is demagnetized as the MMF increases. And then, the overall regions of the lower layer magnet become demagnetized. Lastly, the regions of the upper layer magnet have an irreversible demagnetization. From these analysis results, we can know that more thick magnet in the lower layer compared to the upper layer is effective to avoid the irreversible demagnetization. It is also possible to use the magnet of a different material in the upper and lower layer. The experimental results will be shown to confirm the validity of the analysis results and the proposed design techniques in the full paper.

Design of IPM type BLDC motor considering demagnetization characteristics.

B. Yang, S. Hong, B. Kwon
Hanyang Univ., Ansan, South Korea

Abstract

In this paper, a rotor is designed for the purpose of performance improvement of an Interior permanent magnet(IPM) type brushless DC motor with concentrated flux that takes into consideration demagnetization characteristics.

Introduction

The IPM type BLDC motors have been widely used in industrial appliances. But, the motor researched in this paper has a large leakage flux and a structure that is vulnerable to demagnetization. Methods exist to increase a thickness of magnet or to change a material of magnet to prevent leakage flux and demagnetization [1]. Cost is a factor in these methods due to increased use amount of magnet and material change. Therefore it is necessary to decrease leakage flux and to improve demagnetization performance of magnet without any change of usage amount and magnet material. This paper has designed a rotor for the purpose of performance improvement of an IPM type BLDC motor with concentrated flux that takes into consideration demagnetization characteristics. Through the optimum design of the rotor flux path, demagnetization characteristics are improved, counter EMF is increased, and magnetization is enabled after the inclusion of a permanent magnet.

Design of IPM type Motor

An IPM type BLDC motor with concentrated flux refers to a motor having a larger flux area than the pole area in the gap. The rotor is in the shape of a ferrite permanent magnet inserted into a round rotor core as shown in Fig. 1. Fig. 2 shows the flux distribution of the IPM type motor. Magnetization of the magnet is in a circumference as shown in Fig. 3. Since the leakage flux paths A and B are formed at both end areas on the structure of the rotor, a leakage flux is generated. The shape of the core inside the rotor is to be designed to minimize leakage flux in the IPM type BLDC motor with concentrated flux and to improve performance of the motor.

Fig. 4 represents briefly the distribution of the drag inside the rotor. Leakage flux path A is optimized to improve performance of the motor, and leakage flux path B is optimized to improve demagnetization factors. The limits in the design of the motor include a revolution speed of 1200rpm and peak current of 15A. Table I shows the motor shape and characteristic results following the improvement of leakage flux path B. As shown in Table I, as a result of the optimum design result for the motor characteristics by motor shape, the demagnetizing current of the proposed model is decreased about 25.9% comparing with the original. Since the allowable current of the inverter is 1.83 times to 15A, application is possible with the counter EMF improved by 14.5%.

Conclusion

This paper looks at the improvement of motor performance in consideration of demagnetization. As a result of an optimum design, this study enhanced the value of the counter EMF and enabled magnetization after assembly.

Characteristic analysis of Permanent Magnet Motor Considering Anisotropic Characteristics of Electrical Steel Sheets.

S. Kwon¹, J. Lee¹, K. Ha², J. Hong¹

1. Department of Mechanical Engineering, Hanyang University, Seoul, South Korea; 2. POSCO Technical Research Laboratories, Pohang, South Korea

I. Introduction

Finite Element Analysis (FEA) is generally used for the analysis and design of electrical machines. To improve its accuracy, more precise material data should be provided. Electrical steel sheets are classified into isotropic and anisotropic, and isotropic steel sheets are generally used for electrical motors and anisotropic steel sheets are used for transformer. Actually, isotropic steel sheets have anisotropic B-H and core loss characteristics reference to rolling direction, and the average value of rolling and transversal direction is provided by manufacturer. Therefore, using average material data leads to difference between experimental and FEA results. Measurement and analysis method considering anisotropic material characteristics are researched [1], however, it requires complex technique in measurements and large computation time to solve governing equation for FEA.

This paper focuses on the motor characteristics of permanent magnet motors considering anisotropic characteristics of electrical steel sheets. Motor characteristics of core loss, back Electro-Motive Force (EMF), and cogging torque are analyzed by FEA considering anisotropy of electrical steel sheets and compared to the results from experiment and general FEA; using single material data for the entire core region. For the analysis, rotating core lamination is not considered.

II. Measurement of B-H and core loss data

B-H and core losses are measured by Single Sheet Test (SST) reference to the angle from rolling direction and results are shown in Fig. 1 and Fig. 2, and angle is defined from rolling direction in the figures. As shown in Fig. 2, 7 samples are cut for the measurements. The size of the sample is 150×150 mm.

III. Analysis Method and Procedure

Measured B-H and core loss data are interpolated and prepared for 2-dimensional FEA. B-H data are consist of B, H, and θ (angle from rolling direction), and core loss data are consist of B, core loss (kW/kg), and θ . Using B-H data, FEA is conducted then core loss is calculated [2] with measured core loss data. Solving procedure of FEA is shown in Fig. 3. As shown in Fig. 3, governing equation is solved with the initial permeability of material then flux density and θ are calculated in each element. With the flux density and θ , new permeability is found from B-H data then governing equation is solved again.

IV. Results and Discussions

Analysis model is an Interior Permanent Magnet Motor of 4kW with 4-poles and 24-slots, and its analysis model(1/4 model) and fabricated appearance are shown in Fig. 4 (a) and (b). In Fig. 5, experimental and FEA results at no-load are compared. FEA results are from general FEA using single isotropic B-H data. For the back EMF and core loss, no significant differences are shown, however, flux distribution is not balanced and due to anisotropic B-H characteristics, therefore, core loss distribution should be unbalanced during one cycle of electrical angle. For cogging torque, significant difference exists. Cogging torque is the source of vibration of permanent magnet motors and supposed to be reduced by skew. However, considering anisotropic material characteristics, cogging torque will not reduced as expected. FEA results with anisotropic B-H and core loss and detailed comparison will be included in full paper.

Spin-wave eigenmodes in small magnetic elements have recently attracted growing attention due to their importance for the understanding of ultra-fast magnetization dynamics in such systems (see, e.g., [1-2]). Up to very recently these investigations were mainly conducted for the case of relatively small excitation amplitudes providing the linear response of the spin system of ferromagnetic films. At the same time, in magnetic nano-devices, e.g., spin-torque-transfer nano-oscillators, the amplitudes of dynamic magnetization are essentially large (see, e.g. [3]), which makes the deep understanding of the nonlinear dynamics necessary for their technical applications.

It is extremely difficult to study nonlinear dynamics in nano-devices directly with a lateral resolution comparable to the device size. In this work we take advantage of the spatial scalability of the dipolar problem for experimental modeling of nonlinear magnetization dynamics of nano-devices on a larger scale [4]. The studied objects are squares with a side length $w = 2$ mm, patterned from low-loss dielectric films of yttrium iron garnet (YIG) films with a thickness of $5.1 \mu\text{m}$. The excitation of dynamic magnetization was performed by means of a wire antenna with a diameter of $50 \mu\text{m}$, attached to the square along its middle line. The power of the exciting microwave signal P was varied from 1 mW, providing the linear response of the system, to 200 mW. A static magnetic field of $H=800$ -2000 Oe, creating a monodomain magnetization state of the square, was applied in the film plane perpendicularly to the antenna. The two-dimensional mapping of the dynamic magnetization was done by means of the space-resolved Brillouin light scattering spectroscopy in the forward scattering geometry.

Using the above technique we were able to record spin-wave intensity maps corresponding to different normal modes of the system. We also investigated how these modes change as the excitation power is increased and the magnetization dynamics becomes essentially nonlinear. An example of the experimental results is presented in Fig. 1, where the intensity maps and their spatial Fourier spectra are shown for the linear ($P=1$ mW) and the strongly nonlinear ($P=200$ mW) cases. The shown data were obtained for $H=800$ Oe, and the excitation frequency of 3.945 GHz which corresponds to the eigenmode (4,1). In the linear regime the spatial intensity distribution of this eigenmode represents a standing wave with four antinodes in the direction parallel to H and one antinode in the direction perpendicular to H . As the excitation power is increased, the spatial profile of the eigenmode demonstrates changes, which can be described as a widening and merging of the neighboring maxima of the standing waves, resulting in a flattening of the standing-wave profile. Similar modifications were also observed for other eigenmodes.

In order to understand the experimental findings a theoretical model based on the complex Ginzburg-Landau equation was developed. This model takes into account the nonlinear shift of the spin-wave spectrum as well as linear and nonlinear damping caused by the parametric excitation of spin waves. Numerical simulations based on this model have accurately reproduced the observed modifications of the eigenmode profiles (see Fig. 2), and have shown that they are caused by the nonlinear cross coupling between the eigenmodes. It was found that the dominating influence of nonlinear damping in the studied system leads to a generation of long-wavelength harmonics, which results in the energy channeling from higher-order eigenmodes to the lower-order ones.

Even though the experimental investigations were performed for millimeter-size squares, the above conclusions should also be valid for nano-scale monodomain square islands. The observed phe-

nomenon of nonlinear mode coupling can be used in practice for nonlinear amplification and/or reduction of magnetic losses of the eigenmodes.

This work was supported in part by the Deutsche Forschungsgemeinschaft and the Australian Research Council (ARC).

Synthesis and Magnetic Properties of Au Doped CoPt Nanowires.

J. Min¹, J. Wu², J. Lee¹, J. Ju³, Y. Kim¹

1. Department of Materials Science and Engineering, Korea University, Seoul, South Korea; 2. Institute for Nano Science, Korea University, Seoul, South Korea; 3. Cooperative Center for Research Facilities, Sungkyunkwan University, Suwon, South Korea

Introduction

Nanowires with enhanced surface functionalities and tailored surface morphology are of great interest owing to potential applications in surface reactions, catalysis, immobilizing molecules, nanomagnetics and nanomagneto-electronics. Magnetic nanowires are promising for biological applications such as cell-separation and magnetic labeling. However, the implementation of such nanowires usually requires surface modification. Based on our previous study of Cu-doped CoPt alloy magnetic nanowires [1], we introduce Au composition in this work to fabricate CoPtAu nanowires, in which Au provides the optical properties and functioning with biological entities, such as immobilization.

Experiment

The CoPtAu alloy nanowires were constructed in anodic aluminum oxide (AAO) nanotemplates with pore diameters of 50 nm and 200 nm. All nanowires were dc electrodeposited at RT in various concentrations from solutions containing HAuCl_4 , $\text{CoSO}_4 \cdot 7\text{H}_2\text{O}$ and PtCl_4 , in a single bath under a given constant current density. Their structure and properties were characterized by SEM, TEM, XRD, VSM and UV-Vis spectroscopy.

Results and Discussion

As shown in Fig. 1 (a)-(d), robust CoPtAu nanowires were acquired with homogenous distribution of the elements of Co, Pt and Au. Dependent on the deposition conditions (solution concentration and current density), the CoPtAu nanowires assume cubic or tetragonal structures and, thus, their magnetic properties are affected correspondingly. The XRD pattern (Fig. 1 (e)) shows that the CoPtAu nanowires prepared from the solution containing 0.28 M $\text{CoSO}_4 \cdot 7\text{H}_2\text{O}$, 0.03 M PtCl_4 and 0.001 M HAuCl_4 under the current of 3 mA/cm² in AAO with a pore size of 200 nm possesses a tetragonal phase, with $a = 2.682 \text{ \AA}$ and $c = 3.675 \text{ \AA}$. The magnetic measurements (Fig. 1 (f)) indicate that the nanowires are ferromagnetic, showing the easy axis along the direction of the nanowires. In Table 1, the magnetic properties of the CoPtAu nanowires are compared to that of the CoPt, CoPtCu nanowire. It reveals that the Au doping has more significant effects than the Cu doping, both in coercivities and squareness. Particularly, the tetragonal CoPtAu nanowires show enhancement in magnetic properties. Their coercivity increases to 700 Oe for the easy-axis and 730 Oe for the hard-axis, compared to 560 Oe and 300 Oe for CoPt, 420 Oe and 270 Oe for CoPtCu, and 520 Oe and 290 Oe for cubic CoPtAu, respectively. The change in the squareness along the easy-axis is more impressive, from 0.24 for CoPt, 0.29 for CoPtCu, 0.44 for cubic CoPtAu to 0.51 for tetragonal CoPtAu, while the effects of doping on the squareness along the hard-axis is less sensitive. Using samples in ethanol, the optical measurements give plasmon peaks characteristic of nanostructured Au in the UV-Vis spectra. For the case of the nanowires with a nominal composition of $\text{Co}_{0.17}\text{Pt}_{0.51}\text{Au}_{0.32}$ by SEM-EDS, the plasmon manifests the unique optical property of the nanowires and the absorption feature peaking at $\sim 720 \text{ nm}$ and $\sim 960 \text{ nm}$ reflects the outcome of the shaped Au segments.

Samples		CoPt	CoPtCu	CoPtAu (cubic)	CoPtAu (tetragonal)
H_c (Oe)	Parallel to wire axis	560	420	520	700
	Perpendicular to wire axis	300	270	290	730
M_r/M_s	Parallel to wire axis	0.24	0.29	0.44	0.52
	Perpendicular to wire axis	0.15	0.18	0.18	0.21

Nanostructured magnetic materials are the focus of many research efforts in the past few years, being very interesting not only from a theoretical point of view but mostly due to the wealth of their potential technological applications. Systems of magnetic nanowires are considered strong candidates for many technological applications as microwave filters, sensors or as materials for advanced data storage [1]. Characterization and understanding of the magnetic properties of nanowire arrays is still a challenging task, the complexity of the interactions among wires making difficult to interpret even the experimental results of classical characterization methods, like ferromagnetic resonance (FMR) [1-3]. The magnetic anisotropy of such arrays is determined mainly by two contributions: the shape anisotropy with a magnetic easy axis parallel to the wire axis, and the magnetostatic coupling among wires, which can develop a magnetic easy axis perpendicular to the wire axis [4,5]. The main parameter that controls the frequency response of magnetic nanowires assemblies is the aspect ratio of the nanowires, i.e., the length to diameter ratio. The aspect ratio can be tuned by changing the length of nanowires keeping the same diameter of wires. In the case of template method for nanowires preparation this can be easily done using different electrodeposition times. In the present work we chose to modify the aspect ratio of nanowires by keeping constant their length and modifying the nanowires' diameter. This approach is more challenging as it requires designing templates of different diameters but with the same average distance between the channels. Moreover, during the electrodeposition the constant length of nanowires for different samples of different diameters is controlled more difficult. The series of samples of different diameters, with the same length, and average distances between the centers of wires are ideal candidates for verifying the models recently proposed [5] to describe the interactions in such systems. Two series of Ni nanowire samples with diameters of 40, 60, 80 nm and constant lengths of 1000 and 500 nm were grown using standard electrodeposition technique in alumina templates. The templates were prepared by anodizing process with highly pure aluminium foils. In order to obtain templates with the same interpore distance of 100 nm and different pore sizes, the templates were etched in H₃PO₄ solution at room temperature using different etching times. The membranes produced following the above procedure have a much better quality than those commercially available, as it can be observed from the Scanning Electron Microscope (SEM) pictures displayed in Fig. 1.

The samples were studied using vibrating sample magnetometer and X-band ferromagnetic resonance experiments, at room temperature. Magnetization data (Fig. 1) confirm that the all magnetic nanowires with the length $L=1000$ nm have a uniaxial effective anisotropy along the wire's axis. However, for the nanowires with the length of 500 nm, depending on their diameter one can have an easy axis or easy plane anisotropic system. The FMR data shown in Fig. 2 substantiate this behavior which is intimately determined by the existence of magnetostatic interactions in these systems. In the full paper a comprehensive study of the magnetostatic interactions is presented explaining the different behavior of the FMR data in the two series of samples of different lengths.

Thermal coercivity mechanism in Fe nanoribbons and stripes.

F. Garcia-Sanchez, O. Chubykalo-Fesenko

POMT, Instituto de Ciencia de Materiales de Madrid, CSIC, Madrid, Spain

Recent advances in lithography and self-assembled techniques opened the possibility to prepare nanostripes and nanoribbons with the aim to study magnetisation dynamics in restricted geometry [1,2]. Alternatively, ribbon-shape objects can be created by extrusion technique [3], although with less control of particle orientations. The micromagnetic simulations have recommended themselves as a useful technique, capable to get insight into hysteretic processes in such nanostructures. It has been established that in thin nanostripes the magnetisation process occurs through nucleation and propagation of domain wall. The coercive field of long magnetic stripes and nanoribbons decreases as a function of their width, due to change of the character of the magnetisation reversal mechanism [4]. However, the coercivity values obtained through micromagnetic simulations rarely coincide to those obtained experimentally due to the exclusion of possible defects present in real experimental situations [5].

In the present work we evaluate the influence of thermally activated process on coercivity values on the timescale, characteristic for typical magnetometer measurement. Namely, as the widths of nanoribbons decrease, the energy barrier, separating the two magnetisation states, becomes comparable to this time scale for fields, below the values obtained through static micromagnetic approach. We have performed micromagnetic modelling of long Fe nanostripes with 4 nm x 30 - 250 nm x 400 nm dimensions. The cubic anisotropy easy axes were directed at 45 degrees to long wire dimension. The energy barriers have been calculated using the Lagrange multiplier technique [6]. Fig.1 represents energy barriers ΔE for zero applied field and various nanostripe widths. The change of the slope in this graph is associated with the change of the character of the saddle point configuration.

Fig.2 represents energy barriers for particles with different elongation as a function of the applied field. The typical magnetometer measurement time of the order of 0.1s gives an estimate of the thermally activated coercive field through the Arrhenius-Néel formula $\tau = \tau_0 \exp(\Delta E/k_B T)$. Finally, Fig.3 represents coercivity values obtained through micromagnetic simulations of nanostripes as a function of their widths. In this Figure we compare static ($T=0K$) coercivity values with those obtained through the energy barrier evaluation. It can be clearly observed that the thermally activated coercivity values at 300K are smaller than those obtained through standard micromagnetic approach for particles widths below 100nm. Finally, Fig.3 represents coercivity values obtained through micromagnetic simulations of nanostripes as a function of their widths. In this Figure we compare static ($T=0K$) coercivity values with those obtained through the energy barrier evaluation. It can be clearly observed that the thermally activated coercivity values at 300K are smaller than those obtained through standard micromagnetic approach for particles widths below 100nm.

Introduction

Magnetic patterning of continuous thin films has numerous applications within the field of magnetic recording [1]. The use of focused ion beam (FIB) irradiation opens new possibilities for magnetic pattern creation by tailoring the magnetic properties locally [2,3]. This technique is potentially useful in the creation of servo patterns for the purposes of high density magnetic recording [4].

Experiments

Nanometer-scale magnetic strip structures were made by patterning a Co/Pd multilayer medium using a focused Ga beam. The atomic force microscope (AFM) image (Fig. 1a) shows a small topographic contrast (0.9 nm) caused by the sputtering effect of the ion beam. After ac-demagnetization the magnetic force microscope (MFM) image (Fig. 1b) reveals typical magnetic domains, but the underlying strip pattern is not apparent. After saturation in a perpendicular field a well-defined strip domain pattern is observed in remanence (Fig. 1c). The irradiated, magnetically softer segments have reversed their magnetization direction due to the demagnetization fields of the adjacent unexposed medium.

The corresponding M-H loop and remanence curve were measured by polar magneto-optic Kerr effect (Fig. 2a). The M-H loop shows a well pronounced step in magnetization (arrow A), indicating the reversal of the soft, irradiated strips. At remanence a reduced magnetization is observed consistent with the MFM image. For reverse field values an additional stable domain configuration appears in remanence (arrow B). This domain configuration was imaged by MFM revealing an additional strip pattern (Fig. 1d).

Micromagnetic simulations

Micromagnetic simulations were performed using the freely available simulation package MAGPAR [5]. Using reduced values of 2/3 for the saturation magnetization and 1/8 for the anisotropy of the exposed strips, the simulation reproduces the experimentally observed features (Fig. 2b).

To follow the reversal process in more detail, the equilibrium spin configuration was extracted at various external field strengths (Fig. 3). Coming from positive saturation to remanence the change in magnetization is dominated by the reversal of the magnetically soft exposed strips. The driving force is a competition between the magnetostatic interaction and the exchange interaction between the hard and soft strips. When applying negative fields, the reversal is mainly due to domain wall motion in the hard magnetic strip material. In remanence a second stable domain configuration is observed where the hard strip splits, approximately, into a central domain pointing antiparallel to its outer parts while the soft parts reveal mainly an in-plane orientation of the magnetization pointing along the strip. This configuration is in qualitative agreement with the measured MFM image shown in Fig. 1d.

Summary

FIB irradiation was used to create strip patterns with modulated magnetic properties in a perpendicular Co/Pd film. Micromagnetic simulations were used to understand the nature of the magnetic domain configuration and their reversal in these periodic strip systems. The strip patterns reveal an antiparallel alignment of neighboring irradiated and unirradiated strips where the coupling

strength can be tuned simply by varying the pattern period and/or exposure dose. The formation of such laterally coupled strips is determined by the competition between the magnetostatic interaction and the exchange interaction.

A novel bottom-up fabrication process for controllable sub-100nm magnetic multilayer devices.

M. Kao, J. Ou, J. Wu

Physics, National Changhua University of Education, Changhua, Taiwan

Introduction:

Recently, nanostructured magnetic devices, such as spin valve and magnetic tunnel junction, have attracted much attention due to the great potential for developing practical and ultra-dense memory cells. For making nanometer-scaled current perpendicular to the plane (CPP) multilayer devices a standard subtractive fabrication process in combination of electron beam lithography and dry etching has been often used. Until the past few years, a bottom-up technique using a trilayer hole template was proposed [1-2] for fast and efficient way of testing nano-devices. The advantage of using this new technique is to avoid the etching process which commonly leads to edge shorting or distorted pattern. However, the cell size was strongly dependent on the lithography process only in the aforementioned new technique. Herein, we present a novel similar bottom-up technique for fabricating controllable sub-100nm spin valve and MTJ devices by tuning the thickness of the insulating layer and adding a buffer layer.

Experiments:

The template structure consisting of Si₃N₄-coated silicon substrate/Au 20/SiO₂ x/Ge 20 (thickness in nm and x is varied to be 100 and 200, respectively) was first prepared by thermal evaporation and sputtering method. A deep submicron hole was patterned into an electron beam resist spin-coated on the top of the template, followed by a dry etching to transfer the hole pattern to Ge layer. The sample was then dipped into a BOE etchant and the SiO₂ underneath the Ge hole was etched out downward and laterally, giving rise to a very good undercutting profile, a hole template was then completed and ready for all sorts of metal films deposition. The controllable nano-devices can be fabricated through smaller hole template which can be achieved using lithography and a trick based on the fact that a buffer film growth vertically may narrow down the template hole at the same time, forming a more and more narrow neck during buffer film growth.

Results and discussion:

Figure 1 shows a SEM micrograph of the top-view of the hole array template. Notice that the grey circle around the hole reveals the laterally over-etched of SiO₂ underneath the Ge film. Figure 2 (a) and (b) are the cross-sectional SEM images of two tested runs of multilayer deposition, in which the SiO₂ layer in each case is 100 nm and 200 nm thick, respectively. The original hole diameter was 175 nm in each case and the multilayer were deposited with sequences of Cu 40/NiFe 10/Cu 5/NiFe 20/Cu 30 and Cu 140/NiFe 10/Cu 5/NiFe 20/Cu 30. With buffer layers of Cu 40nm and Cu 140nm deposited in the hole templates having 100nm and 200nm thick of SiO₂ in each case, one can see the lateral dimension of the active layer, as arrows pointed, is 140 nm and 90 nm, respectively. A single hole template was fabricated for testing spin valve structure and a magnetoresistance was measured using an ac lock-in technique. Figure 3 shows the R-H loop measured on a spin valve device with 100 nm diameter and active layer sequence of NiFe 10/Cu 5/NiFe 20. The steps observed may have been due to local magnetization reversal. More details of fabrication process and electrical characterization will be presented.

The formation of self-organized patterns on a semiconductor surface by ion erosion [1] has been taken advantage of to produce large-scale arrays of uniformly-sized, hexagonally-arranged magnetic nanodots. A special sample design has been used in which a magnetic layer was epitaxially grown by magnetron sputtering on a GaSb substrate; this film was subsequently covered with another GaSb layer, 1000 nm thick. The erosion of this sacrificial layer with Ar⁺ ions leads to the formation of a periodic dot pattern which eventually intersects the buried thin magnetic film. By interrupting this process at the appropriate moment, isolated magnetic nanodiscs can be generated. Different thicknesses and compositions of the intercalated metallic layer have been tested in order to optimize the morphology of the transferred dot pattern and to enhance the resulting magnetic properties. Here we report on the results using pure Co.

The best results were obtained using 400 eV Ar⁺ ions, resulting in dots of 15-20 nm in diameter, 5 nm thickness and 40 nm nearest-neighbor separation. Figure 1 shows the final surface morphology as determined by Atomic Force Microscopy after completing the erosion process.

The system's magnetic behavior was characterized by means of vectorial Kerr magnetometry. The saturation intensity for the dotted sample is approximately 3 times smaller than for the continuous film, confirming the partial removal of material during the patterning process. Furthermore, the coercive field increases by almost one order of magnitude upon patterning, up to ~15 mT. This effect can be explained by a change in the mechanism of magnetization reversal, which in the 2-dimensional film must be achieved by domain wall propagation. The dots, in contrast, have sizes of the order of the domain wall width and can therefore be expected to be single-domain. Their magnetization reversal must hence take place by coherent rotation.

Numerical simulations based on the Stoner-Wohlfarth model have been performed assuming that the sample consists of an array of particles with negligible coupling and randomly distributed 3-fold anisotropy [2]. The total system energy is calculated as a function of the angle between the applied magnetic field and the particles' magnetization; hysteresis loops are determined by total energy minimization. The experimentally observed zero overall anisotropy results from averaging over all field directions, which is equivalent to a random distribution of the easy axes directions among the particles. This calculation correctly reproduces the shape of the experimental hysteresis loops, as demonstrated by Figure 2. This fit could be achieved using only bulk Co parameters taken from the literature, with no adjustable ones. These results thus confirm that arrays of magnetically independent nanodots can be produced by this efficient patterning method; if used as a magnetic storage material, a density as high as 0.4 Tbit per square inch could be attained. Furthermore, the patterning process depends only on the semiconductor capping, and different intercalated magnetic materials can be used with the only limitation that their thickness remains below ca. 10 nm, so that the ordered pattern is preserved. This opens up the possibility to tailor the dots' magnetic properties, such as coercivity or anisotropy, to suit different applications.

Transverse Rectifier Based on Hybrid Magnetic/Superconducting Nanodevices.

Villegas et al (1) reported a magnetic longitudinal rectifier device. This device is fabricated using thin superconducting films grown on top of arrays of periodic Ni nanotriangles. The rectification is due to the ratchet effect. Ratchet effect is the net flux of particles yielded by particle motion in asymmetric potentials when a zero average oscillatory driving force is applied to the particle set. This ratchet effect is relevant in many fields of research as molecular motors or dynamics of colloidal particles. In the hybrid magnetic/superconducting rectifier the particles are the magnetic vortex flux lines which are pinned by the Ni nanotriangles, which are the asymmetric potentials. In summary, in this device, injecting an ac input current yields an output dc voltage.

Recently, Gonzalez et al. (2) have reported a transverse nanorectifier which is based on superconducting thin films grown on top of array of non-magnetic asymmetric nanodefects. In the present work, we explore the properties of similar device based on arrays of magnetic nanocenters. In comparison with the non-magnetic rectifier the magnetic nanodevice shows larger output signal values for similar temperature and frequency ranges, besides the amplitude of the input signal, which is needed to yield rectification, is shifted to higher values in comparison with the non-magnetic rectifier.

In brief, the nanodevices are Nb films (100 nm thickness) on top of rectangular array (800 nm x 750 nm) of Ni nanotriangles (triangle side 600 nm and height 40 nm). These devices are fabricated on Si (100) substrates using electron beam lithography, magnetron sputtering, conventional lithography and ion etching techniques. The film is patterned with a cross-shaped measuring bridge that allows us applying, at will, currents and measure the output voltage parallel or perpendicular to the triangle basis. The sample is kept at constant temperature in the superconducting mixed state, close to the superconducting critical temperature. A small magnetic field (around 100 Oe) is applied perpendicular to the films to produce the vortex lattice. The magnetotransport experiments are done with a commercial He cryostat and ac current with frequency up to 10 kHz. Finally, the Ni triangles show a magnetic vortex state as has been published elsewhere (3).

Figure 1 shows the layout for the usual longitudinal (a) ratchet effect (1) and the layout (b) for the transverse ratchet effect (2).

In this work we show an enhancement of the transverse ratchet effect using magnetic traps for the vortices in comparison with the nonmagnetic device. In comparison with the non-magnetic rectifier the magnetic nanodevice shows larger output signal values for similar temperature and frequency ranges, besides the amplitude of the input signal, which is needed to yield rectification, is shifted to higher values in comparison with the non-magnetic rectifier. We will also show a comparison between the longitudinal and transverse ratchet effect for both cases magnetic and non-magnetic pinning centers.

Recently there has been a renewed interest in investigating superconductor (S)- Ferromagnet (F) hybrid structures [1], in particular structures containing F layers with inhomogeneous magnetizations. So far most of the works have been focused on S-F multiple layers. In this paper, we study experimentally the electrical transport properties of an S-F-S lateral junction with a patterned F layer which exhibits a well-defined domain structure. The sample consists of a niobium (Nb) strip with a width of 2 μm and a gap of 150 nm. Centering on the gap and overlaid with the Nb layer at two sides is a 2 $\mu\text{m} \times 2 \mu\text{m}$ square of NiFe. Both the Nb and NiFe layers have a thickness of 60 nm. As a control, an S-normal metal (N)-S (Cu as N layer) sample with similar configuration as S-F-S sample was fabricated. The samples were characterized by both magnetic force microscopy (MFM) and electrical transport measurements. The latter was performed in a four-probe configuration as shown in figure 1a.

Fig.1b shows MFM image of the S-F-S sample at room temperature. A multi-domain structure is distinguishably observed in both the gap and overlaid regions. As the gap region is very small, the overlaid region is essential to create a multiple domain structure inside the gap which otherwise would be most likely in a single domain state. By cooling the sample from 20 K to 1.4 K, the resistance of the gap region decreases sharply from 440 ohm to 3.5 ohm in the temperature range of 5 K to 4 K, indicating that the critical temperature of this specific sample is about 4.5 K. From dI/dV curves at zero field and at 1.4 K, a superconducting gap of 0.6 meV was deduced which agrees well with the theoretically predicted value of 0.68 meV with a critical temperature of 4.5 K. The gap-related features disappear at about 3.5 T which can be considered as a critical field for the Nb film used in this sample. Fig.2 shows the dI/dV curves at 1.6 K and different applied field. The dI/dV curve shows a large fluctuation in the gap region at low field. Upon applying a small magnetic field (100 Oe) two conductance peaks appear at around 0.3 mV of bias voltage and these features disappear at a magnetic field above 0.4 T. Figure 3 shows the dependence of difference between these two peak positions (V_d) on magnetic field. V_d increases quickly at low field and saturate at higher field (> 0.3 T). In addition to these features, a slight reduction of zero bias conductance (ZBC) with magnetic field in the region between 0 to 0.2 T is observed; it then decreases linearly at magnetic field above 0.2 T. The ZBC at zero field is about 1.5%~ 8% higher than that at 0.2 T.

Although the underlying mechanism for the appearance of split peaks in the dI/dV curve is not well understood at the moment, judging from the V_d dependence on magnetic field, it is presumably caused by the annihilation of domain walls in the overlaid region. There is an exchange coupling between NiFe and Nb in the overlaid region. The effective exchange field increases with the degree of alignment of magnetization in the NiFe layer [2]. Due to this exchange coupling, the superconducting gap near the NiFe/Nb interface will be reduced as compared to that of the region which is further away from the interface. This may explain why additional conductance features appear in the gap region of Nb when a magnetic field is applied, which are not observed in the S-N-S sample. On the other hand, the presence of domain walls at the gap region allows the formation of Cooper pairs of opposite spin electrons stemming from neighboring domains magnetized in opposite directions, promoting the so-called crossed Andreev reflection (CAR) [3]. The CAR is known to contribute excess conductance in the gap region. As the field is increased, the magnetization in

different domains become gradually aligned, resulting in a suppression of CAR and thus a decrease of conductance in the gap region. Above 0.2 T, Nb enters into a resistive mixed state due to the large exchange and applied field, causing a significant decrease of ZBC with the magnetic field. Further investigation is ongoing to understand quantitatively the experimental data using theoretical models. We are also fabricating and characterizing samples with NiFe of different lateral dimension and thickness. The results will be presented in the conference.

In the semimetal bismuth both, the electronic mean free path l_{mf} and Fermi wavelength are large compared to conventional metals, making it an ideal material for studies on the nanoscale because classical and quantum size effects are expected [1,2]. Of particular interest [3] is the scaling of conductivity by the ratio l_{mf}/D in granular conductors with average grain size D . In the present study we examine the artificial control of grain-boundary resistance and its contribution to magneto-transport properties of [Co/Bi]*n* multilayer line-structures. [Co/Bi]*n* and Bi lines were produced by a two-step micro-fabrication process. Scanning Electron Microscopy (SEM) was used to examine the granularity of these [Co/Bi]-line structures. Magneto-transport measurements have been carried out with a Quantum Design SQUID magnetometer.

Fig.1 shows the temperature dependence of resistance, R , at $H=0$ Oe (warming) and $H=3$ kOe (cooling) in [Co(1nm)/Bi(2.5nm)]*n* ($n=10$ or 20) and pure-Bi line structures. The decrease of R (that is normalized to $R_{FC}(5K)$ value in the FC curve of Bi and [Co/Bi]10 respectively) observed above 150 K in Fig.1A is due to finite size effects inside the granular microstructure of Bi. In addition, Fig.1B shows that a doubling of the total line thickness, from 45 nm in [Co(1nm)/Bi(2.5nm)]10 to 70 nm in [Co(1nm)/Bi(2.5nm)]20 line-structures, causes a slight increase of R below 150 K and a sharper drop of R above 150 K for the thicker lines, indicating that grain-size effects affect predominantly the electrical conductivity of these structures in the examined temperature range. Fig.2 shows the transverse magnetoresistance (MR) from a [Co(1nm)/Bi(2.5nm)]10 line structure at 10 K. The MR ratio: $\Delta R/R=80\%$, is much larger than that expected from the known anisotropic-MR (AMR) ratios, indicating that finite size effects are very important at low temperatures. This MR ratio decreases significantly above 100 K and becomes equal to about 1% at 280 K.

It is demonstrated that grain-boundary effects induce significant changes of the magneto-resistance, depending on the granularity of [Co/Bi]*n*-wires, which indicate that these multilayered structures might be potential candidates for applications in granular electronic systems [4].

Recently, the current-induced spin-transfer torque [1] has been proposed as a convenient writing process in high density magnetic random access memory [2]-[4]. A spin-polarized current can switch the magnetization of a ferromagnetic layer more efficiently than a current induced magnetic field. In a typical spin-transfer memory cell, the current is sent along the z direction across a multilayer element with layers parallel to the (x,y) plane. The element consists of a "fixed" magnetic layer with magnetization pinned along the x axis, a nonmagnetic spacer, and a "free" magnetic layer exposed to the torque due to x -directed spin-polarization that the electrons acquire from fixed layer. A spin-transfer transmission mode [3] or a spin-transfer reflection mode [4] can be used to write the information. With increasing demand on the access time the current pulse shape becomes important. Also, with memory area density increasing and the memory cell size further shrinking the study of thermal fluctuations becomes of extreme importance for their recording thermal stability.

In this paper we have studied the dynamic switching in spin-transfer memory and its dependence on thermal effects. The model is based on stochastic Landau-Lifshitz-Gilbert equation [5], which is numerically integrated. As ferromagnetic material, Co with saturation magnetization $4\pi M_s = 12$ kOe and damping constant $\alpha = 0.01$ was chosen. The free magnetic layer is assumed to be ellipsoid shaped, making the demagnetizing field uniform across the entire layer, and also it is assumed to be a single domain. The ellipsoid's principal axes are taken along x , y and z : long-axis length of 100 nm (along Ox axis), short-axis length of 75 nm (along Oy axis), and thickness $d = 2$ nm, leading to demagnetizing factors $N_x = 0.014$, $N_y = 0.022$, $N_z = 0.964$. The effective field consists of applied field, demagnetizing field, anti-ferromagnetic coupling between the fixed layer and free layer $\mathbf{H}_{ex} = -4\pi(N_y - N_x)M_s h_{ex} \mathbf{m}_p$ where the unit vector \mathbf{m}_p gives the direction of the spin polarization (along x direction in our case), and thermal field.

At a given temperature the switching properties are discussed as a function of applied current pulse amplitude, duration and shape. Because an instantaneous change of the applied current from zero to some other value is not very realistic, sinusoidal time dependence for the current pulse rise and fall are assumed. The rise/fall time is a function of the pulse's amplitude so that the current sweep rate v_f , defined as the ratio between the amplitude and pulse's rise/fall time, is constant. If initially the magnetic moments of fixed layer and free layer are parallel aligned there is no torque acting on the free layer. However at finite temperature the thermal agitation assure that at no time this happens.

From Fig. 1 we can see that the switching diagrams have layer-like structures with switching/non-switching areas. A "comblake structure" of the switching diagram is experimentally obtained in Ref. 6 and it is explained taking into account the statistics of the possible initial states due to thermal fluctuations. In the full paper we present how the current sweep rate, damping constant, and also the thermal fluctuations affect the switching, the reliability, and the writing speed of spin-torque devices. Instead of a clear border between switching and non-switching areas we have a transition region where the final state is sensitive to thermal fluctuations.

Work at AMRI was supported by DARPA under grant No. HR0011-07-1-0031. Calculations were performed on computational facilities provided by Louisiana Optical Network Initiative (<http://www.loni.org>) which is supported by the Louisiana Board of Regents.

Fig. 1. Anti-parallel (AP) to parallel (P) (left) and P to AP (right) switching diagrams at $T=0K$, as a function of current pulse amplitude and duration, for a current sweep rate $v_f=1mA/ps$, and different values of the anti-ferromagnetic coupling h_{ex} . Initially the magnetization of the free layer is in the film plane, making an angle of 10^{-3} degree with the direction of the fixed layer. Black areas represent $m_x=-1$, white areas represent $m_x=1$, and the intermediate values of m_x are represented with shades of gray.

Analysis of spin transfer switching speed in magnetic nano-structures.

J. Guo¹, T. Seng Ghee², J. Mansoor Bin Abdul¹, L. Lin¹

1. National University of Singapore, Singapore, Singapore; 2. Data Storage Institute, Singapore, Singapore

Recent experimental evidence [1-2] of spin transfer switching at reasonably low current density (J) of $10^6 \sim 10^8$ A/cm² in magnetic nanostructures has triggered keen interest in this research topic, which was initiated by the theoretical predictions of Slonczewski and Berger in 1996 [3]. However, the magnetization switching speed under the influence of spin transfer torque, which has far-reaching consequences to device operation has not been studied in depth. A long switching time poses a limit to the speed of device operation; while an underdamped “ringing” [4] switching behavior makes the device prone to radio-frequency (RF) noise. In this article, we investigate the effect of current density (J) and spin polarization of current (P) on the magnetization switching dynamics of an exemplary Co magnetic nanostructure of dimensions $50 \times 50 \times 50$ nm³. A three-dimensional dynamic micromagnetic model of the current-induced magnetization dynamics was developed, which incorporates the Slonczewski spin transfer torque term [3] and the damping effects of eddy current following the scheme by Torres *et al.* [5]. For the micromagnetic calculations, the magnetic nanostructure is discretized into cubic unit cells of length 10 nm. Figure 1(a) shows a significant improvement in the switching time (t_{sw}) to 2.5 ps for J of 2.3×10^9 A/cm², compared to $t_{sw} \approx 3$ ps for lower J values of 2.3×10^7 A/cm² and 2.3×10^8 A/cm². Figure 1(b) shows that, in general, a faster magnetic reversal can be achieved with a larger P for a specific J value. This may be explained by the fact that a higher P results in a larger transfer of momentum per conduction electron to the local moments, thus generating a larger effective field and a faster precessional motion. Additionally, we found that the effect of P becomes more significant as J increases. As shown in Fig. 1(b), when $J = 2.3 \times 10^9$ A/cm², t_{sw} is reduced by about a third when P is increased from 0.1 to 0.9, while at $J = 2.3 \times 10^8$ A/cm², the reduction in t_{sw} is only $\sim 5\%$ for the same increase in P . The numerical results of our simulation indicates that the spin transfer switching time in the presence of eddy current can be optimized by a careful choice of J and P . The use of a large J to monotonically increase switching speed is not a viable option since a large J causes electromigration in metallic materials, while high spin polarization P which approaches 100% cannot be easily achieved, even with half metallic materials. However, with a suitable choice of J , the switching speed can be improved significantly while keeping to the experimentally observed range of P .

Current induced domain wall motion in ferromagnetic wires with out-of-plane magnetization.

H. Szabolcs^{1,3}, J. Toussaint^{1,3}, A. Marty⁴, I. Miron², L. Buda-Prejbeanu^{2,3}

1. Department of Nanosciences, Institut Neel, CNRS, Grenoble, France; 2. Laboratoire SPINTEC, CEA-CNRS, Grenoble, France; 3. Institut National Polytechnique de Grenoble, Grenoble, France; 4. Laboratoire SP2M, CEA-CNRS, Grenoble, France

The possible applications of magnetic domain wall (DW) motion induced by spin-polarized current injection are rather numerous; this is why many efforts are invested in studying this phenomenon. Several theoretical approaches were developed, but even though all kind of systems can be described by them, experimental results refer mostly to systems with in-plane magnetization. In such a system the large width of the DWs makes them less sensitive to pinning and the current-generated Ampère field can be neglected. On the other hand, an out-of-plane magnetized system presents very narrow DWs and thus pinning plays an important role, but also increased DW velocities are expected [1]. We present here a study on such a system, a 120nm wide and 11nm thick Co/Pt nanowire where the DW width is around 10nm.

The modeling of DW motion induced by a spin-polarized current is based on the modified Landau-Lifschitz-Gilbert equation (LLG):

$$\partial \mathbf{M} / \partial t = -\gamma_0 (\mathbf{M} \times \mathbf{H}_{\text{eff}}) + \alpha / M_s (\mathbf{M} \times \partial \mathbf{M} / \partial t) + (\partial \mathbf{M} / \partial t)_{\text{ST}} \quad (1)$$

By γ_0 we denote the gyromagnetic factor, α is the Gilbert damping constant, M_s is the spontaneous magnetization and \mathbf{H}_{eff} is the effective field summarizing the main contributions in a micromagnetic system: exchange, magnetocrystalline anisotropy, demagnetizing, Zeeman field and, in the case of perpendicularly magnetized nanowires, the stray field issued from the adjacent domains. The effects of the Ampère field are neglected in this paper.

To describe the effect of the current on the DW we used the approach proposed by Thiaville et al. [2]:

$$(\partial \mathbf{M} / \partial t)_{\text{ST}} = -(\mathbf{u} \cdot \nabla) \mathbf{M} + \beta / M_s \mathbf{M} \times [(\mathbf{u} \cdot \nabla) \mathbf{M}] \quad (2)$$

The first term is the adiabatic term, occurring when the spin current follows approximately the direction of the magnetization within the wall. This term is responsible for the distortion of the DW. The second term is the non-adiabatic contribution due to the mistracking of the electrons. It is responsible for the DW displacement. β is the non-adiabatic spin transfer parameter. The velocity \mathbf{u} is a vector directed along the direction of electron motion, having the amplitude:

$$\mathbf{u} = (g \mu_B P J_{\text{app}}) / (2e M_s) (1 \ 0 \ 0) \quad (3)$$

Here g is the free electron's Landé factor ($g=2$), μ_B is the Bohr magneton, J_{app} is the current density, P is the current polarization rate and e is the charge of the electron.

For all the simulation reported below the material parameters used are the following:

$\mu_0 M_s = 0.32 \text{ T}$, $\mu_0 H_{\text{anis}} = 1 \text{ T}$, $A_{\text{ex}} = 10^{-11} \text{ J/m}$, $\alpha = 0.01$, $P = 1$. Since the value of the parameter β is not well known and to analyze its effects, several values were considered.

The above mentioned equations were implemented in the micromagnetic solver WALL_ST® based on the finite differences approximation.

Walker already determined that in the case of field induced DW motion there are two linear regimes: a steady and a precessional regime [3]. These regimes are also observed in the case of current induced DW motion and a critical current density J_c can be determined. Two relations connect the wall velocity to \mathbf{u} , β and α :

$$\mathbf{v}_{\text{steady}} = (\beta / \alpha) \mathbf{u} \quad (4)$$

$$\mathbf{v}_{\text{prec}} = (1 + \alpha \beta) / (1 + \alpha^2) \mathbf{u} \quad (5)$$

The simulations showed that β plays a very important role: it can lead to the presence or absence of one of the above mentioned regimes in a velocity versus current density curve. Indeed there are three possibilities:

Case $\beta=0$ For $J_{\text{app}} < J_c$ the magnetization in the DW tilts towards the hard axis reaching a maximal value of 45° when $J_{\text{app}} = J_c$. Because the force exerted by the current on the wall is equilibrated by an internal restoring force the motion of the DW can not be maintained and the wall velocity goes quickly to zero. For high current densities, the internal force is defeated by the force from the current, the wall starts to precess becoming periodically Bloch/Neel and moves with a finite velocity in the direction of the current.

Case $\beta=\alpha$ leads to a new kind of motion: the DW motion occurs for all current densities, without any changes in the wall structure, the wall velocity being always equal to the velocity-like quantity \mathbf{u} .

Case $\beta \neq 0$, α gives a “normal” behavior of the DW, where both the translation and oscillatory regime are present.

In Figure 1 a summary of the behavior of the DW under the influence of a spin-polarized current is shown. J_c is 20^{10} A/m^2 ; the corresponding highest possible value for the DW velocity is around 100 m/s ($\beta=0.02$). The transition region between the two linear motion regimes is quite narrow and one can remark that finally all the curves tend towards the $\beta=\alpha$ line.

The next step in our study is to determine the effect on pinning on the DW motion. Unfortunately this is a very controversial subject, as there is no proper definition of pinning centers. Thus several scenarios have to be taken into account: geometrical constrictions, anisotropy distribution, etc.

Fast magnetization switching with short pulses.

W. Scholz¹, T. M. Crawford², T. W. Clinton¹, T. Ambrose¹, S. Kaka¹, S. Batra¹

1. Research, Seagate, Pittsburgh, PA; 2. USC NanoCenter, Univ. of South Carolina, Columbia, SC

In this paper we study the magnetization reversal process of single domain Stoner-Wohlfarth particles subject to short pulses using analytical and numerical models. We investigate the effect of short unipolar and bipolar field pulses, which are applied perpendicular to the magnetocrystalline anisotropy axis, on the magnetization switching dynamics (cf. Fig. 1a). We find very fast precessional switching events (<100 ps) with field amplitudes down to about 1/4 of the Stoner-Wohlfarth switching field (cf. Fig. 1b), which is lower than the fast sub-Stoner-Wohlfarth switching described previously.[1,2] Our full micromagnetic simulations of nanodots confirmed that fast precessional switching with short field pulses is possible for technologically relevant magnetic nanostructures with sufficient margins for variations in the material parameters and timing. This mechanism of fast precessional switching [3,4,5] with short pulses at low fields could find important applications in magnetic recording or magnetic random access memory devices. We show that (theoretically) even smaller switching fields are possible which are even independent of the anisotropy field.

Micromagnetic Simulations of Domain Wall Depinning Forced by Oscillating Fields.

O. Alejos Ducal¹, E. Martínez Vecino², L. López Díaz³, L. Torres Rincón³

Notches in thin ferromagnetic strips may act as pinning centers for the domain walls (DW) existing in them, due to the locally lowering of the DW magnetostatic energy associated to the presence of the notch, that is, the formation of a pinning potential well. The analysis of DW depinning from notches has acquired a certain technological relevance due to its application to promising logic and storage devices [1].

The work presents the study of the DW dynamics under the application of an in-plane magnetic field directed along the largest dimension of the strip. The strip has a couple of symmetric notches placed on it, where a head-to-head DW has been pinned. The applied field is composed of two terms: a constant value plus a harmonically oscillating one. The constant part B_0 is fixed to five different values lower than the required constant field to force the DW depinning. The amplitude B_z of the harmonic part is then investigated in order to produce this depinning for different frequencies.

As the theoretical model proposed in [2] predicts, a resonant behavior can be observed if the frequency of the harmonic field is near the DW natural oscillation frequency (see Fig.1). However, the resulting DW energy absorption peak is not centered at this natural oscillation frequency, and it shifts to lower frequencies.

This result can be explained if it is considered that the DW structure noticeably changes as the DW oscillates by the effect of the applied field. In fact, its width shrinks so that the DW equivalent mass increases. This increase is thought to be the responsible for the frequency shifting.

Effects of Shape Anisotropy on the Walker Breakdown Field in Field-Driven Domain Wall Motion.

W. Kim¹, S. Jung², H. Lee², K. Lee¹

1. Korea University, Seoul, South Korea; 2. POSTECH, Pohang, South Korea

I. Introduction

Recently, the domain wall (DW) motion in nanowires has received a considerable interest because magnetic DWs can be used for logic [1] or information storage devices [2]. In the field-driven DW motion, DW velocity decreases with increasing magnetic field when the field magnitude is larger than a certain value, i.e. the Walker breakdown field (H_W) [3, 4]. The Walker breakdown is caused by DW precession around the in-plane easy axis. Because an out-of-plane tilting of DW costs energy due to shape anisotropy, it has been believed that the H_W increases with the shape anisotropy. In this work, using micromagnetic studies, we show that the H_W is almost independent of the shape anisotropy because of the anti-vortex injection during the DW precession.

II. Numerical and Theoretical Approaches

We performed 1-dimensional (1D) and 2-dimensional (2D) micromagnetic simulations and compared numerical results with theoretical ones. Micromagnetic simulations are based on the Landau-Lifshitz-Gilbert equation (Eq. (1)).

$$\partial \mathbf{M} / \partial t = -\gamma \mathbf{M} \times \mathbf{H}_{\text{eff}} + \alpha / M_s (\mathbf{M} \times \partial \mathbf{M} / \partial t), \quad (1)$$

where the gyromagnetic ratio (γ) is $1.76 \times 10^7 \text{ s}^{-1} \text{ Oe}^{-1}$, α is the Gilbert damping constant ($= 0.02$), M_s is the saturation magnetization ($= 800 \text{ emu/cm}^3$), H_{eff} is the effective field including the external field applied along the in-plane easy axis of the nanowire, the magnetostatic field, and the exchange field (exchange constant $= 1.3 \times 10^{-6} \text{ erg/cm}$). A head-to-head transverse wall (TW) is initially placed in a rectangular-shaped $\text{Ni}_{80}\text{Fe}_{20}$ nanowire with cross-sectional area of 720 nm^2 and length of $5 \mu\text{m}$. The unit cell dimension is $4 \times W \times T \text{ nm}^3$ in 1D model and $4 \times 4 \times T \text{ nm}^3$ in 2D model, where W is the width and T is the thickness of nanowire. The aspect ratio ($= W/T$) is varied to examine the effect of shape anisotropy on the H_W . We also performed a theoretical study through a use of the collective coordinate approach with variables of DW position, tilting angle, and DW width [5].

III. Results and Discussions

Fig. 1a (1b) shows numerical results of 1D (2D) micromagnetic simulations. In 1D model, the H_W clearly increases with the shape anisotropy whereas in 2D model, it does not vary much. Another interesting point is that in 1D model, the field ($= H_{\text{max}}$) for the maximum velocity is smaller than the H_W . In 2D model, however, the H_{max} is identical with the H_W .

All the results including theoretical ones are summarized in Fig. 1c. The H_W and H_{max} obtained from 1D model show excellent agreement with theoretical ones. From the collective coordinate approach, we obtained analytical formula of the H_W (Eq. 2) and H_{max} (Eq. 3).

$$H_W = \alpha K_{\perp} / M_s, \quad (2)$$

$$H_{\text{max}} = (\alpha K_{\perp} \sin 2\phi_{\text{max}}) / M_s, \quad (3)$$

where $\sin 2\phi_{\text{max}}$ is $[\sqrt{(K^2 + K \times K_{\perp}) - K}]^{1/2} / \sqrt{K_{\perp}}$, K_{\perp} is the hard-axis anisotropy ($=$ shape anisotropy) and K is the in-plane easy axis anisotropy which determines equilibrium DW width. The coefficient $\sin 2\phi_{\text{max}}$ appears in the Eq. (3) because the DW velocity is proportional to the DW width which varies with the external magnetic field. Because the $\sin 2\phi_{\text{max}}$ is smaller than unity, the H_{max} is always smaller than the H_W in case of rigid DW.

In 2D model, the DW shows the periodic oscillatory motion with cyclic transformation between the TW and the anti-vortex wall (AVW) at $H > H_W$ as reported in Ref. [6]. We attribute the disagreement

between 2D model and theory (or 1D model) to the AVW formation. In 1D model, the tilting angle of DW measured from the wire plane at H close to H_W is almost 90° . In 2D model, however, the tilting angle is 90° at a vertex of triangular shaped DW, but is only 45° in other parts of DW. In case of uniform precession as in the theory or 1D model, the energy cost for the DW precession originates from the demagnetization energy and thus the shape anisotropy directly affects the H_W . In case of AVW formation as in the 2D model, however, the energy cost originates from the exchange energy, not the demagnetization energy. Therefore, the H_W in 2D model is almost independent of the shape anisotropy.

IV. Conclusion

We investigated the effect of shape anisotropy of nanowires on the Walker field through the use of the micromagnetic modeling and the collective coordinate theory. It was found that the Walker field is almost independent of the shape anisotropy in contrast to the theoretical prediction. It is because the DW precession occurs by the periodic transformation between a transverse wall and an anti-vortex wall.

Testing the theory of nucleation in infinite square prism—micromagnetic simulations.

K. M. Lebecki

Institute of Physics, PAS, Warsaw, Poland

Analytical solutions are rare in micromagnetism, thus they are all the more valuable. Among them are theories of nucleation field of infinitely long structures. They are still popular due to recent interest in one-dimensional ferromagnetic samples. Infinite circular cylinder model is already well known and has been compared with many experiments and simulations. Less known theory of circular tube can also be helpful, as increasing number of authors report successful growth of ferromagnetic nanotubes. The case of infinite prism is more complicated, as no exact analytical solution is known. Brown has calculated the upper and lower bounds for the nucleation field of a square prism [1]. Aharoni suggests that theory of infinite circular rod can be employed in this case, if only an appropriate cross-section area factor is taken into account [2].

We compared these theories with simulations. We used publicly available micromagnetic simulations package OOMMF [3]. To account for infinite sample length we applied periodic boundary conditions (PBC) in one dimension. For that purpose, an algorithm implementing PBC with high accuracy was used [4]. The results of our modeling show qualitative agreement with the above-mentioned theory, see Fig. 1.

Fig. 1. Coercivity obtained by simulation (open points) and nucleation field predicted by the theory (lines) [1, 2], versus the square prisms half-base, a . Due to the rectangular shape of the hysteresis loop the coercivity and the nucleation field can be directly compared. Dotted- and dashed- lines concern the curling mode. Solid line represents the coherent mode. Insets show sample cross-sections of the simulated structure. Magnified in-plane magnetization component for two different cases is presented here, $a = 0.5$ and $a = 4$. These snapshots were taken just before abrupt change of the magnetization direction.

Finite difference and edge finite element approaches for dynamic micromagnetic modeling.

A. Manzin¹, B. Van de Wiele², O. Bottauscio¹, M. Chiampi³, L. Dupré², F. Olslager⁴

1. Istituto Nazionale di Ricerca Metrologica, Torino, Italy; 2. Department of Electrical Energy, Systems and Automation, Ghent University, Ghent, Belgium; 3. Department of Electrical Engineering, Politecnico di Torino, Torino, Italy; 4. Department of Information Technology, Ghent University, Ghent, Belgium

The development of ultrahigh density storage media has led to an increasing attention towards the numerical integration of the Landau-Lifshitz (LL) equation [1]. However it is difficult to define validation procedures for establishing the accuracy of the computational codes. Analytical relationships can be obtained only under simplifying assumptions about geometry and physical properties. Moreover, the comparison with experiments is made difficult due to the nanometer dimensions of the samples and to the need of reproducing the exact working conditions. Hence, it is useful to define test bench problems as the ones proposed by the Micromagnetic Modeling Activity Group of NIST or to compare different numerical approaches. To this aim, this paper presents two 3-D micromagnetic algorithms, differing both for the space-time solution of the LL equation and for the magnetostatic field evaluation. In the first procedure (#1) the magnetic body is discretized using identical cubic finite difference cells, while the time integration is performed with a semi-analytical predictor-corrector scheme able to preserve the constraint on the magnetization amplitude [2]. To reduce the computational burden, the magnetostatic field is calculated by fast Fourier transforms, starting from the Green formulation of the Poisson equation. In the second procedure (#2) the spatial discretization of the LL equation is handled by a finite element method, employing tetrahedral elements and edge vector shape functions for the magnetization approximation [3]. The time evolution is handled by a finite difference scheme based on the middle point rule [4]. The magnetostatic field is obtained by solving the Poisson equation with a hybrid finite element/boundary element method, in order to treat the open boundary condition.

To evidence the accuracy of the numerical schemes, the simulation results are compared to the ones obtained using the NIST/OOMMF code, focusing the attention on switching phenomena in magnetic thin films.

As an example, Fig 1 reports the time evolution of the magnetization component subjected to reversal in the case of damping switching ($\alpha=0.02$), considering only the magnetostatic and Zeeman terms. The rectangular film (500 nm x 250 nm x 5 nm) lies in the x-y plane. The reversal is obtained by applying an external field almost antiparallel to the initial magnetization state, which makes an angle of 10 degrees with the z-axis. With method #1 the film is discretized with cubic cells having side of 2.5 nm. With method #2 a coarser discretization is used, refining the mesh towards the edges (spatial step $\Delta s = 10.8$ nm) with respect to the sample centre ($\Delta s = 21.6$ nm) to account for demagnetizing fields. One subdivision is imposed along the film thickness.

In the fast precessional switching case (Fig. 2), the same film is subjected to an external field applied along the y-direction, and an initial magnetization along the x-axis. When accounting for the exchange contribution, algorithm #1 needs a small time step to ensure convergence ($\Delta t = 7.5$ fs). Method #2 requires the introduction of a regular mesh with spatial step $\Delta s = 8.3$ nm (smaller than the exchange length), in order to reach more accurate results. However, the mesh refinement leads to a high computational burden mostly in the evaluation of the magnetostatic field.

The comparison with the NIST/OOMMF code evidences how, with an appropriate choice of the space and time discretization parameters, both procedures give accurate results.

Computation of magnetization normal oscillations and resonant frequencies for ferromagnetic nanoparticles.

M. d'Aquino¹, C. Serpico², G. Miano², G. Bertotti³

1. Dipartimento per le Tecnologie, Università di Napoli "Parthenope", Napoli, Italy; 2. Dipartimento di Ingegneria Elettrica, Università di Napoli "Federico II", Napoli, Italy; 3. Istituto Nazionale di Ricerca Metrologica (INRiM), Torino, Italy

The determination of the resonances of ferromagnetic particles has great importance in the study of magnetization dynamics driven by microwave applied fields. In typical experimental situations, a small magnetic nanoparticle is saturated by applying a sufficiently strong DC magnetic field along a given direction. Small magnetization motions around this state are then excited by applying a small (compared to the DC component) radio-frequency (RF) applied field. In this condition, the ferromagnetic resonance curve is obtained by slowly varying the RF field frequency and measuring the power absorbed by the particle. From the observation of the peaks in this curve one determines the frequency values corresponding to the excitation of certain magnetization normal modes. In order to treat this problem from the theoretical point of view, analytical approaches limited to particles of special shapes were proposed by Brown and Aharoni[1]. Recently, numerical computations of normal modes for particles with generic shapes have been the focus of considerable research[2,3].

We propose a general formulation of the problem for arbitrarily shaped particles in terms of eigenvalue problem for suitable linear self-adjoint operators. This approach naturally leads to straightforward numerical computations of magnetization normal modes when a spatial discretization is introduced, for instance based either on finite difference or finite element methods. From the theoretical point of view, magnetization dynamics is described by the Landau-Lifshitz-Gilbert equation (LLG). The effective field takes into account exchange, magnetostatic, uniaxial anisotropy and Zeeman interactions. We assume that the particle is saturated along the z-axis by the DC field. Therefore, the equilibrium configuration is aligned with the cartesian unit-vector along the z-axis. The small oscillations of the magnetization around the saturated state are studied by linearizing the LLG equation around the equilibrium configuration. The analysis is carried out in the frequency domain.

For a given applied field, the problem of finding the (normal) resonant modes of the ferromagnetic particle, usually referred to as exchange-magnetostatic modes, consists in determining the values of the frequencies for which the linearized LLG equation admits nonzero solutions.

We formulate this problem as an eigenvalue problem involving appropriate linear self-adjoint operators acting on vector fields in

L^2 . Details on these operators, their spectral properties and the orthogonality conditions for the normal modes will be given in the full paper.

This approach has several advantages as far as the numerical computation of the normal modes is concerned: i) particles of arbitrary shape can be considered; ii) the discretized operators can be assembled by using the classical exchange and magnetostatic operators implemented in both finite differences and finite elements micromagnetic codes; iii) the discretized version of the continuum eigenvalue problem is a standard self-adjoint matrix eigenvalue problem which can be efficiently solved with well-established techniques of linear algebra; iv) the solution of this problem gives directly all the resonant frequencies and the normal magnetization modes.

In order to test the effectiveness of the proposed technique, we have computed the normal oscillation modes and the resonant frequencies of a magnetic square thin-film subject to a saturating DC field along the z-axis. Here a spatial discretization based on finite differences has been used. Some results of the computation are reported in fig. 1. We observe that the first resonant mode is spatially (quasi) uniform. More numerical results will be reported in the full paper.

Nanoscale time resolved images of magnetization dynamics induced by spin torque [1] have shown that the switching takes place through inhomogeneous magnetization spatial configurations. This fact points out the necessity of using full micromagnetic modeling to describe accurately the magnetization reversal mechanisms. In the last two years, magnetic tunnel junctions with high tunnelling magnetoresistance (MgO) have been one of the most investigated systems due to their potential for device applications in magnetic storage [2].

In this digest, micromagnetic simulations of nanopyllars of CoFeB(8nm, exchange biased fixed layer) / MgO(0.8nm) / CoFeB(4nm, free layer) with elliptical cross sectional area (90nm x 35nm) [2-4] are presented. Differently to previous works [3,4], we focus this study on the temperature dependence of the switching mechanisms. Furthermore, the effect of the non-uniform spatial distribution of the current density which depends locally on the resistance during the magnetization switching process is also considered. Temperatures from 50 K to 300K are analyzed in steps of 50K, computing for each case 50 stochastic realizations, in order to make reliable statistics. In Fig. 1 the average switching from the Anti Parallel State (APS) to the Parallel State (PS) is shown at both 50 and 300 K, while in Fig. 2 the PS to APS transition is presented. In both cases, an external field of 50 mT is applied along 'x' direction (long axis of the ellipse) and positive or negative current densities of 10^7 A/cm² are applied respectively. It can be observed how the effect of the temperature is higher in the PS to APS transition which indicates an asymmetry in the energy barrier. Finally, in Fig. 3 the dependence of the average switching time (defined as the time elapsed till the magnetization crosses zero) with temperature is depicted. The thermal activation helps the PS to APS switching producing a decrease of the switching time with temperature.

Effect of Sawtooth Shape on Switching Process of Write Head.

S. Wang¹, D. Wei¹, K. Gao²

1. Dept. of Materials Science and Engineering, Tsinghua University, Beijing, China; 2. Seagate Technology Seagate Technology, Bloomington, MN

Micromagnetic simulation is widely utilized to simulate magnetic recording read write process. Due to irregular shape of the write head, 3D micromagnetic simulation is required. Magnetostatic interaction is one of the most time and memory consuming aspects in micromagnetic simulation. Previously, there are two primary approaches [1,2]. The first is based on the regular mesh but utilize 3D FFT for magnetostatic field calculation. This approach in principle can be fast and accurate, but have issue to deal with arbitrary geometry and typically require extensive memory. Due to small discretization cell used in this approach, simulation time is also very significant. The other approach is based on irregular mesh; for the magnetostatic interaction, the simulation follows the same approach as FEM calculation. This approach in principle can be accurate and with reasonable speed since away from the point of interest, the mesh size can be large. However, it is arguable that too large size of the mesh may lead to incorrect results in dynamic simulation, especially for the region where domain wall motion dominates. Until now, there is no good approach to be both accurate and fast in simulation time. In addition, no appropriate method has been found to give accurate measure of the two previous approaches in term of accuracy. Thus, accurate study here will be extremely important for both recording simulation, especially for write head and Spin-RAM application due to irregular shape nature of the basic cell structure.

In this paper, we investigate the effect of sawtooth shape [3,4] on simulation results of switching based on micromagnetic simulation. The analytical calculation of demagnetization matrix for isosceles right-angle triangular prism has been done. In this work, static states of write head and reversal of magnetization in the direction perpendicular to medium (y-axis) are studied.

In simulation, the main pole of write head, with a total thickness of 40nm, is divided into 10nm×10nm×10nm clusters in Model A (all clusters are cubic) and Model B (clusters at hypotenuse are triangular prism). Magnetic parameters for material simulated are shown in table 1. Static states (with zero external field) in Model A and B are illustrated in Fig.1. The static states in Model A and Model B have slight difference.

The evolution of scaled averaged magnetization $m_y(t)$ are demonstrated in Fig.2. The reversal properties of magnetization are studied with a 24,000Oe driving magnetic pole applied on the top surface of main pole. Several differences can be found for $m_y(t)$ in Model A and Model B. Firstly, difference between two models is not very large but evident when $m_y(t)$ is between -0.4 and -0.9. Secondly, reversal of magnetization is slightly swifter in Model A. Thirdly, the saturated domain pattern in Model A and Model B are similar. And finally, the averaged ultimate magnetization $m_y(t)$ reaching the required error in Model A and Model B are also similar.

Micromagnetic study of read sensitivity: Influence of curved hard bias and granular media.

L. Wang, G. C. Han, S. G. Wu, B. Liu

Spintronics, Media and Interface, Data Storage Institute, Singapore, Singapore

Hard biases (HBs) are indispensable to stabilization of free layers in various read heads. Transfer curve [1], [2], initial magnetization [3], and microtrack profile (read sensitivity) [4], [5] have been utilized to study stabilization properties and read performance. Almost all the HB shapes studied are non-curved with an exception in [4]. However, there have been other scopes in [4] and hence detailed examinations of curved hard biases by micromagnetics are lacking. Meanwhile, curved HBs are also of practical interest [6].

By using FEM micromagnetics, we here model curved hard bias with various shapes (see Fig. 1) and focus on their influences on microtrack profiles. Media is integrated in the simulation. For simplicity and speed-up, reference layer and shield layers are not considered. For comparison, rectangular HB and the case without HB have been simulated. Some typical parameters used are: free layer: track width (TW) x thickness x stripe height = $10 \times 2 \times 8$ (nm³); hard bias: width x thickness x height = $10 \times 6.666 \times 8$ (nm³); media: width x length x thickness = $1 \times 10 \times 6$ (nm³). The gap between FL and HB (FL and media) is 2 (1) nm. The damping constant is 0.2.

Fig. 2 shows the corresponding microtrack profiles. Important observations are: (i) The microtrack profile without HB is asymmetric. Such asymmetry has been identified that part of media field can act as forward or backward bias on the FL magnetization. (ii) The introductions of HBs result in better symmetry, compared to the case without HB. Thus, the symmetry of microtrack profile can be a signature of good HB stabilization. (iii) Case (e) – wall taper HB leads to better sensitivity, compared to cases (b), (d), and (c). (iv) Microtrack profiles of cases (b), (d) and (c) are nearly overlapped and approach that of case (c) (cf. the inset of Fig. 2). Normalized results also confirm such approaching trend. Geometrically (cf. Fig. 1), one may gradually transform from (b), to (d), and then to (c). (v) Symmetric and non-symmetric HBs respectively result in smooth and oscillatory profiles when the free layer is on track. Fortunately such oscillations are fairly small (see the inset of Fig. 2).

We have varied the position of the free layer along the HB thickness direction and found that generally speaking, the obtained profiles are smooth when the middle points of the FL and HB thicknesses are aligned. Note, however, that: (i) For case (d), the microtrack profiles can be still smooth with a larger variation range along the HB thickness direction, compared to other cases; (ii) For case (b), when the FL is near the upper-right corner, the profile is smooth and less sensitive due to shorter gap and hence larger stabilization.

Furthermore, for case (b), we have varied the base point of the curve along the HB width direction and found that hard bias with longer curve (with HB thickness unchanged) has larger signal. But this does not mean that the longer curve, the better the read performance. The tradeoff is that the microtrack profile may become asymmetric for the hard bias with very long curve (with HB thickness unchanged).

We have also performed MRW₁₀ and MRW₅₀ analyses and we conclude that curved hard biases, as long as they are properly designed, are capable of stabilizing free layers resulting in smooth, sensitive and symmetric microtrack profiles.

In above simulations, uniform medium were used. The effects of granular media on microtrack profile can also be considered. Some observations are: microtrack profile is sensitive (insensitive) to intergranular saturation magnetization (intergranular anisotropic and exchange constants).

Remanence analysis of nanocrystalline, epitaxial SmCo_5 films in high pulsed fields up to 35 T.

V. Neu, J. Freudenberger, A. Singh, L. Schultz

Institute for Metallic Materials, IFW Dresden, Dresden, Germany

The remanent magnetization as a function of the maximum applied magnetic field of a permanent magnet starts from zero for the fully demagnetized state, increases and then eventually saturates. The field required for this full saturation will depend on the anisotropy and easy axis distribution and can reach several ten Tesla in highly anisotropic Re-Co materials.

In this paper we study the magnetization process of nanocrystalline, SmCo_5 films, which are grown epitaxially such that the c-axes are oriented along two perpendicular in-plane directions of the single crystal $\text{MgO}(100)$ substrate [1]. A typical SmCo_5 (11-20) pole figure measurement and an appropriate sketch of the easy axis distribution is seen in Fig. 1. Starting from the demagnetized state, the magnetization is measured in increasingly higher fields up to 7 T in a VSM along the $\text{MgO}[001]$ direction. For even larger fields, the film has been additionally magnetized in the IFW High Pulse Field Laboratory at 10, 15, 25, and 35 T and after each field pulse the hysteresis was measured in a field cycle of ± 7 T. Minor loops are shown in Fig. 2a up to 10 T. For higher magnetizing fields the hysteresis is largely identical with the outermost curve. The coercivity and the remanent moment as a function of the maximum applied field show a rather modest increase until about 1 - 2 T, when the first irreversible magnetizing processes lead to a steep raise, and level off at about 5 T (Fig. 2b). Whereas coercivity reaches real saturation, there is a small but measurable increase in remanence for the highest fields (see Fig. 4).

We interpret the observed field dependent remanence as originating from a combination of the particular easy-axis distribution and a $1/\cos\theta$ angle dependency of the switching field as known for domain wall de-pinning. The idea is sketched in Fig. 3, where the easy axis distribution of the film is given as the superposition of two Gaussian distribution functions around the $\text{MgO}[001]$ and $\text{MgO}[010]$ direction. θ denotes the angle between the easy axis and the applied field. From previous angle dependent measurements, it is known, that the switching field closely follows a $1/\cos\theta$ law [2], which is scaled with the overall coercivity of $\mu_0 H_c = 3.4$ T. Due to the texture spread of a few degrees, grains with θ close to 90° will also switch magnetization (e.g. from Γ to III^+) if the applied field exceeds $H_c(\theta)$. This is exemplified by the shaded area under the distribution function. The effect on the remanence will be small due to the small projection of the magnetization vector onto the field axis, but will depend very sensitively on the width of the distribution function.

The increase of the remanence above the plateau is calculated by a spherical integration of the parallel moment component over the Gaussian distribution function up to a threshold angle θ_{\max} determined from the applied field and the coercivity function. The result for a distribution width of 8° compares very well with the experimental data (Fig. 4). The performed remanence analysis after magnetization in high pulsed magnetic fields thus proved to be a successful method to clarify the magnetization process and determine the angular distribution spread of these highly anisotropic, well textured SmCo_5 films.

Effect of Ga addition on the magnetic properties of $\text{Nd}_{60}\text{Fe}_{30}\text{Al}_{10-x}\text{Ga}_x$ alloy.

W. Kaszuwara, B. Michalski, M. Leonowicz, J. Latuch

Faculty of Materials Science and Engineering, Warsaw University of Technology, Warsaw, Poland

Effect of additional elements on the magnetic properties of Nd-Fe-Al alloys has been a subject of extended studies. It has been reported that partial substitution of Nd by Y stabilizes the RFe_2 (R – rare earth element) phase, which leads to decrease of the remanence. Substitution of Fe by Co, up to 5%, increases both the coercivity and remanence. However, for higher Co contents the remanence deteriorates. Similarly addition of Ni, up to 10%, leads to remanence growth, which for higher Ni contents abruptly decreases. On the other hand Ni addition does not affect the coercivity. All these elements, for some concentrations, improve the tendency for producing an amorphous-like structure. Substitution of Si for Al improves the coercivity of the magnets, which is, however, accompanied by small deterioration of the remanence [1]. Silicon addition is advantageous in rapidly solidified ribbon alloys only, because the Si deteriorates the ability for amorphisation; bulk material contains too large fraction of the crystalline phase. The ability for amorphisation decreases also with addition of boron [2]. On the other hand B, substituting Al, improves the coercivity and deteriorates the remanence.

The literature reports prove that addition of the fourth element in the Nd-Fe-Al system appears to be an effective method for improvement of the magnetic properties. In this study the effect of Ga for Al substitution in the $\text{Nd}_{60}\text{Fe}_{30}\text{Al}_{(10-x)}\text{Ga}_x$ (in at.%) system was analyzed.

The master alloy was prepared from elemental Nd, Fe Al and Ga with a purity of 99.9%, or better, by arc melting in a titanium-guttered argon atmosphere. The bulk samples were cylindrical in shape (rods) with a diameter of 1mm. They were prepared by casting the material into a copper die. The alloys were melted in a quartz crucible by induction and pushed into the die by helium over-pressure.

Magnetic measurements were done using a Lake Shore vibrating sample magnetometer. As-cast rods were characterized by XRD. Thermal analysis was performed differential scanning calorimeter (DSC) at a heating rate 40K/min.

Substitution of gallium for aluminum leads to substantial growth of the coercivity up to 384 kA/m for $x=8$ (Fig.1). For higher Ga contents the coercivity decreases down to 104 kA/m. The remanence is constant up to $x=8$ and for higher Ga concentrations abruptly decreases. The saturation magnetization (measured in a field of 1600 kA/m) changes in the similar way. Astonishingly the saturation magnetization and remanence for the alloy containing $x=10$ Ga is exceptionally high. The Ga addition also substantially affects the hysteresis loop shape (Fig.2). For the low Ga contents the shape of the initial magnetization curve points to the existence of domain walls pinning centers; for $x=0-8$ the initial susceptibility changes in a range of 740×10^{-6} – 380×10^{-6} emu/gGs. For $x=10$ the magnetic susceptibility equals to $4,6 \times 10^{-3}$ emu/gGs, and the initial magnetization curve shows a shape characteristic of the demagnetization mechanism by nucleation of domain walls.

X-ray diffraction (XRD) (Fig.3), showed that growing Ga content results in a higher intensity of diffraction peaks and formation of new crystalline phases. Effect of Ga on the amorphisation ability is analogous to that presented in the literature for Si and B [1,2]. On the other hand, for the Ga contents in a range $x=1-8$, a remarkable increase of the coercivity, without loss of the remanence, is observed.

Ab initio calculation of the magnetic structures in Nd₂Fe₁₄B/ α -Fe nanocomposite materials.

Y. Toga, H. Tsuchiura, A. Sakuma
Applied Physics, Tohoku University, Sendai, Japan

1) Introduction

Exchange-spring magnets are nanocomposite materials that are composed of hard- and soft-magnetic phases that interact by magnetic exchange coupling. These are promising systems for advanced permanent magnetic applications because they are expected to have a large energy product compared to conventional single-phase materials. The magnetic properties of these systems are significantly affected by the nanocomposite structure. This implies that the electronic structure of the system is susceptible to the grain boundaries. Thus it is crucial to have information on the electronic states near the grain boundaries in exchange-spring magnets. Here we study the electronic states near the boundaries between Nd₂Fe₁₄B(hard) and α -Fe(soft) multilayers, as a mock-up of exchange-spring magnets, by using ab-initio calculation based on the density functional theory (DFT).

2) Calculation method and model

In this work, DFT calculations have been used to determine all structural, energetic, and electronic results. The Kohn-Sham equations are solved self-consistently in a projector augmented-wave (PAW) method, in conjunction with the generalized gradient approximation (GGA) which describe the electron-ion interaction, as implemented in the Vienna ab initio simulation package (VASP)³⁻⁴⁾.

The calculations were performed for two kinds of structures. The first structure is a multilayer film of Nd₂Fe₁₄B(100)/ α -Fe(110) as shown in Fig. 1(a) where the commensurate structure is achieved by a lattice expansion of the Fe lattice as much as about 3% within the (110) plane. The second structure is a multilayer film of Nd₂Fe₁₄B(001)/ α -Fe(001) shown in Fig. 1(b), where the expansion of the α -Fe lattice is 3% within the c-plane. We investigate mainly the magnetic structure of each system in Fig. 1, varying the interfacial spacing between Nd₂Fe₁₄B and α -Fe. The number of the α -Fe(110) layer we consider is 4 to 8, and for the Nd₂Fe₁₄B layer we consider two unit cells both for (100) and (001) stacking systems

3) Results

Figure 2 shows the total energies of (a) Nd₂Fe₁₄B(100)/ α -Fe(110) and (b) Nd₂Fe₁₄B(001)/ α -Fe(001) multilayer systems as functions of the interfacial distance. The solid and dashed lines correspond to the parallel (P) and ant-parallel (AP) configurations, respectively, of magnetic moments of Nd₂Fe₁₄B and α -Fe layers. In Nd₂Fe₁₄B(100)/ α -Fe(110) structure, the total energy has minimum at an interfacial distance of 1.8Å for both the P and AP configurations, which is a little bit smaller value than the (110) interlayer distance of bulk α -Fe. We should stress here that the AP configuration is stable around the equilibrium spacing (1.8Å), whereas the P configuration is stabilized in rather large spacing. This result is robust against the number of Fe layers. The distribution of the magnetic moments at the equilibrium spacing (1.8Å) is plotted in Fig. 3. It is found that the moment in α -Fe reaches to that of bulk α -Fe ($\sim 2.2\mu_B$) in a few layers from the interface. At the equilibrium spacing, the interfacial exchange coupling of Nd₂Fe₁₄B(100)/ α -Fe(110) is estimated to be $-29\text{erg}/\text{cm}^2$. In Nd₂Fe₁₄B(001)/ α -Fe(001), on the other hand, we observe that the P configuration is always stable in the region of the realistic interfacial distance. The interfacial exchange coupling at the equilibrium spacing ($\sim 2.2\text{\AA}$) is about $120\text{ erg}/\text{cm}^2$ which may be around 10 times larger than the values expected from measurements²⁾.

Nanostructure and Magnetic Properties of Nd-Fe-B Thin Film Fabricated by UHV Sputtering.

D. Ogawa¹, T. Akiya², M. Oogane¹, H. Kato^{2,3}, Y. Ando¹

1. Department of Applied Physics, Tohoku University, Sendai, Japan; 2. New Industry Creation Hatchery Center (NICHe), Tohoku University, Sendai, Japan; 3. Department of Applied Mathematics and Physics, Yamagata University, Yonezawa, Japan

Although exchange-coupled hard / soft nanocomposite magnets are predicted to exhibit remarkably high maximum energy product $(BH)_{\max}$ beyond 100 MGOe [1], it is not easy to achieve such high values experimentally. However, recent progress in thin-film fabrication technique enabled us to obtain Sm-Co/Fe-Co multilayer films which exhibit $(BH)_{\max}$ value of 32 MGOe, being larger than that of the commercially available bulk-type SmCo sintered permanent magnets [2]. In such multilayer geometry, however, the interface area between hard and soft phases is smaller and the exchange coupling become less effective than that for random dispersed geometry. Therefore, we have been fabricating nanophase-dispersed hard / soft thin films with crystallite orientation of hard phases [3]. Magnetization values of these films, however, were much smaller than the bulk values owing to the existence of non magnetic phases, resulting in low $(BH)_{\max}$ values. In this paper, we tried to make a higher magnetization Nd-Fe-B thin film by using a UHV sputtering system, which is a first step of our project to realize the nanophase-dispersed $\text{Nd}_2\text{Fe}_{14}\text{B}/\alpha\text{-Fe}$ thin films with high $(BH)_{\max}$ values.

Thin films were deposited by dc-magnetron sputtering onto SiO_2 substrates in an Ar atmosphere. The base pressure of the sputtering system was below 2×10^{-6} Pa. Thin films have the form of $\text{SiO}_2/\text{Ta}(t_{\text{Ta}} \text{ nm})/\text{Nd-Fe-B}(40 \text{ nm})/\text{Ta}(10 \text{ nm})$. In order to achieve higher orientation and magnetization, we adjusted various parameters such as substrate temperature during sputtering (T_s), Ar pressure (P_{Ar}), and Ta buffer layer thickness (t_{Ta}). Sputtering power was fixed at DC 150W. In order to obtain information about the degree of alignment, average grain size and volume fraction of each phase, we made a Rietveld analysis of X-ray diffraction patterns. Magnetization curves were measured at room temperature by using VSM and SQUID with the maximum applied field of 15 kOe and 50 kOe, respectively.

Fig.1 shows the example of an observed X-ray diffraction pattern. It should be noted that the Miller index l of strong reflections is large, such as (105) and (006). This indicates that the c -axis of $\text{Nd}_2\text{Fe}_{14}\text{B}$ grains are well oriented along the direction perpendicular to the film plane. The result of Rietveld analysis is shown by the solid line in Fig. 1, which tells us that the half width of distribution of c -axis directions, $\Delta\theta$, is about 7° along the normal of the film plane.

The reflections at $2\theta = 30^\circ$ and 62° could be indexed as those of fcc-type [4] Nd oxide. The volume fraction of NdO phase was estimated to be about 4% according to the Rietveld analysis. It is possible to roughly estimate the average grain size d_{cry} from the full-width with half maximum (FWHM) of reflections by using the Scherrer's formula. We found that d_{cry} increases with increasing substrate temperature T_s , and reaches about $d_{\text{cry}} = 30 \text{ nm}$ for $T_s = 600^\circ\text{C}$.

We also found that the magnetization value depends strongly on the Ar gas pressure and takes a maximum at $P_{\text{Ar}} = 0.7 \text{ Pa}$. The maximum magnetization value is 15 kG, which is comparable with the bulk value. We then fixed the two parameters as $P_{\text{Ar}} = 0.7 \text{ Pa}$ and $T_s = 600^\circ\text{C}$, and adjusted the Ta-buffer thickness. Fig. 2 shows the coercivity H_c and $(BH)_{\max}$ as a function of Ta-buffer thickness, t_{Ta} . Both H_c and $(BH)_{\max}$ exhibit a maximum around $t_{\text{Ta}} = 5 \sim 7 \text{ nm}$. Magnetization curves shown in Fig. 3 are those for the film with $t_{\text{Ta}} = 5 \text{ nm}$, which yields $(BH)_{\max}$ of $36 \pm 7 \text{ MGOe}$.

Nd-Fe-B magnet is known as a permanent magnet, and it has been widely applied for sensors, actuators and motors [1]. Also a lot of studies have been done not only for bulk samples but also thin films [2][3]. Recently, a further improvement of magnetic properties of Nd-Fe-B magnet is required due to an increase of a number of hybrid vehicles by environmental situation. In order to improve the magnetic properties of Nd-Fe-B magnet at high temperature environment, heavy rare earth elements such as Dy and Tb have been necessary added. Furthermore, the effect of Nd rich phase or oxide phase existing at the grain boundary has not been cleared yet. In this study, in order to understand the coercivity mechanism, we have studied the effect of the introduction of heavy rare earth elements such as Nd and Nd₂O₃ to Nd-Fe-B film.

The samples were prepared using an ultra high vacuum sputtering system. The base pressure is below 5×10^{-8} Pa. Cr seed layer of 1 nm was deposited on MgO(100) substrate, and consecutively an epitaxial Mo buffer layer of 20 nm was grown at room temperature (RT). The Nd-Fe-B layer is co-deposited of Fe, Nd and B at the substrate temperature of 625°C. The thickness of Nd-Fe-B layer was changed from 2 to 50 nm. The heavy rare earth layers of 1 nm is deposited at RT and then the sample was heated up to 600°C. Finally, a Cr capping layer of 1nm was deposited at RT to avoid the oxidation. The magnetic properties were measured by a superconducting quantum interference device (SQUID) magnetometer. The film composition was determined by electron probe micro analyzer (EPMA). The structure was examined by the X-ray diffractometer (Cu K α). The surface morphology was observed by an atomic force microscope (AFM).

Magnetization curve of Nd-Fe-B thin films with introducing rare earth layers, Nd layer (a), Nd₂O₃ layer (c) and without capping layer (b) are shown in Fig.1. The film thickness of Nd-Fe-B layer is fixed at 3 nm. The coercive force H_c of 17.4 kOe was obtained at the film without rare earth capping layer. With introducing a Nd layer, enhancement of H_c of 22.6 kOe was obtained. However, on the contrary, H_c was drastically decreased to 4.5 kOe for the film with Nd₂O₃ layer. From this results, Nd layer plays an important role for increasing the hard magnetic property.

Refinement of surface morphology of Nd-Fe-B thin film by low temperature deposition.

H. Kato¹, I. Honda¹, T. Sato², T. Shima¹

1. Faculty of Engineering, Tohoku Gakuin University, Tagajo, Japan; 2. Toyota Central R&D Labs., Nagakute, Japan

More than 2 decades have been passed since the discovery of Nd₂Fe₁₄B compounds [1]. Since then, Nd₂Fe₁₄B magnets have been widely used for many applications such as sensors and motors. Due to a high maximum energy product, a lot of studies have been performed for Nd-Fe-B sputtered films [2, 3] and it was found the crystal structure of Nd₂Fe₁₄B is generated from the interface between substrate and/or buffer layers [4]. In particular, downward growth of strongly textured Nd₂Fe₁₄B columnar grains can be prepared by triggering crystallization of sputter deposited amorphous Nd-Fe-B layer by the deposition of crystalline Cr overlayer [5]. Since hard magnetic properties and the microstructure of Nd-Fe-B films were strongly affected by a number of deposition parameters. In this study, in order to control the surface morphology of sputtered Nd-Fe-B films, two kinds of preparation methods were adopted. One is a low temperature deposition (LTD) procedure and post-annealing at high temperature after a capping layer was deposited at room temperature (RT). The other is a high temperature deposition (HTD)

Samples were prepared using a dc-magnetron sputtering system. The base pressure was under 5.0×10^{-8} Pa. A Cr seed layer of 1nm was deposited on a MgO(100) single crystal substrate, and consecutively an epitaxial Mo (001) buffer layer of 20nm was grown at RT. Nd-Fe-B layer was co-deposited at substrate temperature (T_s) in the range between RT and 700 °C. Also the samples were annealed at T_a in the range between RT and 700 °C for 1 hour. The nominal thickness t of Nd-Fe-B layer was varied from 10 to 100 nm. The magnetic properties were measured by super conducting quantum interference device (SQUID) magnetometer. The structure analysis was performed by X-ray diffractometer. The film composition was determined By electron probe micro analyzer (EPMA)

From the X-ray diffraction profiles, the peaks from the c-plane of the Nd₂Fe₁₄B phase (such as 004, 006 and 008) were clearly observed at HTD samples. However, no remarkable peaks were also observed at LTD samples. Magnetization curves of LTD and HTD films are shown in Fig.1. The detailed procedure of LTD and HTD films are as follows, LTD: Nd-Fe-B film was deposited on Mo buffer layer at 300 °C and then the film was post-annealed at 625°C for 1 hour. HTD: Nd-Fe-B films was deposited on Mo buffer layer at 625°C. The coercivities measured in the perpendicular direction $H_{c\perp}$ of LTD and HTD film are 17.5kOe and 12kOe, respectively. It is confirmed from an atomic force microscope image, the surface of LTD film is flatter than that of HTD film. High $H_{c\perp}$ was achieved at LTD film. It is thought to due to the refinement of surface morphology.

Enhancement of coercivity for Nd-Fe-B thin films with Tb and Dy layer.

T. Sato¹, N. Oka², H. Kato², T. Shima²

1. Toyota Central R&D Labs., Inc., Aichi, Japan; 2. Faculty of Engineering, Tohoku Gakuin University, Tagajyo, Japan

Nd₂Fe₁₄B alloy [1] has been practically used as a magnetomotive force for applications such as motors, actuators and sensors, because it has a large magnetocrystalline anisotropy and a high maximum energy product. In particular, the consumption of Nd-Fe-B sintered magnets has been increased by the expansion of hybrid vehicles' (HVs) market for environmental and energy issues. One of the problems for Nd-Fe-B sintered magnets is using heavy rare earth materials (Tb, Dy, etc.) to enhance of the coercivity H_c at high temperature use. Recently, another problem of the amount of material resources has been occurred and it urges us to reduce the amount of these elements. Furthermore, the coercivity of Nd-Fe-B magnets is actually lower than the theoretical nucleation field [2] and the reason for the difference has not been clarified yet. In this study, in order to elucidate the mechanism of the coercivity of Nd-Fe-B magnets, we have investigated the magnetic properties of the Nd-Fe-B thin films covered with rare earth elements (RE) such as Tb and Dy layers.

The Cr (1 nm) / Mo (20 nm) / Nd-Fe-B / Tb or Dy (1 nm), w/o / Cr (10 nm) films were prepared onto single-crystal MgO(100) substrates using an UHV-compatible dc-sputtering apparatus (base pressure of $< 1 \times 10^{-8}$ Pa). The nominal thickness for Nd-Fe-B layer t was varied from 2 to 50 nm. The films were heated at 625 °C during the deposition of Nd-Fe-B layer, and then the films were annealed at 600 °C for 1 hr after depositing RE layer. The magnetization curves were measured in the applied magnetic field perpendicular to the film plane by using a superconducting quantum interference device (SQUID) magnetometer in the field up to 55 kOe (for some cases, 70 kOe). The structural analysis was performed by an x-ray diffraction with Cu-K α radiation. All measurements were performed at room temperature.

The x-ray diffraction patterns from Nd₂Fe₁₄B compound, NdFe₄B₄ compound, and Mo were observed for all films. The orientation relationship among the substrate and the layers is (001)_{MgO} // (001)_{Mo} // (001)_{Nd₂Fe₁₄B}. Fig. 1 shows the changes of H_c of Nd-Fe-B films by covering with Tb and Dy layers. For comparison, the film without a capping layer is denoted. For all films, H_c increases with decreasing t and shows a maximum at less than $t = 8$ nm. With further decreasing t , H_c decreases. The maximum value of H_c for the Nd-Fe-B film without RE layer was 21 kOe at $t = 8$ nm. The initial magnetization curve indicated that the film is a mixture of single-domain states and multi-domain states [2]. On the other hands, H_c was enhanced for the film with RE layer. The maximum value of H_c was 36 kOe for the film with Tb layer at $t = 3$ nm, and 30 kOe for the film with Dy layer at $t = 5$ nm. Since these initial magnetization curves increased slowly with the applied magnetic field, the magnetization process is mainly governed by a rotation of the magnetization. The enhancement of the coercivity of Nd-Fe-B films by covering with RE layer is thought to be due to the formation of RE₂Fe₁₄B phase, whose anisotropy field is twice larger than the value of Nd₂Fe₁₄B phase [4].

FePt-based nanocomposite ribbons as exchange coupled magnets.

A. Crisan^{1,2}, O. Crisan¹, N. Randrianantoandro², I. Skorvanek³

1. National Institute for Materials Physics, Bucharest-Magurele, Romania; 2. Laboratoire de Physique de l'Etat Condense, Université du Maine, Le Mans, France; 3. Institute of Experimental Physics, Slovak Academy of Sciences, Kosice, Slovakia

The interest for FePt based alloys increased recently due to their outstanding potential for technological applications as, for example, magnetic recording media, magnetic field sensors, and exchange spring magnets. In the form of nanocrystalline alloys, these nanocomposite spring magnets have high corrosion resistance and exhibit, upon appropriate annealing, the ordered hard magnetic tetragonal L10 FePt phase with a large magnetocrystalline anisotropy. In this study, we focus on the magnetic and crystalline microstructure of melt spun Fe51Pt27Nb2B20. The sample was prepared by melt spinning technique in Ar controlled atmosphere. The analysis of the crystal structure of sample and the phase composition was examined by X-ray diffraction (XRD) using a Bruker G8 diffractometer with Cu K α radiation. The magnetic measurements were done with a superconducting quantum interference device (SQUID), with the applied field up to 5 T, parallel to the ribbons plane. Annealing of the as-cast sample has been done at 500°C for 30 minutes followed by another 30 minutes at 600°C. Other annealings were performed at 700°C for 40 minutes and 2 hours respectively. The annealings were done in an inductive furnace with strict control of the temperature under Ar atmosphere. It can be observed that the XRD spectra (Fig. 1) of annealed samples exhibit sharp Bragg peaks, indicating the high degree of crystallinity in these samples. On the contrary, the as-cast state was found to be mainly a mixture of an amorphous state with a nanocrystalline solid solution of apparently cubic symmetry, as proven by the very broad lines in the diffraction spectrum and the indexation of their Bragg reflections that correspond mainly to the f.c.c. cubic FePt-rich solid solution. As the samples are annealed, the microstructure evolves into refining the width of the Bragg reflections, kept at the same angular position. This result proves that the incipient nucleation sites with a cubic symmetry from the as-cast state, evolve into larger nanocrystals but keeping the same crystal symmetry. The main phases that are indexed in the XRD spectra of annealed samples are mainly the f.c.t. L10 FePt and f.c.c. A1 FePt, together with small amount of boride, formed in later stages of annealing by polymorphic crystallization of the remaining amorphous phase. The average crystallite size in the as-cast state was 4.2 nm as determined by Scherrer's formula, corrected for instrumental broadening. Upon annealing, the grain size increases, since both tetragonal FePt and cubic FePt crystallizes from the initial solid solution. But the values, even at annealing temperatures as high as 700°C and for annealing times as great as 2 hours, are still below or around 15 nm. This shows that upon annealing the obtaining microstructure is formed by small enough grain so that the requirements for an exchange spring magnets to be fulfilled.

The magnetic measurements performed with a superconducting quantum interference device (SQUID) at 5K (Fig. 2) show outstanding exchange spring behavior for the annealed samples, compared to the as-cast sample that is essentially a soft magnet with high saturation magnetization and virtually no hysteresis. The annealed samples show extremely high coercivity values of 14.5 kOe at 5K, that are comparable with the nanocomposite exchange spring magnets reported in the literature and important values of the remanent magnetization, which gives an extremely elevated energy product that makes the signature of a very performant exchange spring magnet.

In conclusion, an amorphous melt spun ribbons of the composition Fe51Pt27Nb2B20 has been synthesized by the rapid solidification technique and its microstructure and magnetic properties were

studied. After appropriate annealing, an ordered L10 phase is formed and this produces magnetic hardening of the alloy. The annealed samples show co-existence of hard and soft magnetic phase, a two-phase behavior accompanied with a well-refined grain microstructure. These features are the key issues for the extremely high coercivity values that we have obtained here, values that are comparable with the best exchange spring magnets reported in the literature.

Genetic algorithm for Jiles-Atherton parameters optimization.

F.A. Cuéllar¹, A. Mendoza²

1. Physics Department, Universidad Nacional de Colombia, Bogotá, Colombia; 2. Grupo de Materiales Magnéticos y Nanoestructuras, Universidad del Quindío, Armenia, Colombia

The Jiles-Atherton Model (JAM) of Ferromagnetic Hysteresis[1], which expresses the magnetization process in soft-magnetic materials, based mainly on domain walls motion; has been used to analyze the pinning behavior depending on different materials characteristics[2,3]. The model parameters are coupled between them, and to the measurement temperature; besides, these parameters depend also on the particular characteristics of the samples. Mathematically, the JAM expresses the Magnetization in terms of Magnetic Field by means of the differential equation: $dM/dH = (M - M_{an}) / [(\delta k / \mu_0) - \alpha (M_{an} - M)]$; the solution equation has a convergence condition expressed as an inequality between two parameters ($a > k$), and is a redundant in M derivatives summation[1]: $M = \sum [(-1)^n (k\delta)^n L^n((H + \alpha M)/a)] + \delta C(H_{max})$. Where k is the Pinning; δ is ± 1 depending on the field direction; L^n is the n-th derivative of the Langevin Function; α is the Mean Field Constant; a is the Thermal Fluctuation term and C is an integration constant. Jiles et al. purpose that some model parameters can be expressed not only as constants but as functions of other physical quantities; taking this into account, Fecioru-Morari et al. have purposed a Gaussian Function to stand for pinning[4]; this modification improves fitting of the H-M curves to the JAM, and was implemented in this work. To surpass the redundant characteristic, an iterative system was used to calculate the magnetization. The redundant characteristic makes more difficult to find the parameter values when fitting. Based on the above described characteristics of the JAM and the solution equation, it was necessary to implement a parameters optimization system to easily fit experimental curves. In a Genetic Algorithm (GA) each individual is represented by its chromosome, which is composed by its set of genes (in our case JAM parameters). The individuals are tested in their environment and their development is evaluated using the Fitness Function. GA's also include Mutation mechanisms. When the whole population has reached the convergence limit, the algorithm is ended and the solution individual is the best fitted among all of them. The GA here presented has the following characteristics: The Search Space is defined from characteristic values of the hysteresis experimental curve. The GA is real coded. The Fitness Function is a Least Squares (LS) calculation, made point by point between the experimental and simulated curves. Generation 0 is created randomly in the Search Space. Reproductive Trials are assigned using Fitness Ranking Technique. Population Size must be a multiple of four. Parents Selection is realized choosing two individuals to mate from different Ranks. Uniform Crossover was used to create the offspring, and total population replacement was adopted. The Crossover technique creates non valid individuals because they do not complain the solution's convergence condition ($a > k$); thus, the GA remaps them by mutating the non valid gen. Two mutation mechanisms were implemented, Random Mutation and Exploratory Mutation, the first one mutates a random gen into a random value; the second one mutates a decisive gen by changing it in a small quantity to obtain a finer adjust of parameters. The ending criterion was based on the population's convergence, when their mean deviation is lower than 0.5% the GA is ended. An experimental curve measured from a NiZn ferrite thin film, grown by RF sputtering technique at a deposition temperature of 600 K, is shown in Fig. 1; inset shows the set of fitted parameters. Since it is not possible to know the individual parameters influence over the whole curve, the uncertainty is expressed as a percentage of curve deviation (C.U.). Pinning parameter k_0 is expressed in terms of the sample's volume. Acknowledgments: This work was par-

tially supported by COLCIENCIAS under Research Project 1106-05-17612 and CENM, under contract 043-2005.

Angle Difference between B vector and H vector in Anisotropic Electrical Steel.

K. Fujisaki^{1,2}, S. Satou³

1. Technical Development Bureau, Nippon Steel Corporation, Futtsu-city, Japan; 2. Graduate School of Environmental Studies, Tohoku University, Sendai-city, Japan; 3. N-Teck Ohita Corporation, Ohita-city, Japan

Introduction

Since electrical steel has superior magnetic property, it is used as a material of motor or transformer and then expected to be solving the environment and CO2 problem. When magnetic flux density B is related to magnetic field H as the magnetic property, the usual magnetic property is treated as though B vector was parallel to H vector. However, measurement data reported that B vector was not parallel to H vector and then there is an angle difference (θ_{BH}) between B vector and H vector [1]. Since it is expected to be important to clarify the mechanism of the angle difference (θ_{BH}) between B vector and H vector to design the electrical motor as well as electrical steel, numerical model is considered to obtain the angle difference (θ_{BH}) between B vector and H vector.

Numerical Magnetic Property Model

The angle difference between B vector and H vector is observed in measured magnetic property of grain oriented steel (GO) as well as non-oriented steel (NO) as shown in Fig. 1. In Fig. 1, where GO steel is used, B vector is controlled to be rotational as sinusoidal wave. Then the angle of B vector (θ_B) and the angle difference between B vector and H vector (θ_{BH}) is defined as Fig. 2. Since the magnetic field is not sinusoidal, the angle difference (θ_{BH}) is clearly observed as shown in Fig. 1 (c). According to the measurement data [1], the angle difference (θ_{BH}) of GO changes from -90 deg to $+50$ deg as shown in Fig. 1 (c), though the one of NO changes from $+10$ deg to $+45$ deg. Then the strong anisotropic characteristics such as GO material seems to have large angle difference (θ_{BH}).

To express the strong magnetic anisotropic characteristics, we consider the finite element method model in which steel bars and air are arranged reciprocally in two dimensions plane as shown in Fig. 3. The longitudinal direction of the steel bar is considered to be in easy axis of this model and the orthogonal direction in which the steel bar and air are arranged reciprocally is considered to be in transverse axis. Outside the region arranged the steel bar and air, external magnetic field H_{ext} is supplied by means of the four edge boundary conditions. At a center of the region, an equivalent area A is considered as shown in Fig. 3. The average magnetic flux density vector B_{ave} and the average magnetic field vector H_{ave} are introduced from the average of B vector and H vector respectively in an equivalent area A. The external magnetic field H_{ext} is controlled so as that B_{ave} and H_{ave} are sinusoidal. The average B_{ave} and H_{ave} are expected to have strong magnetic anisotropic property.

Calculation Results

The results are shown in Fig. 4. The magnetic flux density at the center region A in Fig. 4 is sinusoidal. The calculated angle difference (θ_{BH}) changes from -90 deg to $+90$ deg. This characteristic is the same as the measurement one. The difference between the calculation and the measurement is considered to be an effect of hysteresis which is ignored in the calculation model. The angle difference (θ_{BH}) is considered to be derived from the magnetic anisotropic characteristics.

Data collapse and viscosity in three-dimensional magnetic systems.

A. Adedoyin, A. Petru

Electrical and Computer Engineering, Florida State University, Tallahassee, FL

Viscosity phenomena in magnetic systems have drawn much attention in the last decade mainly because of their negative implications in the magnetic recording industry. At temporally constant external conditions the total magnetization of a magnetic system exhibits a relatively slow but irreversible loss of its magnetic history, which is usually detrimental for the time reliability of recording information. The viscosity coefficient, generally defined as $S(H,T) = dM/d(\log t)$ (where t is time, H is the applied field, T is the temperature, and M is the magnetization) can be approximated as $S(H,T) = S_0(T) * f(H/H^*(T))$, where f is a temperature independent function. The universality of the above scaling has been referred to as data collapse in magnetic viscosity. This scaling has been verified by both theoretical computations and experimental measurements [1] in isotropic materials by assuming that the direction of the magnetization is along the direction of the applied field (scalar models). In this work we investigate for the first time the validity of the above scaling technique to vector models of hysteresis for both the isotropic and anisotropic cases.

The generalization of scalar viscosity coefficient to vector magnetic systems [2] is challenging particularly because the trajectory of the magnetization in the case of vectorial relaxation phenomena (see Fig. 1) can deviate substantially from a straight line [3]. However, we show that the geometrical length of the magnetization “creep” (computed in integral form) depends approximately linearly on $\ln t$. This observation allows us to define the vector magnetic viscosity coefficient in a way that is consistent with the generally accepted definition for scalar magnetization and investigate data collapse phenomena in vectorial systems. Sample simulation results for the vector viscosity coefficient as a function of the applied field are presented in Fig. 2. These simulations were performed for an isotropic system in which a strong magnetic field was first applied to saturate the sample, then decreased to some fixed value, rotated, and kept constant. After that the components of the magnetization vector were recorded as a function of time and the vector viscosity coefficient is computed. At $t = 0$ the magnetization vector is not align along the direction of the applied field, hence both the direction of the magnetization vector and its magnitude are changing slowly. Surprisingly, one can observe that the viscosity as a function of the magnetic field does not show the usual “bell-shaped” curves but has one or more peaks depending on the past magnetic history of the sample. The *multiplicity of these peaks is a pure vectorial effect* and their origin seems to be attributed to rotational changes of the magnetization during aftereffect. It is apparent from the figure that the data collapse phenomena fail for viscosities measured in multidimensional systems mainly because of the multiplicity of peaks on the viscosity curves.

A concise mathematical definition of the viscosity coefficient for vectorial magnetization processes will be presented at the conference. Simulation results for the vector viscosity phenomena in isotropic and anisotropic media will also be presented and discussed. The aftereffect phenomena are modeled by using the vector Preisach model of hysteresis in which thermal perturbations are modeled by a stochastic magnetic field superimposed over the external applied field [4]. The expected values of the magnetization as a function of time are computed by using the Monte Carlo method [3], which proves to be a computationally efficient approach that can be applied to any vector model of hysteresis such as the vector Jiles-Atherton, Energetic, or Della Torre models.

A Simplified Iron Loss Model for Laminated Magnetic Cores.

E. Dlala

Department of Electrical Engineering, Helsinki University of Technology, Espoo, Finland

The modeling of electromagnetic devices containing laminated cores requires an adequate description of the properties of the magnetic material. The shape of the dynamic hysteresis loop has to be modeled, and hence the power iron loss is predicted under arbitrary magnetization conditions. This means that an impeccable, systematic procedure that starts from a static hysteresis model must be embraced with Maxwell equations (diffusion equation). The excess loss related to the magnetic viscosity, which is also rate-dependent, needs to be included through the dynamization of the static model.

The diffusion equation of the lamination is non-linear, hysteretic, and time-dependent and thus requires an iterative time-stepping procedure. Moreover, when, for example, the 1D diffusion equation is integrated into the 2D finite-element analysis of electrical machines, convergence problems and complications are inevitably faced [1], [2].

On the other hand, the delay in the magnetic flux density

B behind the field strength H resulting from the solution of the diffusion equation can be achieved differently and more efficiently without its solution. In the work of [3], an illustration of this idea was provided by considering a differential equation that delays its input with respect to the real value. Another similar method that is based upon two components, hysteresis and eddy currents, applied to grain-oriented materials has been introduced in [4].

In this article, we propose a methodology based on the procedure introduced in [5], and later refined in [6], to model, in a simple manner, the dynamic hysteresis loop, and hence the iron loss. The idea is to separate the magnetic field strength into three components, which are responsible for the static hysteresis, classical eddy-current, and excess losses. The drawback in [6] is that the $B(H)$ relation is assumed to be linear in the calculation of the classical eddy-current loss, and thus the model is applicable only in the frequency

range where the skin effect is negligible, or to magnetic cores with low conductivities or thin sheets.

This article aims to generalize model [6] in which the effect of the non-linearity on the classical eddy-current loss is considered. It is well known that the eddy-current loss is dependent on the $B(H)$ relation, especially at saturation, where the skin effect becomes insignificant. Here, the dependency of eddy currents on non-linearity is achieved through the use of a non-linear function.

The proposed model can be applied to the prediction of core losses in non-oriented and grain-oriented materials. Here, numerical results of a non-oriented laminated steel of electrical machines are shown and compared with experiment. The simplified model has been identified for a soft magnetic steel of a thickness $d = 0.5$ mm and conductivity $\sigma = 2.2 \times 10^6$ S/m. Figure 1 shows the model predictions of dynamic hysteresis loops compared with experiments. It is clear that when the effect of the non-linearity was considered, the model produced accurate results in good agreement with experiment.

Modeling of Vector Hysteresis of Soft Magnetic Composite Material.

Y. Guo¹, H. Lu², J. Zhu¹, Z. Lin¹, J. Zhong¹, S. Wang³

1. Faculty of Engineering, University of Technology Sydney, Sydney, NSW, Australia; 2. Faculty of Information Technology, University of Technology Sydney, Sydney, NSW, Australia; 3. Faculty of Electrical Engineering, Xi'an Jiaotong University, Xi'an, China

1. Introduction

Thanks to the unique magnetic properties, soft magnetic composite (SMC) materials and their application in electromagnetic devices have achieved significant development in the past decade [1]. A typical example of SMC application is the electrical machine with complex structure [2], in which the magnetic flux is basically rotating. To design and analyze such devices, vector magnetic properties of the core material should be properly determined, modeled and applied.

This paper presents the modeling of vector magnetic hysteresis of SMC based on a Stoner-Wohlfarth (S-W) elemental operator. A phenomenological mean-field approximation is used to consider the interaction between particles [3]. With the presented model, the magnetization processes of SMC under both alternating and rotating fluxes are numerically simulated. The simulations have been verified by experimental measurements.

2. Modeling of Vector Hysteresis

Under a magnetic field H , the magnetic moment m_s of an S-W particle rotates to the orientation which results in a minimum energy. The position of m_s changes with respect to H , and the domain rotation can be reversible or irreversible. The equilibrium orientation of m_s can be evaluated by the asteroidal rule in the plane containing H and the easy axis as shown in Fig.1, where H_e and H_p are the H components along the easy axis and the perpendicular direction respectively, $H_k = 2K/(\mu_0 m_s)$, and K is the domain crystal anisotropy constant.

A mean field term is added to account for the macroscopic effect of interaction between S-W particles [4], $H_{eff} = H + kM$, where k is a constant feedback coefficient and can be theoretically determined from experimental data [5]. The contribution of an S-W particle can be expressed by $M = S(H_{eff})$, where $S()$ stands for the S-W model.

The bulk material can be considered as a collection of many S-W single domain particles and the total magnetization is the vector sum of contributions of all these constitute domains. In numerical implementation, the magnetization is computed by the vector sum of m_s of a group of magnetic particles.

3. Numerical Implementation

The magnetization processes of SMC with isotropic magnetic properties under both alternating and rotating magnetic fields have been simulated numerically. The results (Fig.2 and Fig.3) show that in an isotropic magnetic material M and H vector are collinear for an alternating magnetic field excitation, while for a rotating magnetic field excitation of constant magnitude M vector lags the H vector for a certain angle.

The detailed implementation process and more simulation results will be presented in the full paper.

4. Experimental results

The B-H relationships of SMC samples under various alternating and 2-D and 3-D rotating magnetic excitations have been measured by the authors[6]. The simulation and experimental results will be compared and analyzed.

Analysis of the local material degradation near cutting edges of electrical steel sheets.

G. Crevecoeur¹, P. Sergeant¹, L. Dupre¹, L. Vandenbossche¹, R. Van de Walle²

1. *Departement of Electrical Energy, Systems and Automation, Ghent University, Ghent, Belgium;* 2. *Department of Electronics and Information systems, Ghent University, Ghent, Belgium*

The introduction of stresses and strains caused by cutting processes on electrical steel, induces an alteration of the local magnetic properties of the material. Electrical machine manufacturers are often not aware of how the magnetic material is degraded quantitatively near the cutting edge. In order to be able to incorporate the material degradation into the design of electrical machines, it is necessary to characterize the local change of the magnetic properties in an accurate way.

The conventional way of performing local magnetic flux measurements on soft magnetic materials is the search coil method. This method however is destructive, while the method used in this paper – the needle probe method – is non-destructive, see [1]. The needle probe method enforces a certain magnetic induction in a steel sheet. Potential differences, which are dependent on the local material characteristics, are measured on the surface of the steel sheet, see Fig. 1.

This paper mainly deals with the interpretation of the measured needle potentials, i.e. the link between the measured needle signals and the local mechanical state of the material, and with the validation of the proposed method. The determination of the mechanical state uses a numerical ‘forward’ model of the material with the mechanical state as input and the needle potentials as outputs. As the inputs are unknown, the problem is an inverse problem. By using the numerical procedure, developed theoretically in [2], we are able to interpret the needle signals.

The numerical model is a 2D finite element model (FEM) with a material model, a Preisach distribution function (PDF), which fully characterizes the magnetic material. Two possibilities exist for building the PDF: propose an analytical expression for the PDF or build a so-called Everett PDF. Using an analytical Lorentzian expression of the PDF, discrepancies occur between calculated and measured hysteresis loops for plastically deformed samples. See Fig. 2, where a measured needle potential is compared with the closest calculated needle potential, using an analytical Preisach model. Therefore, we introduce the use of an Everett PDF, where the PDF is obtained directly from a set of measured hysteresis loops, following the Everett theory, see also [3]. This paper uses the local mechanical state, i.e. the plastic strain, of the material as material parameter. The link between the mechanical state (plastic strain) of the material and the magnetic material characteristics (Everett PDF) is made by macroscopically deforming the steel sheet for several levels of plastic deformation and to build the Everett PDF for these levels of plastic deformation.

A fully processed non oriented steel sheet designated as 800-50 A (thickness 0.5mm, 1.3% Si) was cut using a continuous CO₂-laser. Results of the locally recovered magnetic properties show that the degraded zone can extend to 3 mm from the cutting edge. The local peak differential permeability can be 5 times lower in the degraded zone and a local magnetic hardening is observed.

In order to validate the approach, proposed in the present paper, for the local identification of the magnetic properties, we numerically calculate the global macroscopic hysteretic characteristics of the steel sheet and compare these global characteristics with the macroscopic BH-loop measured on the strip. Indeed, differently cut steel sheets, have different macroscopic BH-loops. The local material degradation influences the global behaviour of the steel sheet. Loss increase, coercive field, etc., describe macroscopically the material behaviour and are used for making the comparison possible. The comparisons show that a fully characterized magnetic material (through an Everett PDF) is a better means for locally characterizing the magnetic material.

The needle probe method: the needle potentials are dependent on the local material characteristics, which spatially vary (different material properties in the N subregions).

Measured relative needle potential near cutting edge of a steel sheet and closest simulated potential using a Lorentzian PDF (at 50 Hz). The needle potential can not be accurately simulated using the Lorentzian PDF, as indicated in the box. The correspondence between measured and computed signals is improved by using an Everett PDF.

Modelling of magnetostrictive material and linear controlling of nonlinear magnetostrictive drive system based on SVM.

J. An, Q. Yang, Z. Ma, H. Chen, L. Hou, W. Yang, F. Liu
hebei university of technology, Tianjin, China

Abstract—The disadvantages of the nonlinear dynamical system identification method based on neural networks are analyzed in this paper. A SVM method to construct inverse model of magnetostrictive material is presented. And the linear control of nonlinear magnetostrictive drive system is achieved. Simulative result indicates that the method presented in this paper can effectively construct the inverse model and well compensate for the hysteretic nonlinearity of magnetostriction actuator.

I. INTRODUCTION

Because of the needs of predicting and controlling the unknown system, system model identification[1-2] has become a very important topic. To a nonlinear system, there is not a standard method for system modeling yet, thus the study on identification methods and application of nonlinear system model has caused great attention of scientific researchers. At present, the researches of modeling black box system mainly concentrate on neural-networks-based method[1-2].

Support Vector Machine [3] is a new method based on statistical learning theory. we present a SVM method of modelling and controlling for magnetostrictive material. The better effects are obtained.

II. A practical control system of magnetostrictive material

Under the action of magnetic field, the magnetostrictive material can repeat stretching and shortening. For a magnetostrictive drive system, Fig.1 is the experiment data curve of the length change of magnetostrictive rod with the change of exciting coil current.

III. ON-LINE IDENTIFICATION OF NONLINEAR SYSTEM WITH SVM

To such a complicated multivalued function nonlinear system, how to get a better mathematical model quickly and how to apply it to prediction control at the same time, are very important to improve the precision of precise processing.

For such a complex nonlinear system, in this paper, we apply SVM to the identification and control of the black-box system.

A. Construction method of one-step prediction model.

To identify the nonlinear system of micro-shift driving that is introduced in this paper, two methods are used, which is SVM method presented in this paper and neural network method. The output error of SVM one-step prediction model is shown in Fig.2.. Fig.3 is the one-step prediction output error of model trained with RBF neural network.

B. Result of simulation.

We can see that the output of one-step prediction have very high accuracy from the error curves in Fig.2. The time each training needs is only 0.02s when a new sample is added, so it can be applied to on-line prediction control of many systems. Therefore whether from the training speed or from the accuracy of one-step prediction, the performance of the present method is far better than that of the RBF neural network method.

IV. CONTROL GIANT MAGNETOSTRICTIVE ACTUATOR WITH SVM

In the control of actual system, in order to improve control effect, we expect that the relation between the system input and output is linear even though most of the actual system is nonlinear.

In order to solve the problem, we utilize the nonlinear mapping and self-learning ability of SVM to construct online inverse model of giant magnetostrictive actuator.

To the SVM direct control system in Fig.4, from the simulation result in Fig.5 we can see that the inverse model constructed with SVM can compensate for the hysteretic nonlinearity of actuator and the SVM direct control system achieves the linear control of nonlinear system.

V. CONCLUSIONS

The performance of the SVM method presented in this paper is better than that of the RBF neural network method.

we compensate for the hysteretic nonlinearity of actuator and achieve the linear control of a nonlinear system.

Modelling hysteresis of a first order magneto-structural phase transformation.

V. Basso¹, M. Lo Bue², C. P. Sasso¹, M. Küpferling¹

1. INRIM, Torino, Italy; 2. SATIE, ENS Cachan, CNRS, UniverSud, Cachan, France

Phase transitions where two or more interacting order parameters are involved have been the object of many theoretical studies since Bean and Rodbell paper of 1962 [1]. However the comprehension of hysteresis effect related to the presence of structural disorder remains a major problem

For example the evaluation of the magneto-caloric entropy change associated with magneto-structural phase transformations requires a detailed comprehension of the role played by hysteresis. We have recently introduced a phenomenological description of first order hysteretic phase transformations by means of a statistical distribution of independent bistable contributions [2]. The idea is that, in presence of several intensive variables, i.e. the temperature T and the magnetic field H , the driving force of the transformation is the difference of the Gibbs free energies g_0 and g_1 of the two metastable phases. Hysteresis is then given by to the superposition of bistable loops describing the phase fraction X as a function of the difference of the Gibbs free energies $Z = (g_0 - g_1)/2$. Each bistable change state at the thresholds $g_u + g_c$ and $g_u - g_c$. g_u and g_c are parameters describing the local properties of the material modified by defects and impurities (Fig.1a). Then, while g_0 and g_1 are intrinsic properties of alloy, the statistical distribution of the bistables $p(g_c, g_u)$, takes into account the quenched disorder in the material.

This approach has been recently applied to describe the magneto-structural transformation of Gd-Si-Ge alloys [3] and to predict the entropy change and the entropy production of the material. For that material the magnetic field and temperature dependence of the functions $g_0(H, T)$ and $g_1(H, T)$ were extracted from a set of isothermal hysteresis loops and it was shown that a good agreement with the data was achieved by a distribution $p(g_c, g_u)$ independent of H and T .

This is however not the case for all materials with magneto-structural transitions. In this respect a good example is given by the behavior of the MnAs alloys [4,5]. Here the coercivity decreases when the temperature is increased and eventually disappears when the tricritical point is approached.

In order to describe MnAs one has to allow the distribution $p(g_c, g_u)$ to change with the temperature T . To do this we have to extend the model. Here we follow the approach of Ref.[6]: we introduce the temperature dependence in $p(g_c, g_u)$ by scaling functions. I.e. we limit to describe temperature dependence in which all the bistables rescale in the same way. Having two variables g_c and g_u , we have to introduce two scaling functions: $G_c(T)$ and $G_u(T)$. Normalized variables are $z_c = g_c/G_c(T)$ and $z_u = g_u/G_u(T)$. Normalized driving force is $z = Z/G_u(T)$ and the distribution is $p_z(z_c, z_u) dz_c dz_u = p(g_c, g_u) dg_c dg_u$.

The internal state of the system is due to the time history of $Z(t)$. In Fig.1b it is shown an example of a borderline $b(g_c)$ separating in the (g_c, g_u) plane, the region of phase 0 from those in phase 1. With the normalized variables the line in the plane (z_c, z_u) is $b_z(z_c) = b(g_c)/G_u(T)$. The normalized line has to be always inside the triangular region of Fig.2c, i.e. $|b_z(z_c) - z| \leq z_c G_c(T)/G_u(T)$. In the normalized plane the distribution is temperature independent.

With this extended model we obtain a new expression for the entropy. We have an extra term that was not present in the expression for the constant distribution. The expression for the out-of-equilibrium Gibbs free energy is Eq.(1) (see equations in Fig.2 right), where $A = (g_0 + g_1)/2$. The entropy is Eq.(2). From that one obtains Eq.(3), where X is the phase fraction given by the model (Eq.(4)) and Y (Eq.(5)) is an integral in the (z_c, z_u) plane depending on the distribution. This is the new term appearing because the distribution depends on T . The importance of the term and its physical

meaning will be clarified in the paper by the application of the model to the the literature data on MnAs of Refs.[4,5].

The Preisach distribution and the symmetry of the local hysterons in strongly interacting nanoparticulate systems.

R. Tanasa, A. Stancu

Department of Physics, "Alexandru Ioan Cuza" University, Iasi, Romania

The Major Hysteresis Loop of a collection of magnetic nanoparticles is typically symmetric with respect to the origin. The Preisach model [1] starts from the hypothesis that every particle from this physical system is described by a rectangular local hysteron loop shifted along the field axis (see Fig.1).

Recently, improvements in the experimental techniques, like Magnetic Force Microscopy or Magnetization induced Second Harmonic Generation opened the perspective to perform accurate measurements at the nanometer level in nanostructured systems like patterned media [2] or nanowires [3].

Actually, this type of measurement was already performed and essentially confirmed the validity of the existence of non-symmetric local hysterons [4]. However, when the experimental Preisach distribution calculated as a superposition of these local hysterons is used for the calculation of higher order magnetization curves the results are quite far from the experimental results.

In this paper we are analyzing the physical motivation of this disagreement by investigating the switching at fundamental level on others magnetization curves like the First order reversal curves. Our goal was to record the switching fields from negative to positive saturation H_α of a selected number of particles, like those who have H_β (positive to negative switch) the same with coercive field because in this case we have the biggest number of elements and our statistical results are significant.

We have simulated a nanostructured perpendicular medium (similar to patterned media) using an Ising type model in which each particle has an intrinsic anisotropy. The switching of particles was calculated with a typical Metropolis algorithm in which the energy barrier for each particle was evaluated with the Stoner-Wohlfarth model.

We have simulated a number of reversal curves with reversal field between minimum saturation ($-H_m$) and the coercive field ($-H_c$) (see Fig. 2), to record H_α for selected particles and in the end to calculate the average value and the dispersion. We repeated the procedure for different values of the lattice parameter, d , and the results are presented in Figs.3 and 4. When interactions are negligible, $d=4$, all particles switch at the same positive field $H_\alpha=3$ regardless the reversal curve. The situation changes dramatically for the more interacting systems. For example, we observe that for $d=1$ the same particles switches at a field H_α three times bigger than the absolute value of the negative switching field for the same particle. Their local hysteresis loop is strongly asymmetrical. One observes in this way that the same physical particle will not switch at the same fields on FORCs characterized by different reversal fields.

In the full paper we shall discuss how this analysis can provide new ideas for the proper interpretation of the experimental FORC diagrams for a number of typical nanostructured materials (longitudinal and perpendicular). The relation between the state dependent Preisach distribution and the FORC distribution is also discussed.

Magnetic and magneto-thermal properties of RFe₄Ge₂(R=Er,Dy) compounds.

P. Kumar¹, N. K. Singh¹, K. G. Suresh¹, A. K. Nigam²

1. Physics, IIT Bombay, Mumbai, India; 2. Tata Institute of Fundamental Research, Tata Institute of Fundamental Research, Mumbai, India

Magnetocaloric effect (MCE) in a magnetic material is an efficient tool to understand the correlations between its magnetic, structural and thermal properties [1,2]. MCE in a magnetic material is observed as the isothermal magnetic entropy change (ΔS_M) or as the adiabatic temperature change (ΔT_{ad}) in the presence of an external magnetic field. The recent studies on the MCE of various materials have shown that a large value of MCE is the most important requirement for a magnetic material to be considered as a potential magnetic refrigerant. With the aim of identifying novel magnetic refrigerants, we have studied the magnetic and magnetocaloric properties of DyFe₄Ge₂ and ErFe₄Ge₂ compounds.

Both the compounds are antiferromagnetic with a Neel temperature of 65K for DyFe₄Ge₂ and 42K for ErFe₄Ge₂. They also undergo a structural transition at low temperatures. Furthermore, ErFe₄Ge₂ shows a spin spin-reorientation transition at 8 K. Both these compounds exhibit strong field-induced metamagnetic transitions at low temperatures as shown in the fig.1. The critical fields of the transitions in the case of DyFe₄Ge₂ are 1.6 kOe and 5.6 kOe, at 5 K. In the case of ErFe₄Ge₂, the critical fields are found to be 2.9 kOe and 3.8 kOe. The magnetocaloric effect has been measured in terms of the isothermal magnetic entropy change (ΔS_M) using the magnetization isotherms obtained at temperatures close to the magnetic ordering and the structural transition temperatures. The maximum values of ΔS_M are found to be 2.8 J/kg K and 2.1 J/kg K for DyFe₄Ge₂ and 3.1 J/kg K and 1.2 J/kg K for ErFe₄Ge₂ near the structural transition and ordering temperatures respectively, for a field change of 60kOe as shown in the fig.2.

The refrigerating cooling power (RCP) values are found to be 213 and 162 J/kg for DyFe₄Ge₂ and ErFe₄Ge₂, respectively for a field of 60 kOe. The RCP values observed in the present case compare well with those of many potential materials [1,2], whose magnetic transitions are in the same range as in the present case. A detailed discussion of the magnetocaloric properties will be presented.

 1. CEIT, San Sebastian, Spain; 2. Tecnun, San Sebastian, Spain

ABSTRACT

The effect on magnetic measurements of dislocation density and texture changes during annealing of a cold rolled low carbon steel is analyzed. Low induction values are useful to characterize recovery whereas high induction values can be used to monitor recrystallization.

INTRODUCTION

The microstructure of cold rolled low carbon steels experiences recovery and recrystallization processes during the annealing treatment applied in industry. Recovery involves the annihilation and rearrangement of dislocations, while recrystallization leads to a new grain structure with a low dislocation density and different texture. The typical cold rolled low carbon steel texture intensity concentrates along α fiber (Φ Euler angle=[0-54.7]) with additional γ fiber. Recrystallized low carbon steel texture consists of an intense γ fiber and lower α fiber [1].

The evolution during annealing of the microstructure of a cold rolled extra low carbon steel was studied by metallographic and H_c measurements in [2]. The present paper researches into the use of other magnetic hysteresis loop parameters for the nondestructive characterization of the microstructural changes produced in this steel during the annealing.

RESULTS AND DISCUSSION

Samples from industrially produced low carbon steel, 76% cold rolled, were isothermally annealed in laboratory [2] to promote various degrees of recovery or recrystallization.

Figs 1-2 show, respectively, the evolution of B_r and B_{25} (induction when $H = 2500$ A/m) as a function of annealing time. During recovery at low annealing temperatures, B_r presents a progressive increasing tendency, which is attributed to the reduction of individual pinning site energies caused by the rearrangement of dislocations into lower energy configurations [3]. B_{25} only experiences a slight increase, which is explained by the low sensitivity to variations in the dislocation density at high magnetic fields [4].

During recrystallization both induction values are affected by texture changes [5]. The effect of texture evolution of these type of low carbon steels in terms of the magnetocrystalline energy (E_{crys}) will be discussed in the paper. The material is easier to magnetize when E_{crys} is smaller, so with the same applied magnetic field a higher induction level is reached.

Fig 3 presents the E_{crys} of α fiber calculated by the equation for a bcc crystal [6] when the magnetic field is applied in the transverse direction. The total energy decrease produced by the reduction of α fiber during recrystallization explains the observed higher induction values.

Fig 4 shows correlations between B_r and B_{25} with recrystallized fraction. Although both parameters are able to characterize recrystallization, B_{25} presents larger changes and is better correlated, which is explained because texture effects are usually more pronounced at higher induction levels [7].

CONCLUSIONS

- B_r can monitor the reduction in the dislocation density during recovery processes.
- High induction values are not useful to characterize recovery because the effect of changes in dislocation density is lower at high applied magnetic fields.

- B_r and B_{25} could be used to characterize recrystallization when the magnetic field is applied in transverse direction. B_{25} presents larger variations and better correlation with recrystallized fraction.

INTRODUCTION

Non-destructive evaluation techniques as magnetic hysteresis loop (B-H) and magnetic Barkhausen noise (MBN) are becoming of increasing interest for inspection of several material properties [1,2]. Depending on the aim of the measurements these techniques are applied in different excitation frequency ranges [2,3]. Most measurement systems have been developed using analogue electronics, which implies that they are restricted to a specific small range of frequencies. In most MBN measuring devices, the MBN signal is acquired after analogue filtering [1]. In this paper, the development of a new accurate, fully digital and configurable system, capable of performing simultaneous B-H loop and MBN measurements without changing any hardware, and in a wide band of frequencies (from 0.01 to 80 Hz) is described. All the parameters related with B-H loops and MBN are obtained from only two signals.

PROPOSED SYSTEM

Fig 1 shows the schematic diagram of the hardware of the proposed digital system. The type, amplitude and frequency of the applied excitation waveform can be specified via a user interface. This signal is fed into a power amplifier and delivered to a coil wrapped around a U-shaped magnetic core. Two sensors are used: an encircling pick-up coil to obtain the induced electromotive force (EMF) and a Hall sensor, to detect the tangential field strength, placed next to the pick-up coil at the surface of the sample. The detected signals are acquired with a 24 bit A/D converter.

Fig 2 represents the digital processing of the acquired signals. The values of the magnetic flux density are calculated by numerical integration of the EMF, which allows us to integrate perfectly in a wide band of frequencies, opposite to analogue integration. Moreover, the offset introduced by the amplifier stage is removed by software. The MBN signal is obtained by digital filtering of the EMF signal. The use of digital filters provides the system with the flexibility required to do the measurements at different excitation frequencies for different applications.

Finally, several parameters are computed both from the B-H loop and from the MBN signal, which can be stored for further automatic batch data post-processing and comparison.

RESULTS

Next results present the capability of the system.

Fig 3 shows the B-H loop of two samples S1 (a cold rolled low carbon steel) and S2 (S1 after an annealing treatment at 500°C for 100s) at different excitation frequencies. As the excitation frequency increases, the B-H loops become wider due to the effect of eddy currents.

Fig. 4 shows the root mean square (RMS) envelope of these two samples at different excitation frequencies. The amplitude increases with the excitation frequency, but the shape of the RMS envelope of each sample is maintained.

CONCLUSIONS

- The proposed digital system presents a measurement system capable of performing B-H loops and MBN measurements in a wide band of frequencies acquiring only two signals, reducing significantly the time and the amount of data stored.
- The frequency, shape and type of the excitation signal, the specifications of the MBN filters and the sampling rate of the acquisition are configurable.
- The system stores the results for further post-processing.

Preparation and magnetorheology of solvent-cast magnetite nanoparticle and poly(vinyl butyral) composite.

B. Park, J. You, F. Fang, H. Choi

Department of Polymer Science and Engineering, Inha University, Incheon, South Korea

Introduction

Iron oxide nanoparticles have been widely used because of their unique magnetic, catalytic, and biological properties which can provide potential applications in various areas such as biomedical engineering and magnetic storage device. Composite materials of the iron oxide and polymer have been also investigated for engineering application of the iron oxide nanoparticles due to their enhanced chemical resistance and dispersion stability. Thus the composites of iron oxide and polymer are recently introduced as dispersed particles for magnetorheological (MR) fluid, in which the MR fluid is a stable colloidal suspension composed of magnetic particles dispersed in a viscous or viscoelastic non-magnetic carrier fluid. MR fluids generally show rapid changes of rheological properties with external magnetic fields. The suspension becomes gel-like state under a magnetic field with enhanced both shear viscosity and viscoelastic characteristics.

In this work, the composite materials of poly(vinyl butyral) (PVB) and magnetite nanoparticles were prepared to be applied for MR fluid because of their proper magnetic characteristics and dispersion stability in a viscous medium. The composite was prepared via a solvent evaporation method using PVB and the synthesized magnetite nanoparticles, in which the magnetite nanoparticles were synthesized by a co-precipitation method using ferrous and ferric ionic aqueous solutions. Chemical and physical characteristics of the magnetite/polymer composite were investigated via various analysis methods. The MR characteristics of the composite particle suspensions were also investigated via a rotational rheometer by precisely controlling the magnetic field strength.

Experimental

The magnetite nanoparticles were prepared via a co-precipitation method with ferrous and ferric ionic aqueous solution using PAA as stabilizer. Both FeCl_3 and FeSO_4 were dissolved together in an aqueous medium. NH_4OH was then added to the solution. After that, the PAA was added into the suspension and the mixture was stirred for 3h. In addition, PVB was dissolved in chloroform separately, and then the PVB mixture was added into the mixture of magnetite suspension. The mixture was stirred for 3days until the chloroform was completely evaporated. In order to examine their MR properties, the fabricated composite was dispersed in mineral oil.

Results and Discussion

Chemical structure of the synthesized PVB and magnetite nanoparticle composite was examined via an FT-IR, in which strong peak intensity of the iron oxide for the composite materials around 600 cm^{-1} was reduced compared to that for the pure iron oxide. The characteristic peaks for PVB were also observed for the composite with small shift due to the interaction and magnetic properties of particles. The composites were further confirmed by examining magnetic properties using VSM. Morphology and internal structure of the nanoparticle composite were also observed via SEM and TEM. Figure 1 shows TEM images of the fabricated composite particles which were sliced using an ultramicrotome. It was found that the magnetite nanoparticles were continuously dispersed in the PVB matrix. The particle size of the product was also determined to be $5\sim 10$ micron from the Fig. 1. MR fluids of magnetite-PVB hybrids dispersed in a mineral oil with a particle concentration of 25vol% were prepared and their steady shear properties under various magnetic fields were measured. Figure 2 shows increased shear stress for increased magnetic fields as

a function of shear rate. As the magnetic field strength is increased, the yield shear stress of the MR fluid also increases, exhibiting typical MR effect.

3D Magnetic Field Analysis by Homogenization Method for Thin Steel Plate of Magnetic Field.

Introduction

Electrical thin steel plate is used for magnetic shielding in MRI coil as well as motor core [1], since it has a high permeability. To design and develop the shielding room, numerical calculation method is useful as well as experimental method. Usually shielding room has a size in a few [m] in length, though thin steel plate has a few [mm] in thickness. Since a large number of mesh divided in 3-dimensional space is necessary to calculate, shielding room calculation is almost impossible even by an up-to-date computer machine. Therefore, we propose a new calculation method so called equivalent B-H method, a kind of homogenization method, to reduce the number of calculation mesh, and to make clear the characteristics of magnetic shielding room. Especially in the equivalent B-H method, magnetic non-linear and isotropic characteristics which are important for the magnetizing materials are considered compared with the conventional homogenization method in magnetic field [2, 3].

Magnetic Shielding Room and Equivalent B-H method

A new type of magnetic shield room called open type has superior property such as high performance of shielding and transparent characteristics of shield room, which was invented by Kajima Corporation [4]. Since open type shielding room has a lot of thin steel plate, an equivalent element consisting of thin steel plate and air is considered as one mesh in numerical calculation, as shown in Fig.1. The open type magnetic shield room consists of inner shield (green color in Fig.1 (a)) and outer shield (red color in Fig.1 (a)).

From magnetic circuit theory in the equivalent element, equivalent permeability in each direction of equivalent element is expressed as the next equation (1). In the equivalent B-H method, magnetic characteristics of the equivalent element are directly introduced from electrical steel magnetic characteristics. Since several thousands of meshes in numerical calculation are necessary in the equivalent element, number of mesh extremely decreases. Since the permeability of the electrical steel and the one of the equivalent element are related analytically as in equation (1), the magnetic flux density in the electrical steel is introduced from the equivalent B-H calculation.

Analytical Evaluation

The equivalent B-H method is applied to the magnetic shield room, in which length is 5.8m, width is 3.3m, and height is 3.3m. The experimental leakage magnetic field distribution and the calculated one are almost same.

Since the exiting coil (MRI coil is simulated) is arranged in one-sided (A-side), the leakage magnetic flux density in A-side is larger than the one in C-side. The nearest position in side B and side D has also large leakage magnetic flux density.

The magnetic flux density in the shielding electrical steel is shown in Fig.3. The magnetic flux density in the A-sided electrical steel is larger than the one in the C-sided electrical steel. The nearest position in side B and side D of the electrical steel has also large magnetic flux density.

Field Coil for Magneto-Optic Switching : Capacitance Considerations.

J. Tioh, M. Mina, R. Weber

Electrical and Computer Engineering, Iowa State University, Ames, IA

A tractable method for accurately predicting the parasitic capacitance of a field coil as part of an all-fiber Mach-Zehnder interferometric switch based on Faraday rotation is reported. The effects of the wire insulation layer, inter-turn air gap as well as capacitive coupling to the four nearest adjacent turns are considered in predicting the effective parasitic capacitance. The complex distributed capacitance network is resolved using Kron reduction to yield the equivalent shunt capacitance. Several coil configurations were designed and compared to experimental results. This new approach can be used in conjunction with existing expressions for inductance and loss to enable the complete and accurate a priori design of field generating coils.

The physical layer requirements of electro-optical as well as all optical networking were previously introduced [1] and a fiber-based switch based on the Mach-Zehnder interferometric configuration employing Faraday rotation was proposed to meet these requirements [2]. The switch has shown promising performance and interoperability with existing fiber networks, although the switching time could potentially be lowered to the order of several nanoseconds. Towards this end, detailed modeling and measurement of the coil impedance parameters have been performed in the process of investigating improved driver and coil configurations.

Attempts to realize field-generating elements inevitably results in at least two residual parameters - series resistance and shunt capacitance. Although the existence of this capacity is recognized, it is usually determined a posteriori, with design efforts concentrated on the inductance and loss parameters [3-4]. This paper presents an improved and tractable method for modeling the stray capacitance of field generating coils. The advantage of this approach (as compared to full numerical solutions of the electrostatic field equations) lies in the model simplicity, which affords simple and fast computations of the capacitance.

Winding dimensions of $\lambda/8$ or smaller are approximated as being electrically short. In following with the quasi-static assumption, the following expression (Figure 1) is developed for the turn-to-turn capacitance from one particular winding turn to any neighboring turn "k", where $|k| = 1$ is an adjacent turn :

The various capacitances form a distributed capacitance network (Figure 2) that can be expressed as an NxN admittance matrix, which gives the complete capacitive coupling between all nodes. This matrix is then reformed as a modified primitive impedance matrix and collapsed using Kron reduction [5] to yield the equivalent capacitance between the coil terminals.

Several test structures were fabricated using single-stranded copper wire and tested using an HP 8753C automated network analyzer. The predicted inductance values were calculated using the appropriate Wheeler formulas [6] with an inner coil diameter of 23mm. Good agreement between the predicted and measured parameters are obtained, generally within 8% (Figure 3). It is seen that the expression for the turn-to-turn capacitance is particularly accurate and the assumption of the electric field path to a turn's four nearest neighbors is reasonable. The equivalent capacitance tends to be underestimated as it does not account for fringing capacitance and coupling to nearby conductors on the test structure.

This paper proposes a tractable method for accurately predicting the parasitic capacitance of field generating coils. Six test coils were fabricated and tested. The predicted results are in agreement with the actual measured parameters, indicating the proposed method can be combined with exist-

ing inductance and loss parameter expressions for accurately predicting the circuit performance of field generating coils.

The research reported in this paper is partially supported by National Science Foundation grants 0087746, 0434872 and 0306007.

Power loss measurement and prediction of soft magnetic powder composites magnetised under non-sinusoidal excitation.

P. Marketos¹, J. P. Hall¹, S. E. Zirka²

1. School of Engineering, Cardiff University, Cardiff, United Kingdom; 2. Department of Applied Physics and Technology, Dnepropetrovsk National University, Dnepropetrovsk, Ukraine

Introduction

This paper presents details of studies undertaken to measure the magnetic properties of soft magnetic powder cores and assess the applicability of a numerical modelling technique for the prediction of losses under a range of non-standard magnetisations. The modelling technique aims to allow prediction of magnetic properties under wide ranging conditions, including PWM magnetisation, based on obtaining limited information of the material's near-DC magnetic properties and electrical resistivity. This approach, based on a concept known as magnetic viscosity [1], offers significant advantages and has been shown previously to be accurate in its application with soft magnetic lamination materials.

Experimental Procedure and Results

Experiments were carried out on small toroidal powder cores, 45 mm inner diameter, 55 mm outer diameter, 5 mm core height and 29.21 g core weight, in order to measure their magnetic properties including power loss at frequencies ranging from 5 Hz to 200 Hz and different excitation waveforms. A computerised magnetic measurement system featuring digital feedback control [2] was used ensure that the shape of the excitation waveform was controlled at all times. Typical results under sinusoidal excitation are shown in figure 1.

Six BH loops, measured under 5 Hz sinusoidal excitation peak flux densities ranging from 0.5 - 1.5 T in steps of 0.2 T were used as inputs to the power loss prediction model in order to enable the prediction of loss under any excitation condition. The power loss Ploss of the toroid magnetised under sinusoidal excitation at 1.3 T, 50 Hz was also used as input to the model. Table 1 shows a comparison between measured and predicted Ploss values of the toroid magnetised under sinusoidal excitation for two different peak inductions 1.0 T and 1.5 T and three different frequencies 50, 100 and 200 Hz. Table 1 shows a very good agreement between measured and predicted Ploss values for the frequencies and flux densities tested.

Experiments were also carried out to assess the ability to measure and predict the Ploss of the powder core under non-standard, non-sinusoidal magnetisations. Figure 2 shows an example of such an excitation and the corresponding measured and predicted BH loops. The excitation was achieved by adding 30% of 7th harmonic component to a 50Hz sinusoidal excitation. The difference between measured and predicted Ploss was 2.2%.

Conclusions

Very good agreement was achieved between measured and predicted Ploss data for the range of frequencies and flux densities under test. The computerised measurement system was able to successfully magnetise the cores under different magnetisation conditions and under different frequencies and flux densities. The measurement system was able to measure and supply the input data required by the power loss prediction model which in turn was able to predict the losses of the powder core to within 2.5% of the measured values for all the excitation conditions under investigation.

1. Introduction

The leakage of electromagnetic radiation or information security are of increasing concern given the increasing proliferation of wireless IT devices such as mobile phones, LAN and home robots. There is an increasing need to either to reduce the source of the unwanted radiation or to reduce its impact on the surrounding area. An electromagnetic wave absorber is one possible approach for solving such a problem. There are many approaches to absorbing radiation however in households it is important to use materials that preserve the aesthetics. Moreover, it would be useful to use materials that reduce the carbon footprint. The use of powder-type magnetic wood is one such case in point. Powder-type magnetic wood retains the desirable wood and magnetic characteristics by combining waste wood and recycled magnetic materials. Because this composite material offers a woody texture and is very easy to process, the boards using this powder-type magnetic wood can be used as indoor electromagnetic wave absorbers¹. In addition, the boards also offer moisture absorption characteristics and a diathermancy. Previously, we reported that a change in the mixing ratios of two types of magnetic powder can control the reflection loss of powder-type magnetic wood. The purpose of this paper is to propose a method for calculating the material constants and estimating the reflection loss of a mix of two magnetic powders used to manufacture the magnetic wood from the individual material constants (complex permeability and complex permittivity) of the magnetic powder. Furthermore, the effect of moisture content on the reflection loss of the powder-type magnetic wood is reported.

2. Experiments and Calculations

Formulas <1>, <2> are the formulae for estimating the material constants from volume ratios of two types of magnetic powder.

$$\epsilon_{AB} = A\epsilon_1/(A+B) + B\epsilon_2/(A+B) \quad <1>$$

$$\mu_{AB} = A\mu_1/(A+B) + B\mu_2/(A+B) \quad <2>$$

A : Mn-Zn powder volume ratio

B : Ni-Cu-Zn powder volume ratio

ϵ_1, μ_1 : material constants of powder-type magnetic wood using single Mn-Zn magnetic powder (A)

ϵ_2, μ_2 : material constants of powder-type magnetic wood using single Ni-Cu-Zn magnetic powder (B)

Table 1 shows the constitution of powder-type magnetic wood which is used for the experiments. Sample PMW indicates powder-type magnetic wood. Mn stands for simple Mn-Zn and Ni for simple Ni-Cu-Zn.

Fig. 1 and 2 show experimental and calculated values of the reflection loss RL, respectively. The sample PMW-55 is used for the experiments and the Nicolson Ross method is used for the calculation. The thickness of the samples is 8mm and is associated with a center frequency of 2.45(GHz), which is the operating frequency of a microwave oven. The microwave oven is the strongest emitter of high frequency electromagnetic waves in our home. Table 2 shows calculated values of reflection loss characteristics.

3. Results

The simple calculation method to determine the material constants of powder-type magnetic wood is proposed. A two magnetic powder mixing type magnetic wood with zero moisture content shows the best reflection loss.

The results from our studies can be used to design powder-type indoor magnetic wave absorbers for their intended absorption frequency.

Influence of asymmetry in stator geometry and magnetic circuit on cogging torque in PM brushless machines.

Z. Zhu, J. Chen, L. Wu, D. Howe
University of Sheffield, Sheffield, United Kingdom

Due to high efficiency and high torque density PM brushless machines are widely used in many applications, in which low torque ripple is often an important design consideration. However, PM machines with slotted stator have a common disadvantage that they exhibit cogging torque due to the interaction between PM mmf and airgap reluctance variation. As one of the sources of torque ripple, cogging torque should always be reduced as low as possible. Up to now, numerous methods have been proposed for analyzing and reducing the cogging torque. A comprehensive review may be found in [1]. However, existing analyses of cogging torque are based on the assumption of ideal design and perfect manufacture process [2]. But in practice, this may be not true, e.g. the outer surface of the stator may be not circular but exhibits asymmetries in the stator geometry, causing defects in the magnetic circuit of stator yoke and introducing high localized magnetic saturation. As a result, the amplitude and waveform of cogging torque may change significantly, as will be reported in this paper.

In this paper, the influence of asymmetry in stator geometry and/or magnetic circuit on cogging torque in PM brushless machines is investigated. The investigation is based on 6-pole, 18-slot machine having surface-mounted NdFeB magnet. The stator has flat-cuttings at both sides, one notch, and two diametrically opposite key-bar slots on the outer surface of the stator, its open-circuit equi-potential distribution being shown in Fig.1. The finite element predicted cogging torque waveforms with and without keybar-slots, notch, and flat-cuttings are shown in Fig.2. The influence of flat-cuttings and notch on the airgap field distribution and cogging torque is negligible. However, the deep keybar-slots cause significant changes in cogging torque, both amplitude and waveforms, Fig.2. The peak cogging torque is increased by approximately twice, while the waveform becomes non-periodic, as confirmed by experiment, Fig.3. For a 6-pole/18-slot PM machine, the least common multiple between the stator slots and rotor permanent magnets is 18. Hence the fundamental harmonic order of cogging torque waveform should also be 18 over 360 mech. deg., while its periodicity should be $360/18=20$ deg. mech. Finite element analysis reveals that the maximum flux density in the stator yoke should be 1.4T if the keybar-slots do not exist. However, due to keybar-slots, the maximum localized flux densities in the stator yoke near the keybar-slots become as high as 2.3T, which is found to be responsible for the increase in amplitude and distortion in waveform of cogging torque. In this case, since there are 2 keybar-slots, their interaction (due to corresponding variation of permeance) with 6-pole rotor should produce a cogging torque component of order 6 over 360 deg. mech., i.e. its periodicity should be $360/6=60$ deg. mech., since the least common multiple between 2 keybar-slots and 6-pole rotor is 6, as confirmed by both finite element analysis and measurement, Figs.2 & 3. Consequently, the resultant cogging torque waveform has a periodicity of 60 deg. mech. More finite element predicted and measured results when the machine is equipped with 1 or 2 magnets will be presented in full paper.

Electromagnetic modeling of a novel linear oscillating actuator.

Z. Zhu¹, X. Chen¹, D. Howe¹, S. Iwasaki²

1. University of Sheffield, Sheffield, United Kingdom; 2. IMRA UK Research Center, Brighton, United Kingdom

Linear oscillating actuators (LOAs) employing permanent magnets (PM) are being extensively exploited in industrial applications such as pumps, compressors and vibrators, because of their high efficiency and high power density. Of the various analysis methodologies, finite element method, both 2-D and 3-D, is widely used. An analytical model is proposed in [1] assuming the axial length of LOAs is infinite, and slotting and fringing effects being accounted for by introducing the Carter coefficient and repetitive models, while the magnetic saturation being considered only by introducing a fictitious air-gap. The lumped parameter magnetic circuit (LPMC) modeling is an attractive method to model the field leakage and non-linearity since it is essentially analytical method, but can account for the influence of magnetic saturation [2].

In this paper, axisymmetric finite element model, together with non-linear LPMC, is used to analyze the thrust force characteristics of a novel LOA. It is a tubular moving-magnet type actuator, Fig. 1(a), and consists of a Halbach array mover and two simple stator coils which are accommodated in the stator slots. The stator core may be laminated or employing soft magnetic composite (SMC) (In this paper, it is made of SMC due to its simplicity in manufacturing). In order to assess the merits of Halbach array mover, its electromagnetic performance is compared with that when axially magnetized magnet is removed, Fig. 1(b). The corresponding LPMC models are established, accounting for major flux components. It is worth to note that (1) for the Halbach array mover, each of radially magnetized magnet ring is required to be axially modelled by several parts, being 3 in the example, according to the relative axial position between the stator and the mover; subsequently (2) the central axially magnetized magnet ring is also subdivided radially into several parallel branches; and (3) the mover back-iron also provides the return flux path. Fig. 2 compares the per-turn flux-linkages versus mover axial displacement predicted by LPMC and finite element analysis for the prototype LOA, while Fig. 3 compares predicted and measured thrust force versus displacement for the prototype actuator with axially magnetized magnet in which the radially magnetized magnet ring consists of 8 sintered NdFeB magnets circumferentially. Good agreement is achieved. The full paper will discuss the predicted electromagnetic performance, e.g. thrust force, flux-linkage and back-EMF, by LPMC modeling and finite element analysis, the comparative study of LOAs with and without axially magnetized magnet and mover back-iron, as well as the design optimization.

Non-oriented electrical steel and magnetostriction: a review.

A. M. Severino

Departamento de Física - CCNE, Universidade Federal de Santa Maria, Santa Maria, Brazil

The magnetostriction of non-oriented electrical steels is receiving increasing attention because the need to reduce acoustic noise in many types of magnetic cores. In a magnetic material, the inter-atomic distances can vary with the intensity and the orientation of magnetization. With the study of magnetization processes it is possible to improve the magnetic properties of the steels, reducing the magnetic losses and, consequently, induce the rational use of electric energy. The idea is decrease the mechanical noise and the mechanical vibration in devices based on these materials. At the same time the growing development of technologies involving the miniaturization of magnetic materials, producing them in nano-dimensions and subjecting them to the presence of high magnetic fields induced, in the last years, an increment in the research of magnetoelastic effects in general [1].

In this work we will expand previous explanation about models for description of the magnetization mechanisms related to the variation of magnetostriction in electric steels. A nonlinear constitutive model was recently proposed for magnetostrictive materials by Liu and Zheng [2]. It is based in the fact that a nonlinear part of the elastic strain produced by a pre-stress is related to the magnetic domain rotation or movement and is responsible also for the change of the maximum magnetostrictive strain with the pre-stress.

This nonlinear model was used to compare some recent results obtained by Bohn et al. [3]. These results have shown that the reduction in magnetostriction at high frequencies would have important implications in the analysis and prediction of electrical machine noise. The magnetostriction results are also correlated results of Barkhausen noise and magnetic losses measured in the same sheets. Some of the models for magnetic losses uses the usual separation among component of losses in low induction, related to the movements of walls of magnetic domains and component of losses in high induction, associated the rotation of the magnetization. Though, experimental results shown that in general the component of high induction represents a larger amount than are predicted by the models. The magnetostriction results obtained by Bohn et al shows that the motion of 90 degrees domain walls and magnetization rotation occur at high magnetic induction region. So it is reasonable to associate the motion do domain walls to the process of nucleation, growth and annihilation of magnetic domains or, in other words, to the evaluation of the magnetic domain structure at high induction levels.

We also verified that not just there is a few number of experimental results in the literature for magnetostriction in steels but there is some controversy to explain its mechanisms. With this work we intended to demonstrate that the experimental determination of the magnetostriction, its confrontation with simulations obtained from analytic models and the correct understanding of the magnetization mechanisms are very important to design materials to new applications in the electrical steel industry.

Introduction

Base-band processor voltage becomes lower to avoid overheat. Consequently, current needs to increase up to several amperes in smart phone. In order to achieve small ripple voltage, integrated and miniaturized on-chip power module has been intensively studied. On the other hand, an increase in switching frequency decreases L (inductance) and C (capacitance) in the power circuit, resulting in size reduction and integration of passive components. The switching frequency of commercial dc-dc converter has already been increased up to 5 MHz [1] and higher frequency [2,3]. A high Q inductor is an essential component for a high efficiency dc-dc converter. Therefore, a dc-dc converter with an air core chip inductor was proposed[3,4] to achieve high Q at high frequency. However, the air-core inductor Q is still below 20 in the 10 ~ 100 MHz range.

In this work, we report a design of ferrite planar inductor, which has Q over 50 at 10 ~ 100 MHz, for use in a 1 ~ 2 W buck type dc-dc converter module having 0.25 V and 5 A output. We used DOE (Design of Experiment) method to optimize copper coil, coil shape, ferrite film, thickness, and permeability.

Optimization of design parameters

In DOE process, input X's are Cu line space (2 ~ 500 μm), Cu line thickness (50 ~ 100 μm), ferrite thickness (2 ~ 500 μm), and permeability of ferrite (μ ; 2 ~ 1000), and its response Y's are L (Inductance) at 10 MHz, Q at 10 MHz, and fr (Resonance Frequency). The copper line thickness is 50 μm which is 2 x the skin depth of copper at 10 MHz. Our proposed spiral inductor's coil area with 2.5 turns is 5 x 5 mm to meet the critical inductance of 125 ~ 30 nH at 10 ~ 100 MHz [5]. Cross sectional coil area is designed over 25,000 μm^2 to withstand joule heating by maximum 5 A rated current [6,7]. Therefore, the coil width is fixed at 500 μm . Total, a 25 kind of test conditions is designed for a 4 X's, 3 level and 3 Y's DOE. Each Y is obtained by Ansoft HFSS simulation software.

Results and discussion

The weight of X's on the Y's is shown in Fig. 1. It is found that the most effective X for L is μ , X for Q is square of ferrite thickness, and X for fr is spacing of Cu lines. Correspondence of each X's to Y's is represented by contour plots in Fig. 2. From this optimizations, it is found that ferrite film and permeability need 100 ~ 300 μm thickness and high value, respectively, to achieve high Q greater than 100.

The regression equations are given in Table I. These equations were derived as a result of DOE performance. From this, Y's of L is 125 nH, Q is 197.5 and fr is 316.3 MHz. These values are calculated from X's of A 127 μm , B 67.8 μm , C 130.3 μm and D 156.5. Actually, there are some difficulties to fabricate 130.3 μm thick ferrite film below 400 °C. However, it is possible to select C of sputter deposited 3 μm of ferrite film to obtain Y's of L (66.1 nH), Q (74.6), fr (632.4 MHz) for X's of A (spacing of 210 μm), B (copper thickness of 64 μm), C (ferrite thickness of 3 μm), and D (permeability of 200). Deviations of the equations are found to be -9.1% in L, 2.8% in Q and 4.1% in fr. Therefore, there are confidence levels of roughly over 90% for L and 95% for Q and fr. How-

ever, loss $\tan \delta = 0$ is assumed in all the above estimations. Q will be decreased to 50% at loss $\tan \delta = 0.01$ and to 70% at 0.02.

In conclusion, we have successfully designed 5 mm x 5 mm high Q ferrite inductor which has above 50 of Q at 10 MHz. The following parameters are recommended to design the above high Q and high current ferrite inductor: 2.5 turns, copper thickness > 64 μm , copper width = 500 μm , loss $\tan \delta$ of ferrite < 0.02, permeability > 157, and ferrite thickness > 3 μm .

Magnetic properties of cobalt ferrite nanoparticles obtained by non-aqueous synthesis.

C. Vázquez-Vázquez¹, C. Mateo-Mateo¹, M. Buján-Núñez¹, M. López-Quintela¹, D. Serantes², D. Baldomir², J. Rivas²

1. Facultad de Química. Departamento de Química Física, Universidad de Santiago de Compostela, Santiago de Compostela, Spain; 2. Facultad de Física. Departamento de Física Aplicada, Universidad de Santiago de Compostela, Santiago de Compostela, Spain

Cobalt ferrite (CoFe_2O_4) nanoparticles were obtained by a non-aqueous procedure using acetophenone as reaction medium [1]. The particle size (determined by transmission electron microscopy) was tuned from 2 to 15 nm by changing the synthesis temperature from 120 to 200 °C. These nanoparticles show a superparamagnetic behaviour. From the zero-field-cooling (ZFC) measurements at 100 Oe, it is observed an increase of the blocking temperature from 215 K to above 325 K with increasing particle size (Figure 1).

From the initial magnetization curves up to 50 kOe at 5 K it is observed that the saturation magnetization increases with the particle size. Additionally, the initial magnetization curves were measured at different temperatures from 5 to 320 K in order to determine the temperature dependence of the saturation magnetization and the anisotropy constant by means of the law of approach to saturation [2]. A decrease with temperature is observed for both properties; however, these changes are more important for the smaller nanoparticles compared to the larger ones (Figures 2 and 3). A large decrease of the saturation magnetization and the anisotropy constant is observed at low temperatures (below ~100 K), being more important for the smaller particles. This behaviour is related to the large surface/volume ratio observed for nanocrystalline particles and the larger amount of surface spins at smaller sizes [3]. Above this temperature, the decrease is less marked. For the smaller particles, an increase of the saturation magnetization and the anisotropy constant is observed around 150 K.

In order to get more insights about the magnetic behaviour, the isothermal magnetization curves as a function of the applied magnetic field were measured for both small and large particles (Figure 4). A large difference is observed at low temperatures (below ~100 K) compared to temperatures close and above the blocking temperature. It is possible to observe the different magnetic behaviour of the surface and core magnetic moments. The curves show a larger hysteresis at intermediate magnetic fields compared to the low-range ones. When approaching the blocking temperature, the hysteresis is reduced and finally disappears.

The magnetocaloric effect shown by these cobalt ferrite nanoparticles is reasonably high for nano-materials.

Magnetic Properties of Nano-composite Particles of FePt/FeRh.

Y. Hnin¹, S. Inoue¹, N. T. Nam¹, T. Suzuki¹, Y. Hirotsu²

1. Information Storage Materials Laboratory, Toyota Technological Institute, Nagoya, Japan; 2. The Institute of Scientific and Industrial Research, Osaka University, Osaka, Japan

Magnetic nanoparticles has been attracting much interest for their fundamental properties and and also device applications [1]. A order b.c.c alloy FeRh undergoes a first-order phase transition from antiferromagnetic, AFM to ferromagnetic, FM state at around 100°C [2]. Using the temperature-dependent magnetic behaviour, an exchange coupled FePt/FeRh has been the subject for potential application to high-density magnetic recording media. Although the experimental and theoretical works are reported on the FePt/FeRh thin film system, the magnetic behaviours in the composite nano-particles of FePt/FeRh have not been found in literature. This study is carried out to understand the magnetic and structural properties on nanoparticles of FePt, FeRh and their composites. Nanoparticles of FePt were synthesized by co-reduction of Iron (II) chloride tetrahydrate and Platinum acetylacetonate by super-hydride in the presence of oleic acid, oleylamine, 1,2-hexadecanediol and phenyl ether under the N₂ atmosphere. In the case of FeRh particles, Rhodium (III) acetylacetonate was used as source material [3]. For the preparation of nano-composite FePt/FeRh, the solutions of pre-prepared FePt and FeRh were mixed simultaneously and stirred for a few hrs. The obtained solution was used as a source solution. Post-annealing of samples was carried out in the vacuum < 5×10⁻³ Pa. The structural properties were investigated with TEM, XRD (Cu Kα), and EDX. Magnetic properties were measured by VSM in fiels up to 15 kOe.

Figure 1 shows the x-ray diffraction patterns for the nano-particles of (a) as-deposited and annealed states (600°C-1h) of Fe₆₄Pt₃₆, (b) as-deposited and annealed states (600°C-6h) of Fe₃₉Rh₆₁, and (c) annealed state (600°C-6h) Fe₆₄Pt₃₆/Fe₃₉Rh₆₁, respectively. As-deposited nanoparticles of Fe₆₄Pt₃₆ show the fcc structure of (111) and (200) diffraction peaks. The ordered fct structure is observed in the annealed state showing the super lattice peaks of (001), (110), (311). For as-deposited Fe₃₉Rh₆₁ particles, a broad peak around 2θ=42° is observed, showing a characteristic of the disordered fcc structure of FeRh (111)γ phase. The annealed Fe₃₉Rh₆₁ particles exhibit a peak at around 2θ=43°, implying the coexisting of (111)γ and (110)α phases. Annealed nano-composites of Fe₆₄Pt₃₆/Fe₃₉Rh₆₁ show a broad peak at around 2θ=42°, it may be possibly due to the coexisting of FePt (111) and FeRh (110) peaks. Figure 1(d-e) show TEM images of nano-composite Fe₆₄Pt₃₆/Fe₃₉Rh₆₁ for (a) as-deposited and (b) annealed (600°C-6h) states, respectively. The uniform distribution of particles with a size of 3 nm is observed in the as-deposited state. However, single (about 3nm) and agglomerated (about 50 nm) particles are co-distributed in the annealed state. Figure 2(a) shows M-T curves for nano-composite of Fe₆₄Pt₃₆/Fe₃₉Rh₆₁ annealed at 600°C for 6 hrs under the applied filed 15 kOe during heating and cooling processes. The samples were cooled down from room temperature to -196 °C without the presence of an applied field. After that, measurements were carried out under the applied field. In the heating process, the magnetization decreases from -196 to 250°C showing ferromagnetic behaviour. In the cooling process, it exhibits a small increase with decreasing of temperature. Figure 2(b) shows the temperature dependences of coercivity, H_c and exchange bias field, H_E on field cooling process for the nano-composite of Fe₆₄Pt₃₆/Fe₃₉Rh₆₁ annealed at 600°C for 6 hrs under the applied field. A significant decrease in H_c at around 30°C is observed with increasing temperature. This decrease is due to a strong exchange coupling between Ferro (FePt) and Anti-ferro (FeRh) phases. A unidirectional anisotropy constant, J_K at T = -196°C is estimated to be 0.08-0.2 erg/cm².

Universidade de Brasília, Instituto de Física, Núcleo de Física Aplicada, Brasília DF 70910-900, Brazil, Ribeirão Preto, Brazil

In this work, has been developed a new nano-drug delivery system (NDDS) associating biocompatible ionic magnetic fluid (MF) with a phthalocyanine drug (NzPc) in nanoparticles of bovine serum albumin (BSA). The samples were evaluated for synergic application that combines Photodynamic Therapy (PDT) with Hyperthermia [1]. The NzPc is a second generation of photoactive agents used in PDT that it is preferentially accumulated in the target tumor cells. Biocompatible magnetic fluids have been pointed out as a very promising nanosized-based magnetic material, applicable for tumor therapy. Considering that serum protein are by far the most abundant protein in blood vessels, as well as, they are extremely useful

as model systems for investigation processes, albumin-based beads were prepared containing or not maghemite nanoparticle associated with the NzPc according to the method of heat denaturation using mechanical stirring process at high-speed from an ultraturrax setup to optimize the preparation of the nanoparticles. The entrapped material, in this case NzPc and/or MF, was initially dispersed in the albumin aqueous phase after that the solution is added in a boiling flask containing sunflower oil and Span 80 with continuous stirring using ultraturrax at room temperature. Then, the mixture was emulsified by ultrasound at 150 W at room temperature through an ultra-sound device. In another boiling flask with mineral oil containing Span 80 was pre-heated under continuous agitation. The initial emulsion obtained as described above it was gently dropped directly to the pre-heated oil in the boiling flask with continuous agitation in a total time of 30 minutes. The final suspension was cooled down at room temperature under magnetic stirring. The obtained nanoparticles were washed with ethyl ether for oil separation, following centrifugation at 10.000 rpm for 30 minutes. After washing the "pellet" containing the nanoparticles were lyophilized to remove any remaining water trace [2]. The morphology of the all particles (NzPc, MF and the complex NzPc/MF) was examined by scanning electron microscopy showed a spherical shape with average size of the 320 nm (Figure 1). The albumin-nanoparticles also were characterized for Zeta potential by photo-correlation spectroscopic from light scattering techniques. The Zeta potential was calculated from the electrophoretic mobility using the Smoluchowski equation. The time resolved analyses was obtained for the systems studied. The magnitude of the Zeta potential indicate the physico-chemical stability of the system. The Zeta potential of the particles was of -22.3 mV for NzPc, -22.6 mV for MF and of -24.0 mV for NzPc/MF. The fluorescence lifetime of the sample of NzPc/MF presented monoexponential decay of 4.78 ns with population of 100% and for sample of NzPc presented biexponential decay of 5.19 ns and 1.99 ns with population of 63.9% and 36.1%, respectively. It was evaluate the kinetic release of NzPC in human plasma serum from a comparative study between the nanoparticles associated to the NzPc and the nanoparticles associated to the complex NzPc/MF. It was observed that the albumin nanoparticles entrapped with of NzPc present

a release profile showing small initial burst compared in the albumin nanoparticles entrapped with the complex NzPc/MF, both reaching the maximum at 1 h.

Synthesis of Ni nanoparticles by dc magnetron sputtering.

H. Cui, M. Sanz, M. Maicas, C. Aroca

ISOM, Universidad Politécnica de Madrid, Madrid, Spain

Magnetic materials have been used with grain sizes down to the nanoscale for longer than any other type of material. The biomedical applications cover from magnetic separation of specific biological entities from their native environment to drug delivery, hyperthermia treatments or MRI contrast enhancement [1]. There are many synthesis methods depending on the final applications of the magnetic nanoparticles [2]. Sputtering methods are less extensively used, maybe due to the low efficiency of the process, however these methods have the advantage of a good control on the composition and size of the particles. Some works have already been done on Fe [3] and FeCo alloys [4]. In this work we apply the dc magnetron sputtering technique to the growth of Ni nanoparticles. Inert gas pressure and substrate temperature are the main parameters that control the morphology of the aggregates. High pressure promotes collisions in the gas phase and so the aggregation of atoms into particles while low temperature in the substrate reduces the tendency of joining those particles to become a continuous film. Figure 1 shows SEM images observed under direct sputtering using Ar as inert gas, Silicon substrates at 100K and a power discharge of 40 W. Results show how the porosity of the film increases with the Ar pressure. However, even for the highest pressures used and the low substrate temperature, isolated particles are not obtained but a dark porous film is grown instead. Similar results have been obtained for other temperature and power conditions. Figure 2 shows the early stages of the growing films at $P_{Ar}=0.1$ mbar. Ni nanoparticles with an average size of 4nm are found but they aggregate to make a film. Figure 3 shows the VSM magnetic response of the films. It is observed a decrease in both saturating and coercive fields with the increasing pressure.

A particle gun configuration avoids the mechanism of thin film growing and promotes further aggregation. Figure 4 shows a SEM image of a sample grown using a particle gun configuration like that described in [3]. The growing power was 40w, Ar pressure out of the chamber was 0.1 mbar and the substrate was at room temperature. The particle gun was placed at nearly 10mm of the substrate and had a pipe with a diameter of 1 mm and a length of 5 mm. Clear isolated particles were obtained. In figure 5 it is shown a high resolution SEM image that reveals the particles morphology in more detail. Their size is about 150 nm and some of them appear as aggregates of smaller particles (a), while others look like small crystals (b). No cooling was applied to the chamber during the growing so the increase in the temperature of the chamber at the end of the growing appears high enough to make some particles have a crystal structure.

In summary, nickel nanoparticles of a few nanometers can be obtained by dc sputtering growing at Ar inert gas pressures over 0.1 mbar. Those nanoparticles grow as a porous film even at Nitrogen cooled substrates. A particle gun configuration allows the growing of well isolated nanoparticles at room temperature substrates and can reach diameters over 100 nm.

In the last years, carrier transport mechanisms in magnetic thin films have been of great interest because of their applications in magnetic memories, spintronics, etc. In this context, metal/semiconductor structures play a fundamental role, and it is therefore essential to understand the influence of the substrate on the transport and magnetotransport properties of these magnetic thin films. We have prepared $\text{Fe}_x\text{Ag}_{1-x}$ thin films, with compositions in the range $0.3 \leq x \leq 0.85$, by sputtering and pulsed laser deposition (PLD) techniques. They were deposited simultaneously at room temperature onto a low resistivity ($\rho \sim 0.015 \text{ ohm-cm}$) $200 \mu\text{m}$ thick Si(100) substrate and a high resistivity ($\rho \sim 7\text{-}25 \text{ ohm-cm}$) $380 \mu\text{m}$ thick Si(100) substrate, both with native oxide layers (from now on, we will refer to them as Si1 and Si2, respectively). All the samples deposited onto Si1 present an anomalous thermal evolution of the resistivity, showing a dramatic drop in the range $200 < T < 300 \text{ K}$. In a similar way, magnetoresistance (MR) also drops at the same temperature. This transition is completely reversible with temperature and independent of the applied magnetic field. Several hypothesis have been considered in the literature in order to explain this transition: the formation of a silicide in the interface which suffers an insulator-metal transition as the temperature increases [1], the formation of an inversion layer at the Si-SiO₂ interface which could provide a low resistive path for carrier transport [2] or the current switching to the whole substrate if its ρ is low enough [3]. In this work we report a systematic study of the transport and magnetotransport properties of one of the studied compositions: $\text{Fe}_{55}\text{Ag}_{45}$ in order to get a deeper knowledge of the transition.

The thermal evolution of the resistance and the MR was measured using a conventional six-point configuration.

In figure 1 (left) we present the thermal evolution of the resistance for PLD and sputtered $\text{Fe}_{55}\text{Ag}_{45}$ thin films deposited onto Si1 and Si2 substrates. Samples deposited onto Si2 present a typical metallic behaviour in all the temperature range, while the resistance abruptly drops at $200\text{-}300 \text{ K}$ in those deposited onto Si1. The differences observed in the resistance values for the samples deposited simultaneously should be attributed to the different heat conductivity of each substrate that gives rise to different microstructures. As shown in figure 1 (right), this electronic transition also affects the thermal evolution of the MR: while the response of simultaneously deposited thin films is nearly the same before the transition, after this, the modulus of the MR decreases for the samples deposited onto Si1 substrate. On the other hand, magnetic measurements have shown no appreciable differences between films deposited onto different substrates.

To further investigate the role of the interface between the thin film and its corresponding substrate, we also deposited $\text{Fe}_{55}\text{Ag}_{45}$ granular alloys on Si1 substrate after being treated with fluorhydric acid in order to remove the native SiO₂ layer of the wafer. As it is shown in figure 1 (left), the resistance increases linearly with temperature, which clearly indicates that the presence of SiO₂ is essential for the manifestation of the current switch.

Finally, in order to study the electronic nature of this phenomenon, XAS measurements at the Fe-K edge on PLD samples were carried out at the beamline BL39XU of the SPRING-8 facility as a function of temperature (see figure 2). The spectra obtained are the typical of Fe-bcc, showing no formation of silicides or oxides. Important variations with temperature are observed in the XANES region which indicates clear changes in the electronic structure that should be associated to the anomalous resistivity drop.

In summary, at high temperatures a current switching happens related to the substrate employed during deposition. Based on our experimental results, we propose that some kind of interface layer is formed during deposition at SiO₂/Si, which “activates” above the transition point and allows the current transport switching.

Characterization of nanocrystalline iron oxide powder modified by electroless nickel plating.

C. Lin¹, C. Tsay¹, T. Yang¹, R. Yang², D. Hung³, Y. Yao³

1. Materials Science and Engineering, Feng Chia University, Taichung, Taiwan; 2. Dept. of Aerospace and Systems Engineering, Feng Chia Univ, Taichung, Taiwan; 3. Institute of Physics, Academia Sinica, Taipei, Taiwan

Electroless nickel plating has been used to prepare nanocrystalline powders or coatings and has attracted considerable R&D interests. It has been reported that nanocrystalline powders can be modified by electroless nickel plating to obtain nano-scale powders with unique structure and properties. In the present study, nanocrystalline iron oxide powders were modified by electroless nickel plating. The so-obtained nanocrystalline powders were characterized by X-ray diffraction, transmission electron microscopy, synchrotron X-ray absorption spectroscopy, and vibrating sample magnetometer. Experimental results show that initial nanocrystalline iron oxide powders remained Fe₃O₄ phase. The formation of a core-shell like nanoparticles was observed. Synchrotron x-ray absorption examination confirmed the structural and valence change after surface modification. A decrease in saturated magnetization and coercivity was observed after electroless nickel plating.

Nanocrystalline Fe₃O₄ powders was modified by electroless nickel plating treatment with various processing parameters. Though XRD patterns were not shown here, initial Fe₃O₄ phase can be observed and the relative amount of elemental nickel was different when prepared by solutions with different pH value. In general, the amount of nickel increased with increasing electroless processing time. Transmission electron microscopy was used to examine the particle size and morphology of the modified powders. It can be observed that the thickness of nickel increased with processing time. Fig. 1 shows the TEM image that was prepared with a pH =6 solution. It can be noted from Fig. 2 that the so-obtained powders exhibited a core-shell like structure where iron oxide powder was surrounded by a layer of Ni. The average grain size of initial nanocrystalline iron oxide powders was ~50 nm while the thickness of nickel was ~40 nm.

Synchrotron X-ray absorption technique was used to examine the local atomic environment and electronic state of the core shell powder. Figure 2 shows the variation in Fe valence state as a function of electroless nickel plating time. It can be noted that the initial Fe 3+ (indicated by the peak at 710 eV) was transferred into Fe 2+ (708 eV) at the early stage of electroless plating (say 15 minutes). No significant difference can be noticed thereafter. The magnetic properties of the corresponding nanopowders for those examined in Fig. 3 were evaluated by VSM and the magnetic hysteresis curves were shown in Fig. 3. Significant decrease in saturated magnetization (Ms) after electroless nickel plating was noticed. The original nanopowders possessed an Ms value of 53.8 emu/g and gradually decreased to 9.9 emu/g after electroless nickel plating for 45 mins. While the coercivity (Hc) only decreased slightly. It decreased from the initial 134.1 Oe to 122.4 with 5 mins. of electroless nickel plating and gradually increased back to 132.5 Oe with increasing processing time.

Functionalized silica coated maghemite nanoparticles prepared by the microemulsion method for biomedical applications.

A. Drmota¹, A. Ko šak², A. Znidar šič^{1,2}

1. Kolektor Nanotesla Institute, Ljubljana, Slovenia; 2. Kolektor Magma d.o.o., Ljubljana, Slovenia

Monodisperse magnetic nanoparticles with unique properties which are dominated by superparamagnetism have a great potential to use in biomedical applications such as cell labeling and magnetic cell separation, drug delivery, hyperthermia and MRI contrast enhancement. Applications of nanoparticles in biomedicine impose strict physical, chemical and pharmacological properties, including chemical composition, crystal structure, magnetic behavior, surface structure, adsorption properties, solubility and low toxicity. In this field the main challenge is tailoring the surface of magnetic nanoparticles in order to functionalize and develop strong interactions with specific biological components (dye, drug or effector grafting). Therefore, chemical modification of the nanoparticle surface with biocompatible molecules, such as silica (SiO₂), dextran, polyvinyl alcohol (PVA) and phospholipids, is an important issue that provides biofunctionality and resistance to physiological conditions such as pH and enzymes, binding sites between the particles and the target sites on the cell, cytotoxic drug attaching to a biocompatible magnetic nanoparticle carrier, etc. Superparamagnetic nature and a high degree of specific magnetization of the magnetic nanoparticles are demanded for their applications in drug delivery or magnetic separation to defeat hydrodynamic forces acting on the nanoparticles in the flowing solution and small sizes are required to allow the transport through the vascular system or tisular diffusion of particles [1,2].

Although there are many kinds of interesting magnetic nanoparticles, we have been focused our study on silica (SiO₂) coated iron oxide (γ -Fe₂O₃) nanoparticles because of their non-toxic nature and lower susceptibility to physical and chemical changes.

Recently, a variety of synthesis methods such as coprecipitation in aqueous solutions, high-temperature decomposition, pyrolysis and hydrothermal synthesis were developed and improved to produce monodisperse nanoparticles. Among them, a precipitation in microemulsion has been shown as a perspective method for the preparation of magnetic nanoparticles of controlled size and morphology [3].

A microemulsion can be defined as a thermodynamically stable isotropic dispersion of two immiscible liquids consisting of nanosized domains of one or both liquids in the other, stabilized by an interfacial film of surface-active molecules. The surfactant molecules provide a confinement effect that limits particle nucleation, growth, and agglomeration.

In the present investigation, silica (SiO₂) coated maghemite (γ -Fe₂O₃) nanoparticles were performed in-situ via the precipitation in two different microemulsion systems – water/CTAB, 1-butanol/1-hexanol and water/SDS, 1-butanol/cyclohexane – according to Schikorr's reaction [4]:

$$\text{Fe}^{2+} + \text{Fe}^{3+} + 2\text{OH}^- + \text{O}_2 \longrightarrow \gamma\text{-Fe}_2\text{O}_3 + \text{H}_2\text{O} \quad (1)$$

In this synthesis, the Fe(II) and Fe(III) hydroxides were precipitated during the reaction between two different microemulsions containing an aqueous solution of corresponding ions (μ E-A) and precipitating reagent (μ E-B). In the second step of the synthesis, the Fe(II) hydroxide is oxidized, resulting in the formation of the spinel maghemite (γ -Fe₂O₃) phase. The maghemite (γ -Fe₂O₃) particles obtained by this synthesis method were nanosized with a narrow particle size distribution of around (8 +/- 2) nm. The γ -Fe₂O₃ nanoparticles precipitated within the nano-sized microemulsion domains were surface coated with various thickness of silica (SiO₂) shell, from 1 nm to 10 nm. The thickness of silica shell was carefully controlled by the amount of tetraethoxysilane (TEOS) added

to the microemulsion after the precipitation step as well as with the size of microemulsion nano-domains affected by the water-to-surfactant molar ratio.

The influence of the microemulsion's composition, the pH value after the precipitation of hydroxides, the concentration of reactants in aqueous phase, the temperature and the time of reaction and the type of surfactant, on the nature of the silica (SiO₂) coated maghemite (γ -Fe₂O₃) nanoparticles were investigated.

Coated and uncoated magnetic (γ -Fe₂O₃) nanoparticles were characterized using transmission electron microscopy (TEM, HRTEM), X-ray diffractometry (XRD) and specific surface area measurements (BET). The specific magnetization (DSM-10, magneto-susceptometer) of the prepared samples was also measured.

The results showed a high specific surface area (BET) of around 105 m²/g corresponds to a small particle size with a narrow particle size distribution of around (8 +/- 2) nm for the prepared samples. The specific magnetization was relatively high and decreased from 59 emu/g for uncoated maghemite (γ -Fe₂O₃) nanoparticles to 17 emu/g for maghemite nanoparticles coated with 6 nm thickness of silica shell. The prepared samples did not show any coercivity (H_c) or remanent magnetization (M_r), which is the characteristic of their supermagnetic nature.

Magnetic nanoparticles obtained by ultrahigh vacuum glancing angle deposition technique at high temperature.

X. Bendaña, E. Ferreiro, G. Armelles, A. Cebollada, J. Garcia Martin
Instituto de Microelectrónica de Madrid IMM-CNM-CSIC, Tres Cantos, Spain

The successful application of magnetic nanoparticles in technological devices such as storage media or magneto-optical sensors requires that the nanoparticles preparation can be made at low cost and short processing time. Among the physical vapour deposition techniques, a relevant possibility is the glancing angle deposition (GLAD) method that employs oblique angle deposition and substrate motion [1]. We will show that such latter condition can be avoided in order to obtain nanoparticles if the deposition is made using a substrate at high temperature.

Co nanoparticle films have been prepared onto glass substrates using magnetron sputtering in an ultrahigh vacuum chamber and GLAD with the off-normal deposition angle being 85° . The nominal thickness of Co was varied between 0.4 and 5 nm. Two series of samples have been prepared: one without capping to study the morphology of the nanoparticles, and another one with gold capping to avoid oxidation and to measure properly the magnetic properties. Two different substrate temperatures were applied during the Co deposition, RT and 400°C . It will be described that as the temperature increases not only the self-shadowing characteristic of GLAD but also the diffusion of the adatoms contributes to the formation of 3D nanostructures [2]: as a consequence, the uniformity is improved and as is shown in Figure 1 nanoparticles can be obtained. The magnetic and magneto-optical properties have been measured using Kerr magnetometry and spectroscopy, respectively, both in transversal (sensitive to the in-plane magnetization) and polar (sensing the perpendicular magnetization) configurations. As is shown in Figure 2, the magnetization reversal process depends on the in-plane direction, revealing a small uniaxial anisotropy with the easy axis perpendicular to the vapour flux direction, in agreement with previous results in ultrathin Co films grown by grazing-incidence molecular beam epitaxy [3].

Introduction/Experiment

Thin films of Co metal and its alloys are of interest due to their application in TMR heads, MRAM and other applications [1,2]. In this work we report on an analysis of the evolution of the structural and magnetic properties of Co films with increasing thickness in the range 10 to 170 nm. The films were grown on glass substrates using a HiTUS sputtering system [3]. The base pressure achieved was 3×10^{-7} mbar and the process pressure was 3×10^{-3} mbar. The deposition rate was 0.6 \AA s^{-1} for all films and a 3 nm Ta cap was also deposited on all samples to prevent oxidation. The structure of the films was determined using X-ray diffraction (XRD). The ultrafine nature of the grains was confirmed by TEM. The surface morphology of the films was imaged by AFM. Magnetic properties were measured by transverse MOKE giving the major hysteresis loops and the transverse susceptibility χ_T .

Results and discussion

Figure 1 shows the XRD pattern of Co films of 80 nm and 170 nm thick. The films are polycrystalline with a dominant hcp phase but with some fcc grains detected by a broad peak around $\theta = 51.6^\circ$. The peak at 44.5° is a combination of hcp (002) and fcc (111) reflections. It can be inferred from these spectra that the films develop the hcp <001> texture as the thickness increases. The crystallite size was estimated using the Scherrer formula and was found to increase from less than 2 nm for the thinnest sample to 24 nm for the thickest film. For fcc crystallites the size is always smaller than hcp varying from less than 2 nm up to 4 nm. This is in agreement with theoretical studies which suggest that the contribution from surface energy can stabilise the fcc phase below a critical size of 20 nm [4]. The ultrafine nature of the grains was confirmed by TEM. Figure 2 shows the 3D AFM images of the films for different thicknesses. Island-like features with a wide distribution of size are observed. The roughness (σ_H) and the average height (H) of the surface increase as the Co thickness increases. This fact is associated with the crystallite growth. Magnetic measurements reveal that the samples have an in-plane magnetization. Figure 3 shows the χ_T with the bias field applied along the easy and hard axis of magnetization. The magnetization reversal along the easy axis takes place in a wider range of applied magnetic field values as the thickness increases, involving more rotations as seen in Fig. 3(a). From Fig. 3(b) we can infer three important features: (i) the thinnest samples show two sharp peaks due to low anisotropy field dispersion, (ii) for thicker samples the anisotropy field, the anisotropy field dispersion and the coercivity increase [see Fig. 3(c)], and (iii) the samples become less magnetically anisotropic as the thickness increases, so higher values of the ratio between the coercivity of the hard (H_{CH}) and easy (H_{CE}) axis are detected [see Fig. 3(d)].

Conclusion

Nanocrystalline Co thin films were deposited by HiTUS. Structural analysis revealed that nanocrystals grow mainly in the hcp phase. Also the fcc phase was present but with much smaller crystallites. Soft magnetic properties and a well-defined uniaxial anisotropy were obtained for thicknesses below 50 nm. However, above this thickness the effective anisotropy begins to be controlled by the magnetocrystalline anisotropy of each crystallite due to the increase of its size. This fact gives rise to an increase in the coercivity, the anisotropy, and the dispersion.

Core-shell magnetic behaviour of iron ultrathin films prepared by sputtering at very low temperatures.

F. Jiménez-Villacorta, R. M. Morillas, E. Salas, E. Céspedes, C. Prieto
Instituto de Ciencia de Materiales de Madrid - CSIC, Madrid, Spain

Heterogeneous structures, formed by magnetic transition metal (TM) and its correspondent oxide (TMO), have raised great attention because of their unique properties. Besides other differences in magnetic features between bulk and nanostructures, a very fascinating effect is the interaction between the metal and the oxide, resulting in an overcome of the superparamagnetic effect, enhancement of the coercivity and, if the oxide component has a sufficiently large anisotropy, exchange bias[1,2]. Their microstructure plays a key role in the magnetic behaviour and changes the electrical resistivity and magnetoresistive properties[2]. TM/TMO structures have been largely investigated in several systems as magnetic particles in ceramic matrices[3], core-shell systems[4,5] and thin films[6]. Moreover, exchange-bias has been proposed as an appropriate mechanism to stabilize magnetization in nanostructures against thermal fluctuations[3]. Although the low blocking temperatures observed for TM/TMO systems can limit their potential applications, nanoparticles surface modification has been proposed for magnetic decoupling and consequently applications in magnetic recording[7]; for instance, passivating with an oxide layer. We have reported that partially oxidized Fe films prepared at low temperature consist essentially in granular core-shell magnetic systems, formed by ferromagnetic metallic iron grains surrounded by an iron oxide phase[8]. Samples prepared near $T_S = 200$ K are especially remarkable because they present a magnetic behaviour typical from particle system with random anisotropy axes, in which nanocrystalline grains act as almost decoupled particles, surrounded by an oxide shell, forming exchange biased core-shell systems[9].

In this work, we present a structural and magnetic characterization of partially oxidized Fe ultrathin films with nominal thickness of 6 nm (capped with SiO_2) obtained by sputtering on Si substrates at 200 K as well as the comparison with samples prepared at room temperature. Fig. 1 shows hysteresis loops obtained at different temperatures after cooling sample under an applied field of 20 kOe (FC cycles) and magnetization vs. temperature curves obtained after cooling sample with and without an applied magnetic field (FC and ZFC curves, respectively).

The obtained hysteresis loops as well as ZFC-FC magnetization curves of films prepared at low temperatures are similar to that obtained for thicker samples. All they are consistent with granular core-shell magnetic systems, formed by ferromagnetic metallic iron grains surrounded by an iron oxide phase. At lower temperatures, magnetization loops show that spins from the iron oxide shell (mainly consisting in FeO and Fe_3O_4) behave as a spin frozen system able to interact with the ferromagnetic core spins, leading to exchange anisotropy.

It can be concluded that from the magnetic characterization, ultrathin films prepared at $T_S = 200$ K behave as ferromagnetic nanocrystalline grains acting as almost decoupled particles surrounded by an oxide shell forming exchange bias core-shell systems.

Preparation and magnetic properties of disordered CdFe₂O₄ thin films.

H. Akamatsu, Y. Zong, Y. Fujiki, K. Kamiya, K. Fujita, S. Murai, K. Tanaka
Material Chemistry, Kyoto University, Kyoto, Japan

Cadmium ferrite (CdFe₂O₄) possesses a normal spinel structure in its stable phase, where Cd²⁺ ions occupy tetrahedral sites (A sites) and Fe³⁺ ions octahedral sites (B sites) in a face-centered-cubic closely packed oxide ion sublattice. It is well known that the normal spinel type of CdFe₂O₄ behaves like an antiferromagnet with a Neel temperature of 13 K, although, strictly speaking, spin freezing with only short-range correlation occurs at 13 K and no long-range order is observed down to 0.1 K. But a nonzero magnetization and high magnetic ordering temperature can be observed for CdFe₂O₄ nanoparticles fabricated by coprecipitation method and high-energy ball-milling. Large magnetization and high magnetic ordering temperature are attributed to such a structure that a site exchange between Cd²⁺ in the A site and Fe³⁺ in the B site takes place, and that strong superexchange interaction between Fe³⁺ ions in A and B sites leads to a ferrimagnetic order at least for localized magnetic moments even above room temperature. Our research group recently has fabricated sputtered ZnFe₂O₄ thin films, stable phase of which possesses a normal spinel structure, and is a frustrated antiferromagnet similar to CdFe₂O₄, and demonstrated that a ferrimagnetic behavior of the films is imposed to a site exchange of cations from the analysis of x-ray absorption near-edge structures (XANES).¹⁾

In this presentation, we report on structural and magnetic properties of CdFe₂O₄ thin film prepared by the sputtering method. Sputtered CdFe₂O₄ thin films were deposited on silica glass substrates in an atmosphere of oxygen or argon by using a mixture of CdO and Fe₂O₃ powders as a target. The as-deposited and annealed thin films were subjected to an x-ray diffraction analysis with Cu K α radiation to ascertain that the thin films were composed of a single phase of CdFe₂O₄.

Figure 1 illustrates dependence of magnetization on magnetic field of the sputtered CdFe₂O₄ films deposited in the oxygen atmosphere with or without heat treatment at 200 and 400 °C. Any films show ferro- or ferrimagnetic behavior even at room temperature. This may be due to the site exchange between Cd²⁺ in the A site and Fe³⁺ in the B site. The magnetization of CdFe₂O₄ thin film annealed at 200 °C is larger than the as-deposited thin film, and the film annealed at 400 °C has magnetization smaller than that of the as-deposited film.

Temperature dependence of magnetization for the present films is shown in Fig. 2. Cluster spin glass-like behaviors are observed for the as-deposited film and the film annealed at 200 °C, indicating that a ferrimagnetic order occurs for only localized magnetic moments. The magnetic behavior of the thin film annealed at 400 °C resembles that of bulk CdFe₂O₄. The annealing of the thin films at high temperatures such as 400 °C is apt to bring about the formation of CdFe₂O₄ with the normal spinel structure, leading to the magnetic behavior similar to that of bulk. In the presentation, we will also show results of analysis of XANES and Faraday effect measurements.

Nowadays magnetic nanoparticles (NPs) by using chemical synthesis have been received considerable attention due to their wide range research field such as bio-applications in marker or labeling material, separation, drug delivery, therapy, and sensors [1-4]. The aim of this work is to enhance the saturation magnetization (M_s) of the FePt nanoparticles (NPs) by controlling the initial mole ratio of Fe to Pt precursors and reaction conditions to effectively increase magnetization due to the size-dependent effect and with biocompatibility via surface modification. For a compositionally controlled synthesis with the reduction is as follows: 0.5 mmol for Pt(acac)₂, Fe(acac)₃ ranged from 0.5 to 1 mmol, 4.5 mmol 1,2-hexadecanediol were mixed with 30 ml of phenyl ether. The flask was heated up to 100 °C for 30 min with additive oleic acid (1~2 mmol) and oleylamine (0.5 mmol) stabilizers into flask at the same time. The initial mole ratio (Fe:Pt) of Fe to Pt precursors are varied from 1, 1.25, 1.5 to 2 (Fe):1 (Pt), respectively. And then they were heated up to 260 °C for 0.5~3 hr under the argon blanket. For all as-synthesized FePt NPs with different mole ratios are superparamagnetic at room temperature as shown in Fig. 1(a). The M_s of FePt NPs with reaction time for 0.5 hr increases from 1.5 emu/g (1:1) to 4.5 emu/g (2:1) with increasing Fe:Pt mole ratio due to the contribution of Fe atoms. The temperature dependence of the magnetization in an applied field of 50 Oe between 5 and 300 K using field cooling (FC) and zero-field cooling (ZFC) procedures was studied and showed a blocking temperature (TB) of about 18 K for FePt (2:1) NPs [Fig. 1 (b)]. The Curie temperature (TC) of FePt NPs is strongly composition dependent. It was also found that TC decreases with decreasing sizes of the FePt NPs. The FePt NPs with the disordered fcc structure could monodispersed in hydrophobic solvents without significant aggregation, and the average particle size was 2.5 nm with the narrow size distribution as shown in Figs.1 (c) and 1(d), respectively. It could be realized that the as-synthesized FePt NPs below critical particle size ($D_p \sim 3$ nm) is at superparamagnetic state. The following analysis will be mainly focused on the ratio of 2 (Fe:Pt) with Fe₅₈Pt₄₂ composition as characterized by Nano-EDS, in order to enhance M_s effectively and investigate the effect with different reaction time. The variations of the XRD diffraction patterns and magnetization loops of the FePt (2:1) NPs with reaction time ranged from 1 to 3 hr are shown in Fig. 2. With increasing reaction time of the FePt NPs from 1 to 3 hr, the intensities of the FePt (111) and (200) diffraction peaks increased as shown in Fig. 2(a). It was found that the room temperature saturation magnetization increased from 11 emu/g (1 hr) to 18 emu/g (1 hr) with the increase of reaction time as shown in Fig. 2(b), and reached a maximum value of 36 emu/g while reacted temperature at 260 °C for 3 hr due to the increased size of FePt NPs. The FePt NPs were then transferred from oil- to water-soluble (bio-compatible) state and the covalent protein attachment was prepared by the mercaptoacetic acid (C₂H₄O₂S). Streptavidin conjugation to FePt NPs which was used to cross-link free carboxylic acid groups on FePt NPs with amine-containing streptavidin. To examine the binding activity with antibodies, COOH- and EDC (1-ethyl-3-(3-dimethylaminopropyl) carbodiimide hydrochloride) modified FePt NPs were resuspended in PBS buffer and biotin-antibodies (goat polyclonal IgG) were added. FePt NPs attached with streptavidin-biotin as a bridge for binding selective protein/antibodies/DNA for functional nanoparticles were identified

by using SDS/PAGE analysis as shown in Fig. 3. The further result shows that the binding activity of streptavidin-FePt NPs with antibodies increased in a sigmoidal saturated fashion along with increasing amount of biotin-antibodies. In this study, the high magnetization of water-soluble FePt NPs can be achieved by adjusting the molar ratio of Fe:Pt precursor and reaction time. It further confirms that FePt nanoparticles with high magnetization have been successfully conjugated to streptavidin protein and yet possess the ability to affinity bind to biotin-linked goat polyclonal IgG in aqueous solution as simulated in human body fluid. The potential usages of hydrophilic FePt NPs with high M_s conjugated with functional protein/antibodies/DNA have been attracted more interests in future biomedical development.

Properties of Co-HfO₂ nanogranular magnetic thin films.

M. Chadha, V. Ng

ECE, National University of Singapore, Singapore, Singapore

Granular films comprise of well-defined nanometer size magnetic grains embedded in an insulating matrix has been a topic of active research [1]. Conduction takes place by electron tunneling through the insulator barriers between the magnetic grains giving rise to the spin dependent Tunneling Magneto Resistance (TMR) phenomenon. Owing to their nanometer size, the system also exhibits the coulomb blockade phenomena [2]. However, the most extensively studied Co-Al₂O₃ granular system shows a high content of cobalt oxide in the films [3-4] which results in a decrease in the TMR effect [4].

In the present work we investigate the effect of hafnium oxide (HfO₂) used as a new insulating matrix in the cobalt granular film to decrease the possibility of formation of cobalt oxide during sputtering. Our motivation is related to the heat of formation of hafnium oxide being significantly higher than other oxides [5]. Besides introducing a new oxide material, we utilise a new sputtering method to control the properties of the system.

Granular films were sequentially sputtered on glass and silicon substrates using argon at 5 mTorr and a base pressure of ~10–8 Torr. A thin and discontinuous Co layer of nominal thickness T(Co) is first deposited, forming discrete Co grains. Then a discontinuous HfO₂ layer of T(HfO₂) gets deposited either in-between or as well above the Co grains. This is sequentially repeated to obtain a total thickness of 20 nm, followed by 8 nm of capping HfO₂ layer. The Co grain size and the inter-particle oxide width can be independently adjusted with this method. T(Co) and T(HfO₂) were varied while keeping the total thickness constant.

X-ray photoelectron spectroscopy on the as-prepared Co-HfO₂ films show that the cobalt oxide peak is much smaller than that for Co-Al₂O₃ films. The magnetic properties were measured at Room Temperature (RT) using the vibrating sample magnetometer. Aluminum (Al) contact pads were sputtered by the shadow mask technique. The magnetoresistance (MR) of the samples were measured at RT by DC four-point probe setup with application of a maximum field of 4 kOe along the in-plane direction.

Fig. 1 (i) presents the hysteresis loops for films having T(HfO₂) = 0.9 nm and T(Co) varying from 0.6 to 1.5 nm having 13 to 8 bilayers, referred as film A to F respectively. Fig 1 (ii) is the zoomed in of fig 1(i). Fig 2 (i) show the trends in coercivity (H_c) and Squareness (S) vs. T(Co). For films A-D, with small Co contents, the grains are superparamagnetic which is inferred from their low H_c and S values. With increase in T(Co) for fixed T(HfO₂), the grain density and size increase. This increases the interaction between the grains giving rise to a gradual decrease in H_c and increase in S. Further increase of T(Co), in films E and F produces films of high H_c and S values, implying that of single domain ferromagnetic nature.

Fig. 3 shows the MR graphs. The TMR ratio is defined as $\Delta R/R_0$ where R₀ is the film resistance at zero field and ΔR is R₀ - (film resistance at 4 kOe). Fig 2 (ii) shows the TMR ratio vs T(Co). The superparamagnetic film D shows the maximum TMR ratio. For superparamagnetic films having smaller T(Co) (i.e. films A to C) the spin diffusion length is smaller than the tunneling barrier for effective spin tunneling showing small TMR ratio and gradual MR curve. As the single domain grains have a small contribution to the spin dependent scattering [6], film E and F show low TMR ratio and sharper curves. Similar analysis was carried on films having T(Co)= 0.9 nm and T(HfO₂) varying. The combined results will be presented in full paper. We found T(Co) = 1.0 nm

and T(HfO₂) = 0.9 nm, having 10 bilayers has a maximum TMR ratio of 3.92 % (± 4 kOe, 300 K) and 5.81 % (± 4 kOe, 10.4 K).

A device 200 nm by 200 nm by 20 nm (l by w by t) fabricated with the granular film deposited between the microscopic Al contact pads produced an enhancement in the TMR ratio (by 86% at RT). Devices with smaller dimensions are currently being fabricated.

In conclusion, by introducing a new insulator we have successfully reduced the amount of cobalt oxide content. Using the sequential sputtering method, properties varying with the microstructure were comprehensively studied and an optimum composition of Co and HfO₂ layers thickness is achieved.

Biocompatible magnetic nanoparticles, such as magnetite (Fe₃O₄) and maghemite (γ -Fe₂O₃) have potential biomedical applications including contrast agents for magnetic resonance imaging, cell separation, targeted drug delivery, and localized hyperthermia. External magnetic fields can be used to deliver the magnetic particles in vivo to specific sites for targeted drug delivery applications. However, surface functionalization of these magnetic carriers is necessary for in vivo drug delivery. Liposomes, alginate, and other biopolymers have been commonly used for this purpose. Recently, Panyam *et al* [Pharmaceutical Res. **24**, (2007) 803] have reported a study on Aerosol OTTM (AOT)-alginate nanoparticles as a potential functional unit for enhanced and sustained cellular delivery of the water soluble drugs. This study demonstrated that encapsulation of doxorubicin in AOT-alginate nanoparticles resulted in higher and more sustained (>10 days) cellular delivery and cytotoxicity in tumor cells grown in culture.

Here we report the synthesis and characterization of AOT-alginate nanoparticles (25- 50 nm) loaded with rhodamine 6G (R6G), a water soluble molecule, and Fe₃O₄ nanoparticles (10 nm) using an emulsification-cross-linking process. R6G (1 mg) dissolved in aqueous sodium alginate solution (2% w/v; 0.5ml) was emulsified into AOT solution in chloroform (2.5% w/v; 2 ml) by sonicating for 1 min over ice bath. The primary solution is further emulsified into 15 ml of aqueous polyvinyl alcohol (PVA) solution (2% w/v) by vortexing for 1 min and sonicating for 5 min over ice bath to form a secondary water-in-oil-in-water emulsion. The emulsion was stirred using a magnetic stirrer, and 5 ml of aqueous calcium chloride or ferrous chloride solution (60% w/v) was added gradually to the above emulsion. The emulsion was stirred further at room temperature for ~ 24 hr to evaporate chloroform. Nanoparticles formed were recovered by ultracentrifugation at 30,000 rpm for 30 min, washed two times with distilled water to remove excess PVA and free R6G molecules, resuspended in water and lyophilized. We have prepared Ca²⁺ or Fe²⁺ cross-linked alginate-AOT-nanoparticles without and with incorporating Fe₃O₄ magnetic nanoparticles. For the latter, we added 5 % (by wt. of alginate) Fe₃O₄ magnetic nanoparticles, prepared by a soft chemical method, to the aqueous alginate solution during the processing.

The structural characterization of the R6G loaded alginate-AOT nanoparticles were carried out using transmission electron microscopy (TEM). For example, Figs. 1(a) and (b) show the TEM images of Ca²⁺ cross-linked Alginate-AOT nanoparticles without and with Fe₃O₄ magnetic nanoparticles. The alginate-AOT nanoparticles, varying in size between 25 to 50 nm, show an increased agglomeration due to incorporation of magnetic nanoparticles. It is clearly seen that the Fe₃O₄ nanoparticles are uniformly coated with a thin layer (~5 nm) of polymer as shown in the inset of Fig. 1(b).

The magnetic properties of the nanoparticles suspended in water were measured, using a SQUID magnetometer, with the results shown in Fig. 2. The bare Ca²⁺ cross-linked alginate-AOT nanoparticles are paramagnetic as can be seen in Fig. 2(a) from the M-H curves (inset) showing a linear dependence, and also from the temperature dependence of ZFC-FC curves. However, the composite Fe₃O₄-alginate-AOT nanoparticles show a superparamagnetic behavior at room temperature

with a saturation magnetization of ~50 emu/g of Fe₃O₄. The ZFC-FC curves of this composite exhibits a blocking temperature of TB~ 100 K. Below TB, hysteretic behavior is observed with a coercivity ~ 250 Oe. The sharp drop observed in Fig. 2(b) ~ 270 K is due to blocking of brownian relaxation of magnetic nanoparticles caused by freezing of water. Similar results were observed in the case of Fe²⁺-cross linked alginate-AOT nanoparticles, but with a two-fold increase in magnetization. The details of these results and the effect of magnetic nanoparticles on the R6G loading in AOT-alginate nanoparticles, as determined by HPLC analysis, will be discussed.

Fig. 1: Transmission electron micrograph (TEM) of Ca²⁺ cross-linked (a) alginate-AOT nanoparticles and (b) composite Fe₃O₄-alginate-AOT nanoparticles. Inset in (b) shows an individual Fe₃O₄ nanoparticle embedded inside AOT-alginate nanoparticles

Fig. 2: Magnetic properties of Ca²⁺ cross-linked (a) alginate-AOT nanoparticles and (b) composite Fe₃O₄-alginate-AOT nanoparticles. The main panel shows the temperature dependence of the ZFC-FC curves measured using 200 Oe field. The insets show the field dependence of magnetization.

Iron Oxide Nanoparticles Embedded in Thermoplastic Polymers for Magneto-optical Devices.

Optical plastics filled by nano-sized magnetic particles may have relevant applications in magneto-optics as for optical modulators and insulators and optical shutters, [1]. In this framework, the paper proposes the full characterization of ferromagnetic and superparamagnetic magnetite (Fe_3O_4) nano-particles embedded in polystyrene. These materials are generated by thermal decomposition respectively of iron (II) and iron (III) mercaptide in amorphous polystyrene.

Transparent plastics embedding nano-sized magnetic phases have unique physical features. Because of the small size of the guest phase (less than 50nm), these materials do not scatter visible light, so they are quite transparent in the VIS-NIR spectral region and, at the same time, they have relevant magnetic characteristics. Moreover, the Verdet's constant of a polymeric material filled with ferromagnetic nanoparticles is very large.

Recently, easy chemical method for the synthesis of polymer-embedded noble metal and sulfide clusters have been developed; this method is based on the thermal decomposition of homoleptic mercaptide molecules dissolved in polymers [2]. Thermolysis of mercaptide molecules takes place at temperatures compatible with polymer thermal stability, in addition normal alchyl mercaptides (i.e., $\text{Me}(\text{SC}_{12}\text{H}_{25})_x$) perfectly blend with most techno-polymers because of their non-polar nature. Because of the polymeric structures, mercaptides are hardly soluble in polar solvents (e.g., ethanol, etc.) and therefore they can be simply synthesized by adding the alcane-thiol to a metal salt solution in ethanol or an alkaline thiolate to a aqueous salt solution.

The nature of the inorganic phase generated by decomposition of iron (II) mercaptide and iron (III) mercaptide (i.e., $\text{Fe}(\text{SC}_{12}\text{H}_{25})_2$, $\text{Fe}(\text{SC}_{12}\text{H}_{25})_3$) dissolved in polymer was established by large angle X-ray powder diffraction (XRD). According to XRD data the inorganic phase generated by decomposition of iron mercaptide dissolved in polymer was magnetite (Fe_3O_4). The morphology of inorganic phase generated inside the polymer during the thermal annealing treatment was imaged by TEM. The magnetite/polystyrene nanocomposites obtained starting from iron (II) mercaptide gave aggregates of differently shaped particles (fig1a). The most prominent phase was made of acicular particles (10nm x 50nm) which exactly corresponded to the magnetite texture [3]. On the contrary, the magnetite/polystyrene nanocomposites obtained starting from iron (III) mercaptide showed only one isolated spherical nanoparticles, with an average size of 6 nm (fig. 1b).

The optical properties of the obtained films were analyzed by UV-Vis spectroscopy. The samples resulted quite transparent at wavelengths higher than 550nm (fig.2).

The magnetic characterization has been performed by a Vibration Sample Magnetometer. The results for the annealed iron (II) mercaptide/polystyrene blends are presented in fig.3. They show a ferromagnetic behavior depending on the different mercaptide amounts (down) and an hysteretic behavior, just like bulk magnetite [4].

The characteristic magnetic parameters (i.e. saturation magnetization and remanence) of the magnetic plastics are strictly connected to the amount of magnetite dispersed in the polymeric matrix and present a dependence on the applied field orientation (fig.3 up).

In spite of encouraging progress in recent years, the development of magnetic nanoparticles that can be used as drug delivery vectors remains challenging. Among the multiple hurdles that must be overcome are the provision of a sufficiently high magnetic response and an adequate degree of biocompatibility. Here we synthesize alloyed nanoparticles in the iron-cobalt system through vapour-phase condensation and investigate their coating with magnesia shells to provide exceptional advantages such as environment stability, controlled interparticle interactions, enhanced magnetic moments and non-toxic hydroxyl surface groups that provides intrinsic hydrophilicity and allows surface attachment of drugs or biomolecules [1].

Namely, a target containing mixed powders of Fe, Co and MgO in the desired proportion is vaporized inside a vacuum chamber by focusing the sun heating power from a speculo ustorio as described in Ref. [2]. In the foregoing specification, the invention has been described with reference to specific embodiments. However, further modifications will be apparent to those skilled in the art. Moreover, effect of the process conditions on the synthesized powder, such as particle size, thickness of the shell, magnetic properties, etc., has not been studied systematically. For instance, the particles produced by this method can exhibit a size ranging from 5 to 200 nm, which depends mainly on the gas pressure during evaporation. With increasing argon pressure, a trend for increasing particle size was observed [3] as results from the decrease in the mean free path of the Fe atoms. Transmission electron microscopy (TEM) was used to study the crystal structure and particle morphology. Nearly spherical crystals with negligible shape anisotropy were obtained [Fig 1(a)]. Most likely because of the difference in surface energies, the metal clusters do not wet the MgO surface and therefore the MgO forms a continuous and epitaxial shell over the Fe islands [Fig 1(b)], as previously reported in Fe/MgO(001) thin films [4].

To investigate the magnetic properties of such well-defined and insulated Fe nanoparticles, they were mechanically compacted. In our case the particles thus obtained present a much stronger magnetic response than any composite material produced up to now involving magnetic nanoparticles encapsulated in inorganic matrices [Fig 2(a)]. The MgO capping might explain this behaviour due to the enhanced magnetic moment predicted for Fe atoms in the interface with a MgO layer [5]. According to the Mossbauer studies, 12 % of the iron atoms show a doublet that represents sites that are characterized by the broken translational symmetry at the surface of each particle [inset Fig 2(a)]. Magnetic measurements and TEM analysis were repeated on some of the samples in order to examine any aging effects, but no diminish of the properties was detected over several months' storage under ambience conditions.

Figure 2(b) shows the magnetic field dependence of the resistance for a MgO₅₀Fe₅₀ pellet at 150K. The value of the MR decreases with increasing field as may be explained by an increasing degree of alignment among magnetic moments in the samples. The absolute values of the magnetoresistive effect are small and decrease as the temperature rise, due to electron hopping between metallic grains in a process involving thermally activated tunnelling. Nevertheless, these core-

shell formations constitute a model system for studying the physics of spin-dependent tunnelling because of their well-defined structure. On the other hand, an equivalent level of comprehension of the magnetoresistance effect in planar junctions has only recently emerged through the study of MgO(001) barriers with values of TMR that currently reach 1000% [6]. Also, the use of MgO and Fe makes the batch process cost-effective since the ferropericlas Mg_{1-x}FexO and the (Mg,Fe)SiO₄ silicate are the major constituents of the earth's mantle.

High Perpendicular Anisotropy Layers stacked Exchange Coupled Composite Media.

S. Oikawa, T. Maeda, A. Takeo

Hard Disk Drive Development Dept., TOSHIBA Corporation, Kawasaki, Japan

Introduction

There has been lots of calculation reports about Exchange Coupled Composite (ECC) media consisting of magnetically hard and soft($K_u=0$) sub-grains, since the proposal by Victora et al [1]. Experimentally, it is difficult to make the soft sub-grain saturated in the perpendicular direction of the thin film media due to the demagnetizing field. However, the ECC media with Co-SiO₂ as the soft layer is actually reported that shows a good perpendicular squareness with negative nucleation field H_n , and a excellent read/write performance [2]. In this study, the appropriate design of uniaxial magnetic anisotropy K_u of the soft layer were examined in the shape of thin film by LLG simulation. ECC media show excellent properties when relatively high K_u values are given to the soft layer.

Results and Discussion

The simulated results of one ECC grain magnetic behavior reproduced the study by Victora et al [1], such as the coercivity H_c reduction in a moderate interlayer coupling, and the flat angular dependence of switching field. Extending the simulated medium shape from one grain (8nm square) to thin film (192nm square), the slope of the magnetization curve in the part corresponding to the soft layer (thicker than the hard layer) became small due to the demagnetizing field and the perpendicular squareness R_s had fallen to about 0.6.

Smaller soft layer thickness ratio could improve the R_s . Fig. 1 shows the magnetization curve simulated at 300K condition. M_s and K_u in the hard layer(16nm) were set to 600emu/cc, 4E6erg/cc, respectively, assuming the present CoCrPt-oxide granular layer. K_u in the soft layer(4nm) was supposed as 0erg/cc. The shoulder of the curve seems to be round shape and the R_s is about 0.9 even in the direct coupling (no interlayer; $A_{12}=1.0$ uerg/cm). The ECC media with zero- K_u soft layer could not keep its magnetization in perpendicular saturated states under the thin film demagnetizing field, even if the soft layer was coupled directly with the hard layer.

As experimental comparison, the ECC media similar to that by Shimatsu et al. [2] was prepared using a sputtering system (CoPtCr-oxide hard layer / (interlayer) / Co-oxide soft layer). $R_s=1$, more than 2kOe of H_n and the H_c reduction in the ECC media were obtained successfully. Simulating the magnetization curve and the angular dependence of remanence coercivity H_{cr} with various K_u , M_s , A_{12} in the soft layer, the parameters had been investigated which could explain the experimental results most appropriately. As a result, calculated values in the combinations of $M_s=900$ emu/cc and $K_u=4$ E6erg/cc gave relatively good agreement with experimental results (Fig. 2). These results suggest the possibility that the experimental top Co granular layer has high K_u as the bottom CoPtCr granular layer. It is presumed that the unity of R_s in ECC media requires a large positive K_u of the soft layer (the order of 1E6erg/cc) enough to overcome the demagnetizing field, with the support of the interlayer coupling.

Even if the soft layer has as large K_u as the hard layer, high M_s of the soft layer provides lower anisotropy field H_k than that of the hard layer. The observation of the magnetization reversal process in the simulated ECC media with the high K_u soft layer displayed the prior rotation of the soft layer to that of the hard layer, which makes the switching field of the ECC media reduced.

The additional simulations were performed about the case that the soft layer had a negative K_u [3]. The angular dependence of the normalized H_{cr} for the high K_u soft layer was close to that for sin-

gle hard layer, different from that for the zero and negative soft layer. This property is similar to that of current perpendicular media.

Simply, higher K_u of the soft layer can increase the vK_u/kT in one whole grain of ECC media. The result of thermal decay simulations indicated that the ECC media with positive K_u soft layer had higher thermal stability than that with zero and negative K_u soft layer, as expected.

The perpendicular anisotropy of the soft layer in ECC media are thought to need to take a positive large value in order to realize the ECC media type of magnetization reversal in the shape of thin film, which will lead to the above various advantages.

Segregation Mechanisms in Co-based Oxide Recording Media.

1. Hitachi San Jose Research Center, San Jose, CA; 2. IBM Almaden Research Center, San Jose, CA

Introduction

A key requirement for ultra-high density recording is the development of a microstructure comprising uniform, small, thermally-stable and highly-oriented magnetic grains which are segregated and magnetically-decoupled by non-magnetic secondary phases. Species such as SiO₂, TiO₂ or Ta₂O₅ are incorporated into the target material employed to deposit the recording layer, and the segregation process is empirically controlled by optimizing the deposition parameters. This paper elucidates the mechanisms leading to the formation of the desired recording layer microstructure.

To derive a high degree of crystallographic and magnetic orientation, the use of a multi-layer stack employing seed layers such as NiW (fcc) directly deposited on the SUL followed by growth of hcp intermediate layers (IMLs) such as Ru are employed. Development of a highly oriented recording alloy is a necessary but not a sufficient condition for high density magnetic recording. Two critical processing steps have been found to be essential to yield the desired structural and magnetic properties: a) the optimized addition of oxygen into the sputter plasma for deposition of the magnetic layer and; b) the growth of said magnetic layer on an IML deposited under high pressure sputter conditions. We have used HRTEM combined with EELS analysis, XRD and magnetometry to elucidate the role each of these layers and processing steps play in the evolution of the optimum segregated microstructure.

Results and Discussion

Fig. 1 compares the microstructure of CoPtCr-TaOx grown on 18 nm thick Ru underlayers grown both at high and low pressure. A cursory inspection of the TEM images reveals little differences between them. However, as shown in (C), the magnetic properties are vastly different. Utilizing high angle annular dark field imaging (HAADF) and EELS analysis we note that growth of the magnetic alloy on low pressure Ru, leads to a high degree of bridging between magnetic grains. This leads to intergranular exchange coupling, resulting in coercivity losses. The high pressure regime, leads to interface roughness which drives the grain segregation and removes the bridging.

To verify the role of interfacial roughness in the segregation of the CoPtCr-SiO₂, nanoscale layers were intercalated between Ru (RuCr) IMLs grown at low pressure and the magnetic layer. As an example, sub-nm Ta₂O₅ nucleation layers were deposited at high sputter pressures to generate a discontinuous film at the interface. In Fig. 2 the layer sequencing, the evolution of interface roughness and the dependence of H_c on the nanolayer oxide thickness are given. A boost of ~ 1.5 kOe in H_c was measured when a 0.25 nm layer of the oxide was intercalated. Comparable film coercivity improvements as well as good SNR were obtained using high sputter pressure deposited nucleation layers (Ref 1). Note that as the layer thickness is incremented, the magnetic properties are negatively impacted due to loss of epitaxial growth.

The role of oxygen on the evolution of the CoPtCr-SiO₂ microstructure was investigated by adding O₂ to the sputter plasma during the CoPtCr-SiO₂ growth. The results are given in Fig. 3, in which the influence of Oxygen addition on recording media grain size and film coercivity are given. Measurements were also made of the intergrain boundary zone dependency on oxygen content as well as changes in magnetic anisotropy.

In summary, results will be presented to elucidate the mechanisms driving the segregation process in recording media. These include interface roughness, the oxygen-mediated precipi-

tation of the oxide phase at the grain boundaries, and the influence of the microstructural properties of both the IML and seed layers.

Pseudo-hcp material and its evaluation for perpendicular recording media.

S. Saito¹, M. Takahashi^{2,1}

1. Electronic engineering, Tohoku university, Sendai, Japan; 2. New industry creation hatchery center, Tohoku univ., Sendai, Japan

Pseudo-hcp structure (00.2-oriented hcp or 111-oriented fcc structure with stacking faults) and its structural evaluation will be introduced as showing its typical advantage in the texture control of overlying layer for a nonmagnetic intermediate layer (NMIL: alternatives to Ru) including a seed layer like as Ni-W alloy. Our newly proposed evaluation was also found to be effective in recording layer (RL) materials to clarify relationship between stacking order of atomic layers and uniaxial magnetocrystalline anisotropy (K_u) of Co based materials.

A NMIL plays an important role in controlling the structure of a RL by providing nuclei sites for the growth of magnetic grains in the RL, and by promoting epitaxial growth of the magnetic grains in the RL to afford a *c*-plane sheet texture. A precious metal Ruthenium (Ru) with a *c*-plane orientation and rough surface is widely used as an NMIL material. However, large Ru thicknesses (12–30 nm) sputtered under high P_{Ar} (enhancing the surface roughness) required greatly increase the cost of mass production of the media. From this view point, we propose new fcc materials with highly coherent stacking faults (pseudo-hcp materials) as alternative NMIL materials to replace hcp Ru, focusing on the conditions required for epitaxial growth. Fig. 1 shows the relationship between F_{NMIL}^{RL} and S_{NMIL}^{Co} for granular RL fabricated on various NMILs. Equivalence lines of K_u^{RL} (average value of K_u for CoPtCr-SiO₂ layer) are also shown. Here, F_{NMIL}^{RL} is the misfit defined as equ. (1), the distance between the nearest neighbor atoms in the close-packed plane of NMIL (d_{int}^{NMIL}), and the nearest neighbor atomic distance in the *c*-plane of CoPtCr magnetic grains ($d_{int}^{RL} = 2.56 \text{ \AA}$):

$$F_{NMIL}^{RL} = (d_{int}^{NMIL} - d_{int}^{RL}) / d_{int}^{RL} \quad (1)$$

While S_{NMIL}^{Co} is the spreading coefficient of the wettability of Co for NMIL, and is derived from Young-Dupré's equation:

$$S_{NMIL}^{Co} = \gamma_{NMIL} - (\gamma_{NMIL-Co} + \gamma_{Co}), \quad (2)$$

where, γ_{NMIL} and γ_{Co} denote the surface energy for solid NMIL material and solid Co, respectively, and $\gamma_{NMIL-Co}$ denotes the interfacial energy between solid NMIL material and liquid Co. Remarkable feature is; 1) alloying fcc metals (Ni, Pd, Pt, Ir etc.) with bcc metal former (Cr, Mo, W, Ti, Nb, etc.), equivalent pseudo-hcp structure is obtained. The enhancement of the preferred epitaxial growth of hcp magnetic grains took place on only the specified (111) atomic terraces of the fcc NMIL with stacking faults, suppressing the equivalent variant growth (see ref. [1]), and 2) $F_{NMIL}^{RL} < 6 \%$ and $S_{NMIL}^{Co} > 0.3 \text{ J/m}^2$ are essential requirements for the NMIL material to induce high K_u^{RL} of over $4.4 \times 10^6 \text{ erg/cm}^3$ [2]. According to these guiding principles, not only binary alloys such as Pt-Cr, and Ir-Cr, but also ternary alloy systems with pseudo-hcp structure are suitable for alternative NMIL materials to replace Ru.

We also propose simple measure of the degree of stacking faults by using conventional laboratory-scale XRD. According to the in-plane XRD profile for pseudo-hcp materials, two diffractions can be seen; one originates from pure fcc (220) plane, I_H , which is very common and gives no information of the stacking faults. The other appears at low angle side, I_L , which can not be identified as the fcc structure but reflects the frequency of the stacking faults in the fcc lattice. Note that diffractions of I_H and I_L are equivalent to (11.0) and (10.0) diffractions of the hcp system (see fig. 2 (a-b)). Therefore, intensity ratio of I_L/I_H corrected by Lorentz and atomic scattering factors is defined as the degree of stacking order for pseudo-hcp materials. Theoretically, corrected I_L/I_H can

be expressed by using structure factor of (11.0) and (10.0) diffractions, $E_{(11.0)}$ and $E_{(10.0)}$ as $|E_{(10.0)} / E_{(11.0)}|^2$, where $E_{(10.0)} = N_A + N_B \exp(-2\pi i/3) + N_C \exp(-4\pi i/3)$, $E_{(11.0)} = N_A + N_B + N_C = N$, and N_A, N_B, N_C correspond to the number of total and each atomic layer, respectively. Ideal values of this index are 0.25 for hcp stacking, while 0 for fcc stacking. Fig. 2 (c) shows corrected I_L/I_H for various pseudo-hcp materials as a function of additional material content. By adding various additional elements to host fcc materials, Ir and Pt based alloys are found to strongly enhance the hcp-like structure. In the presentation, relationship between I_L/I_H and K_u of Co based alloys are also discussed.

Magnetic interaction between recording layer and soft underlayer in granular-type perpendicular magnetic recording media with thin intermediate layer.

K. Shintaku

Akita Research Institute of Advanced Technology, Akita Prefectural R&D Center, Akita, Japan

Introduction

For high-density perpendicular recording, reduction of the film thickness of an intermediate layer between a recording layer and a soft underlayer (SUL) is important for saturation recording. A high- B_s soft underlayer is also needed to reduce the film thickness from the viewpoint of industrial production. To solve these problems simultaneously, I proposed CoPt-TiO₂ media with a highly oriented Fe-Co SUL with a high- B_s of 2.45 T and a thin Ru intermediate layer [1]. A CoPt-TiO₂ recording layer on a Ru intermediate layer of only 2 nm had a high crystal orientation, a high H_c , and a high squareness ratio (SQ) [2]. The medium had large reproduced output even for the Ru intermediate layer thickness of 2 nm. Although such an extremely thin intermediate layer thickness seems to influence magnetic interaction between a recording layer and a SUL, no experimental result was reported.

Experiment

Samples were prepared by DC and RF magnetron sputtering in an Ar gas atmosphere. Alloy targets of (Co₈₀Pt₂₀)-(TiO₂) (CoPt : TiO₂ = 80 : 20 vol%), Ru, Fe₇₀Co₃₀, Ir₂₀Mn₈₀, Pt, and Ta were used. Substrates were ϕ 2.5-inch glass disks. A magnetic field of about 100 Oe was applied to induce an in-plane magnetic anisotropy in the radial direction of the disks during deposition. The base pressure is around $1 - 2 \times 10^{-5}$ Pa. Substrate temperature was 20 °C. Magnetic properties were measured by a vibrating sample magnetometer (VSM) and a Kerr effect magnetometer.

Results and discussion

Figure 1 shows a schematic illustration of a prepared medium. Ru intermediate layer thickness was changed. IrMn was used as an fcc underlayer to obtain soft magnetic properties in an FeCo film, and an antiferromagnetic layer to pin the FeCo film. A Pt underlayer is effective in increasing the crystal orientation of the IrMn, which is necessary in order to enhance the exchange coupling energy between the FeCo and the IrMn films. Ta underlayer was greatly effective to enhance the crystal orientation of the whole film. As shown in Fig. 2, the minimum Ru layer thickness for obtaining the SQ of about 1 was 1.6 nm. Figures 3 and 4 show the Ru intermediate layer thickness dependence of H_c of the recording layer and H_{ch} (H_c in the hard axis direction) of the SUL, respectively. The H_c of the recording layer oscillated as a function of Ru intermediate layer thickness. The oscillation period was 0.6-0.8 nm (2-3 atomic layer thickness). On the other hand, the H_{ch} of the SUL oscillated in inversely proportion to the H_c . A medium with Ru intermediate layers of larger H_c (peak position of oscillation) showed better soft magnetic properties than that of valley position of the H_c oscillation. This indicates that magnetic interaction between the recording layer and the SUL can be controlled by choosing an appropriate film thickness of Ru intermediate layer.

A new method for controlling an exchange coupling of perpendicular recording media.

J. Ariake, N. Honda

AIT, Akita Prefectural R&D Center, Akita, Japan

Introduction

There are some proposals to control an exchange coupling of the recording layer in the perpendicular magnetic recording media in order to avoid trilemma difficulties (small grain size, high K_u material, difficult to write). However, many researchers pay attention on controlling it by adding so-called stacked layer such as a soft/soft stacked film. In such structure, the film thickness for two stacked layers is very important for precise control of the exchange coupling between two layers. For so-called “CGC” media (1), a continuous layer should be in the range of 1 to 3 nm in thickness to obtain good performance of the media.

In this paper, we propose a new method to control an exchange coupling of the perpendicular recording films by heat treatment of them.

Experimental

A Co-Pt-TiO₂ granular film was used as a recording layer of the perpendicular media. A Ru/Pt layer and CoZrNb were used as a underlayer and SUL, respectively. All films were deposited at room temperature. Heat treatment for the granular films was applied after depositing the films in a vacuum condition below 1×10^{-5} Pa. Temperature of the annealing (T_A) is from r.t. (no annealing) to 500°C for 30 min. After cooling down, a carbon protective layer was deposited on the Co-Pt-TiO₂ film.

Magnetic characteristics were evaluated by a Kerr effect magnetometer (Kerr: NEOARC, BH-M800UV-HD). Maximum applied field and a field sweep rate in Kerr measurement were 20 kOe and 0.38 ms/Oe, respectively. Magnetic structure was observed by a magnetic force microscope (MFM: Veeco, D3000) at ac-erased state. Surface images were also observed by an atomic force microscope (AFM) with MFM.

Results and discussion

Fig. 1 shows Kerr loops for Co-Pt-TiO₂ films with no annealing and annealed at T_A of 300°C. A Co-Pt-TiO₂ film is known to form separated grain structure in the media efficiently by TiO₂ grain boundary formation (2). Therefore, a very inclined M-H loop slope for the film was obtained as shown in Fig. 1(a). A Kerr loop slope of the annealed sample was steeper as shown in Fig. 1(b) than that of non-annealed one. In this experiment, a loop slope became steep with increasing T_A , indicating that the exchange coupling of the granular films became stronger with T_A . On the other hand, a magnetic cluster size for the annealed films became small in spite of a stronger exchange coupling than that for the non-annealed one as shown in Fig. 2. In the previous paper, there occurred no significant grain growth for the annealed Co-Pt-Cr-SiO₂ films (3). In our films, there seems also no significant grain growth from the AFM image. Furthermore, $\Delta H_c/H_c$ value (4) became small with increasing T_A as shown in Fig. 3. This indicates that the annealed film has a narrower switching field distribution compared with non-annealed one. Fig. 4 shows crystallographic properties of the films in this experiment. It was found that the crystallinity and crystal orientation of the annealed films became improved. This means that the film structure became uniform by annealing. This may bring about the improved magnetic characteristics such as a reduced $\Delta H_c/H_c$ value.

Summary

To summarize this report, it is obvious that the exchange coupling of the granular Co-Pt-TiO₂ films can be controlled by applying heat treatment of the film. The effect of the annealing was not only

to control exchange coupling of the recording layer but also to uniform and reduce the film structure such as magnetic characteristics and crystal orientation.

A study of perpendicular magnetic recording media with an exchange control layer.

K. Tang, K. Takano, G. Choe, G. Wang, J. Zhang, X. Bian, M. Mirzamaani
Hitachi Global Storage Technologies, San Jose, CA

This paper is an experimental study of the hysteresis behavior and recording performance of ECC type media [1]. The magnetic recording layer structure in this study is comprised of a granular oxide magnetic layer, a cap magnetic layer and an exchange control layer (ECL) in between that reduces ferromagnetic exchange coupling strength between the granular oxide and cap layers. Fig. 1 plots saturation field (H_s) vs. ECL thickness (t_{ECL}) of such a medium. At $t_{ECL}=0$, the granular oxide and cap layers are strongly exchange coupled causing a pinning of the magnetic moment in the cap by the granular oxide that limits its role in assisting the switching of the granular oxide layer. This leads to a large value of H_s . As t_{ECL} increases, the exchange coupling strength between the granular oxide and cap decreases, allowing the magnetic moment in the cap to rotate more easily by an external field and thus to assist the switching of the granular oxide layer below resulting in an overall decrease of H_s . When t_{ECL} becomes very thick, the granular oxide and cap layers are so weakly coupled that the cap can only provide limited assistance in switching the granular oxide, resulting in an increase in H_s . These two regions define a minimum H_s point in the H_s vs. t_{ECL} curve. At very thick t_{ECL} values, weak exchange coupling leads to a two-stage switching mechanism where the cap and the granular oxide layers switch independently. Hysteresis loops at different t_{ECL} values are shown as inserts in Fig. 1. Smooth switching curves are observed at thin t_{ECL} , but hysteresis curves at thicker values of t_{ECL} show discontinuities.

Fig. 2 shows that media SNR and OW are improved with the incorporation of the ECL layer, and best performance is achieved near the t_{ECL} value that gives minimum H_s . In order to eliminate the effect of OW on media SNR, we compare an ECL medium with a non-ECL medium with similar OW. The two media use the same granular oxide and cap materials, and their OW's are matched by cap adjustment. The results indicate that the ECL medium offers a 0.5dB media SNR advantage. This suggests that the ECL plays a role in reducing noise introduced by the highly exchange coupled cap layer.

To study the effect of ECL properties on ECL media, we select a series of ECLs with different M_s values by varying the content of a non-magnetic element. In the case of high ECL M_s , no minimum H_s is observed suggesting that strong exchange coupling resulting from the high M_s of the ECL is enough to maintain one stage switching and therefore H_s decreases continuously with increasing t_{ECL} in the entire ECL thickness range studied. As M_s of the ECL decreases, two stage switching can occur at thick t_{ECL} and a minimum H_s point appears. Another study of varying M_s of the ECL is done on a second series, in which both ECL materials have low enough M_s so that minimum H_s point occurs. For the lower M_s ECL, the minimum H_s point shifts to thinner t_{ECL} , indicating that an ECL with lower M_s can sufficiently weaken exchange coupling between the granular oxide and cap and result in two-stage switching at a thinner t_{ECL} (Fig. 3). Optimum ECL thickness is closely related to magnetic properties of the ECL.

The coupling strength between granular oxide and cap layers also depends on M_s of the cap layer. Since lower M_s of the cap layer gives rise to weaker interfacial exchange coupling between the ECL and cap, two-stage switching behavior of the granular oxide and cap layer is reached at a thinner t_{ECL} . However, when the M_s of ECL is very low, the granular oxide-to-cap coupling strength is limited by the ECL layer, and the t_{ECL} at minimum H_s becomes less sensitive to M_s of cap layer. Accordingly, the optimum magnetic and recording properties of ECL media have to be designed

with consideration of both ECL and cap properties, which will be discussed in more details in the full paper.

In summary, recording performance of perpendicular media can be improved with addition of an ECL. Thickness and magnetic properties of the ECL combined with magnetic properties of the cap layer are key factors to media optimization.

1. Dept. of Electronics Engineering, Tohoku University, Sendai, Japan; 2. New Industry Creation Hatchery Center, Tohoku University, Sendai, Japan

Introduction

Perpendicular magnetic recording media presently consist of a soft magnetic underlayer (SUL), a nonmagnetic intermediate layer (NMIL), and a recording layer (RL). Granular materials consisting of Co-base magnetic grains with oxide-rich grain boundaries are widely used for the RL, and the NMIL plays an important role in controlling the structure of such an RL by providing nuclei sites for the growth of magnetic grains in the RL, and by promoting epitaxial growth of the magnetic grains in the RL to afford a *c*-plane sheet texture. Ruthenium (Ru) with such a *c*-plane orientation and rough surface is widely used as an NMIL material. [1,2] However from the aspect of high density media, it is hard to realize further reduction of grain size retaining highly *c*-axis orientation and rough surface by only modification of Ru deposition process. As one of solutions of this problem, we think that it is important to achieve epitaxial growth of Ru grains on seed layer through the precise control of both the wettability and the lattice matching. In this presentation, we introduce hexagonal-nitride seed layers with covalent bond, AlN with Wurtzite ($P6_3mc$) structure and Ta_2N with the $L3$ ($P6_3/mmc$) structure. On these seed layers, Ru grains are expected to start from small initial nuclei due to not so good wettability nor lattice matching. The lattice miss fit ratios, $(a_{\text{seed}} - a_{\text{Ru}})/a_{\text{seed}} \times 100$, of AlN, Ta_2N to Ru are +14.8 %, +12.5 % respectively.

Experimental Procedure

All the samples in the present study were fabricated by dc magnetron sputtering under the total gas pressure of 0.6 Pa at room temperature onto amorphous glass substrate. The surface roughness of glass substrate was 0.3 nm. Film stacking structure is sub./ buffer (10 nm)/ seed (0-20 nm)/ Ru (0-20 nm)/ CoPtCr-SiO₂ (16 nm)/ C (7 nm). The Al-N and Ta-N seed layers were deposited by reactive sputtering using Ar and N₂ mixed gas with varying N₂ flow ratio. As the buffer layer, Ta, Ni₆₀Zr₄₀, Ni₆₀Ta₄₀, Co₉₁Zr₄Nb₅, (Fe₆₅Co₃₅)₈₈B₁₂ were adapted. Crystallographic texture, grain dia. of Ru, GD_{Ru} , and *c*-axis direction distribution of Ru, $FWHM_{\text{Ru}}$, were analyzed using transmission electron microscope (TEM) and x-ray diffractometer (XRD) using Cu-K α radiation. Magnetic properties were measured by the polar Kerr equipment.

Results and Discussion

At first, the fabrication condition, especially flow ratio of Ar and N₂ mixed gas, *f*, is optimized. As a result it was found out that the hexagonal AlN and Ta_2N films with *c*-plane sheet texture are realized under the condition of *f* = 40 % and 20 %, respectively. Fig. 1 shows a bright-field image obtained by cross-sectional TEM for a sub./ FeCoB/ AlN/ Ru/ C film. An enlarged view of the AlN layer is also shown on the right. Concerning the Ru layer structure, it is found that both highly oriented *c*-plane sheet texture and rough surface of over 2 nm in peak to valley are realized even though Ar gas pressure is as low value as 0.6 Pa. Furthermore, focused on the AlN layer, lattice stripes in the AlN grains representing the (00.2) plane are oriented parallel to the film plane from the initial growth region. Fig. 2 shows the Ru thickness dependence of grain dia. and *c*-axis direction distribution of Ru, GD_{Ru} and $FWHM_{\text{Ru}}$, in AlN/ Ru stacked film with various buffer layers. Focused on the buffer layer materials, the $FWHM_{\text{Ru}}$ decreases with changing in buffer structure from nano-crystalline to amorphous. As the results, both the low GD_{Ru} of 7 nm and low $FWHM_{\text{Ru}}$ of 3.5 deg. are obtained even for the sample deposited on glass substrate without special polishing.

Fig. 3 shows the Ru thickness dependence of coercivity H_c for an AlN seed medium, together with that of a NiFeCr seed layer as a comparison. The H_c value of the AlN seed medium is larger than that of the NiFeCr seed medium in every Ru thickness. Note that the media plotted in fig. 3 show almost the same H_k of 14.7 kOe obtained from 625 emu/cm³ and 4.6×10^6 erg/cm³ in M_s and K_u . These results indicate that the AlN seed medium is more magnetically isolated than the NiFeCr seed medium. Therefore, it is concluded that the AlN seed layer has a great potential to realize magnetic isolation, low grain size, and highly *c*-plane orientation of granular-type perpendicular media through the control of Ru layer structure. The results of the Ta-N seed medium will be also discussed in the presentation.

I. Introduction

Exchange coupled composite media (ECC) consists of both magnetic hard and soft layers, has been proposed to address the “trilemma effect” in perpendicular magnetic recording media [1-3]. The soft layer assists the reversal of main recording hard layer, and results in the reduced switching field, narrowed switching field distribution (SFD), and less-sensitive angular dependence when compared to the conventional perpendicular recording media. However, a granular structure and relatively low anisotropy field are crucial requirements for the soft layer. In this work, we developed a new type of soft layer, [CoPtCr-SiO₂/Pt] multilayers, which possessed tunable perpendicular anisotropy, and resulted in a low switching field and high thermal stability for the ECC media.

II. Experiment

All samples were prepared at room temperature using an 8-target magnetron sputtering system with the base-pressure of 1×10^{-7} Torr. The layer structure of conventional perpendicular media and ECC media were Ta 3/Pt 7/Ru 30/CoPtCr-SiO₂ 17.5 and Ta 3/Pt 7/Ru 30/CoPtCr-SiO₂ 17.5/Pt 0.75/[CoPtCr-SiO₂ 1.1/Pt 0.75]₅ MLs (unit: nm), respectively. The magnetic properties of prepared samples were measured by a vibration sample magnetometer, and the microstructure was determined by transmission electron microscopy.

III. Results and Discussions

The conventional perpendicular media showed $H_c \sim 4600$ Oe, $M_s \sim 380$ emu/cm³, and good grain isolation with an average grain size of 7nm. The Pt and [CoPtCr-SiO₂ 1.1nm/Pt 0.75nm]₅ MLs were designed as the spacer and soft layer (SL) for novel ECC perpendicular media, which possessed perpendicular anisotropy and low coercivity ~ 200 Oe, as shown in Fig. 1. The ECC perpendicular media, substrate/Ta 3/Pt 7/Ru 30/CoPtCr-SiO₂ 17.5/Pt 0.75/[CoPtCr-SiO₂ 1.1/Pt 0.75]₅ (unit: nm), revealed the significant reduction of coercivity ($H_c = 2900$ Oe) and saturation field ($H_s = 6200$ Oe), as shown in Fig 1, which may improve the writability. The [CoPtCr-SiO₂/Pt]₅ multilayer of full stack ECC media became granular due to the preferred segregation of SiO₂ at the grain boundaries of the recording layer (RL: CoPtCr-SiO₂). Therefore, this kind of media exhibited grain-to-grain epitaxial relationship between RL and SL, as shown in Fig. 2. In addition to the granular microstructure, the adopted [CoPtCr-SiO₂/Pt]₅ multilayer structure enabled us to tune the magnetic anisotropy energy K_U of SL by simply controlling the Pt layer thickness or the number of total layers. The measured K_U by the rotation method [4] were 1.33×10^6 , 7.19×10^5 , and 3.76×10^5 erg/cm³ when Pt thickness of [CoPtCr-SiO₂ 1.1nm/Pt]₅ were 0.37nm, 0.75nm, and 1.13nm, respectively. The tunable anisotropy energy of the SL can be quite useful for advanced media, e.g. graded media [5].

In addition, remanent coercivity and angular dependence of ECC media showed the reduction of H_{cr} , 38%, and angular insensitivity, compared to the conventional PMR, as shown in Fig.3, which was considered to be helpful to improve writability and signal to noise ratio (SNR). Concerning about the thermal stability factor, $K_U V / k_B T$ of the conventional PMR and the ECC was 100 and 129, respectively, which indicated that the ECC perpendicular media composed of a RL CoPtCr-SiO₂ and soft MLs [CoPtCr-SiO₂/Pt]₅ with perpendicular anisotropy led to enhancement of thermal stability.

In summary, this work demonstrated that [CoPtCr-SiO₂/Pt] MLs was a promising soft layer for ECC media, which showed the advantages of a granular microstructure and tunable anisotropy energy. In addition, the improvement of thermal stability, reduction of H_c , H_s , H_{cr} and less-sensitivity of angular dependence were also achieved when the perpendicular soft layer was employed in ECC media.

Introduction

CoPtCr-SiO₂ granular perpendicular magnetic recording media requires (001) texture of CoPtCr magnetic grains and well-isolated grain structures^[1] to attain better playback performance. We prepared a Ru-oxide layer as a seed layer of Ru/CoPtCr-SiO₂ bilayer to attain (001) texture of the Ru underlayer which enhanced an epitaxial growth of CoPtCr (001) texture at room temperature. To attain the properties mentioned above, a Ru layer and a CoPtCr-SiO₂ layer were deposited at low gas pressure and high gas pressure, respectively^[2]. In this study, we investigated the effect of a deposition condition of Ru-oxide layer. Some improvements of magnetic properties were attained by changing gas pressure for deposition of CoPtCr-SiO₂ layer.

Experimental

Ru-oxide/Ru/CoPtCr-SiO₂ thin films were deposited directly on glass substrates at room temperature using Facing Targets Sputtering (FTS) system. Ru-oxide/Ru/CoPtCr-SiO₂ films were prepared at 4 mTorr, 4 mTorr and 26 mTorr of gas pressure, respectively. Ru-oxide layers were prepared by reactive sputtering method using a gas mixture of 90 % Ar and 10 % O₂ as flow ratios into the sputtering chamber. Background pressure was 4.0×10^{-6} Torr. Magnetic properties were measured using a vibrating sample magnetometer (VSM). Crystallographic and microstructures were observed by X-ray diffraction (XRD) and a transmission electron microscopy (TEM).

Results and Discussion

In our previous study, it was found that a Ru-oxide layer was required to attain (001) texture of the top Ru layer. Coercivity of 3.0 kOe and squareness ratio of 0.92 in the perpendicular direction were obtained with Ru-oxide(8 nm)/Ru(15 nm)/CoPtCr-SiO₂(30 nm) thin films.

Fig.1 and 2 show XRD diagram and coercivity and squareness ratio in the perpendicular and in-plane directions of Ru-oxide(x nm)/Ru(15 nm)/CoPtCr-SiO₂(30 nm) thin films for various Ru-oxide layer thickness. When the thickness decreased below 5 nm, Ru (002) diffraction intensity decreased and perpendicular magnetic properties deteriorated. It indicated a Ru-oxide layer was required a certain amount of the thickness to improve the crystallographic orientation.

Fig.3 shows the cross-sectional TEM image of Ru-oxide(10 nm)/Ru(20 nm)/CoPtCr-SiO₂(30 nm) thin film. We observed the different crystal structures between a Ru-oxide layer and a Ru layer. Although the XRD patterns of a Ru-oxide layer with 15 nm did not show any diffraction lines, a Ru-oxide layer with 100 nm exhibited a diffraction peak corresponding to Ru (100) or RuO₂ (200) peaks which implies that a Ru-oxide layer has some crystallographic orientation.

Fig.4 shows the changes of saturation magnetization, coercivity and squareness ratio in the perpendicular and in-plane directions as a function of Ar gas pressure for a CoPtCr-SiO₂ layer. Although the higher Ar gas pressure causes the smaller saturation magnetization, because of a columnar grain structure caused by a high gas pressure condition, the higher Ar gas pressure condition promotes fine granulation of magnetic grains with grain boundaries and high perpendicular coercivity above 3.0 kOe and high squareness ratio.

Remanence measurements of perpendicular recording media.

T. Deakin¹, C. Bunce¹, K. O'Grady¹, S. Z. Wu²

1. Department of Physics, The University of York, York, United Kingdom; 2. Seagate Media Research, Fremont, CA

Introduction and Experimental

Remanence measurements are important for the complete characterisation of magnetic materials, as they separate out the reversible and irreversible components of magnetisation. Also, information may be obtained from remanence data on the orientation of the easy axes, as the moment returns to the easy direction after saturation. The remanence can be measured from either a demagnetised (IRM) or saturated (DCD) initial state. Remanence measurements have been used extensively in the characterisation of longitudinal recording media due to the correlation to grain switching and the relationship to intergranular exchange, obtainable via ΔM measurements [1].

Following the paradigm shift to perpendicular recording in 2005, the issue of measuring the remanence and other parameters has had to be readdressed because of the strong demagnetising field, $H_D = -4\pi M$ [e.g. 2]. Recording media in general is specified in terms of the remanent coercivity, H_{cr} , determined from DCD curves. However, to measure H_{cr} , it is necessary to correct H prior to measuring the remanence and to measure the entire recoil loop so that the magnetisation when the total effective field, H_T , is equal to zero can be determined. As such, this is a time consuming process. In this work, we describe a technique for the direct measurement of a remanence curve, hence giving the value of H_{cr} and the SFD. Similar techniques can be used to measure the remanence in true zero field in order to determine the distribution of the easy axes.

We have studied a set of exchange-coupled composite (ECC) media. This type of media is composed of both hard and soft layers and was initially proposed by Victora [3]. The samples have a 12 nm CoPtO hard layer and a CoNiO soft layer with thicknesses, t_s , in the range 4 to 20 nm. All measurements have been performed on a PMC AGFM. DCD and IRM measurements have been made, both with and without a correction for H_D , the latter being made with custom-developed software that calculates the true effective applied field ($H_T = H_{appl.} - H_D$) at each field step [4]. For a field step of 160 Oe, this gives an error in H_T of ± 80 Oe, but higher resolution measurements are possible with smaller field steps.

Results

An example of both uncorrected and corrected DCD curves for a sample of the ECC media with $t_s = 8$ nm is shown in Figure 1. It is clear that without the correction, a false value for H_{cr} is obtained, with the deviation in this case being 1.15 kOe or 20%.

It is also clear that the self-demagnetising field reduces the remanence determined at $H_{appl.} = 0$ for the uncorrected case making data interpretation difficult. The region of the change in H_{cr} is complex due to the presence of the hard and soft layers. A single layer film of the soft composition showed a single stage reversal with $H_{cr} = 1.45$ kOe. No separate reversal of the soft layer was observed in any of the composite films. This implies that the layers are exchange coupled and reverse as a single entity.

We also observe that as the thickness of the soft layer is increased the width of the switching region (SFD) decreases. However, a limiting value on the width of the SFD is reached corresponding to the width of the SFD for the soft layer itself. Hence it is the intrinsic properties of the soft layer that control the reversal of composite media. It is also noteworthy that the extrinsic SFD width due to the exclusion of flux closure at near saturation is more prominent in exchange decoupled layers.

The tremendous developments within data storage devices are leading researchers to think about areal density beyond 10Tbits/inch². One key limiting factor for producing high areal density is the superparamagnetic effect [1]. An increase in anisotropy is favourable for small grains which can help increase the energy barrier restricting the effect of the superparamagnetic effect. However, limited write fields, directly proportional to anisotropy, is another limitation. In order to cope with this problem, numbers of other techniques are under consideration e.g. heat-assisted magnetic recording, composite media, and bit patterned media.. Recently, microwave assisted (MW) magnetization reversal in hcp-Co nanoparticle has been shown experimentally by Thirion et al[2]. We present micromagnetic simulations of microwave assisted switching of data-storage grains with a diameter of 5 nm and a thickness of 15 nm. Exchange spring media (ESM) having hard ($K_u = 0.8\text{MJ/m}^3$) and soft ($K_u = 0.2\text{MJ/m}^3$) magnetic material is compared with single phase media (SPM)($K_u = 0.42\text{MJ/m}^3$). where as $J_s = 0.6\text{T}$, $A = 1\text{e-11J/m}$, $\alpha = 0.02$ are constant for both media. The use of exchange spring media, that is coupling a magnetically soft and hard layer together, allows switching fields to be reduced whilst maintaining a high thermal stability. Here we solve the Landau-Lifshitz equation for a single grain of either ESM or SPM media under the influence of a static magnetic field together with a rotating field perpendicular to the grain's easy axis. Temperature effects are not taken into account.

We investigated the full parameter space of microwave switching computing the switching fields of ESM and SPM grains for

- (a) different frequencies of the rotating field,
- (b) different amplitudes of the rotating field, and
- (c) different field angles of the static external field.

Table 1 summarizes the effect of a microwave assist field on magnetization reversal. The switching field is normalized by the static switching field of the grain, H_{stat} . Without microwave assist the switching field are 1.24 T, 1.05 T, and 0.896 T for 10, 20, and 30 degree field angle and the ESM grain; and 1.32 T, 1.07 T, and 0.897 T for 10, 20, and 30 degree field angle and the SPM grain. Figure 1 shows the computed demagnetization curves for the two different media for a field angle of 10 degrees as function of the microwave frequency.

The results confirm that microwave assisted switching is highly effective in ESM. As compared to SPM, the maximum reduction of the switching field is found at lower values of microwave frequencies in ESM. For the ESM grain (10 degree field angle) a reduction of the switching field to 0.87 H_{stat} can be achieved at microwave field of only 15 GHz with an amplitude of 20 mT. The switching field is reduced to 0.82 H_{stat} for a microwave field amplitude of 40 mT. At an assist field of 20 mT no significant reduction of the field can be achieved for the SPM grain. For the SPM grain a reduction to a switching field 0.8 H_{stat} requires a microwave field of 20 GHz with an amplitude of 40 mT. For both type of media the maximum possible reduction of the switching field is found for a field angle of 20 degree. Whereas the minimum possible switching field of both media is comparable, the ESM grain shows an energy barrier that is 17 percent higher than the energy barrier of the SPM grains.

In summary, we showed that microwave assisted reduction of the switching field is possible in exchange spring media. As compared to single phase media a lower microwave frequencies are sufficient to achieve a similar reduction of the switching field. In exchange spring media a reduction of the switching field by 20 percent as compared to the non-assisted case can be achieved in a rotating field with frequency of 15 GHz and an amplitude of 20 mT.

Micromagnetic Simulations of Cluster-pinned Recording Media.

C. Loke, S. Greaves, H. Muraoka
RIEC, Tohoku University, Sendai, Japan

To achieve high areal density recording in hard disks, grain sizes have to be reduced to maintain signal-to-noise ratio. However, this leads to a decrease of the energy barrier, which results in super-paramagnetism. In perpendicular recording, the maximum anisotropy of the grains, which increases thermal stability, is limited by the write field of the head. To overcome this trilemma, a media in which domain wall pinning plays a role is proposed. The continuous/cluster-pinned media [1] is modeled with a continuous layer with high uniaxial anisotropy, exchange coupled to an adjacent layer of high anisotropy nanoscale clusters. The continuous layer facilitates easy nucleation and domain wall motion whilst the clusters act as pinning centres for the domain walls, controlling the coercivity and transition jitter. In this study, CPR media are investigated for the parameters determining the pinning field on domain walls.

A micromagnetic model based on the LLG equation was used. A 200nm wide \times 300nm long continuous layer was modeled using regular, hexagonal cells with diameters of 3nm and height 4nm. The continuous layer was exchange coupled to a cluster layer which was modeled using grains of various sizes and shapes arranged on a square lattice with a pitch of 25nm. Both layers were 12 nm thick. The exchange coupling constant, A , between the two layers was 2.5 erg/cm². The other magnetic properties are listed in Table 1.

The two halves of the medium were initially magnetized in opposite directions, causing a domain wall to form between them in the continuous layer. An external field was then applied to move the domain wall, and the velocity of the domain wall was calculated for media with different cluster sizes to determine the parameters affecting the pinning field of the clusters. The pinning field was defined as the minimum field required to un-pin a domain wall.

Simulations with cubic clusters revealed that larger clusters exerted a higher pinning field on the domain walls, while a thinner continuous layer and increased cluster layer M_s also significantly increased the pinning field. The pinning fields for various cluster sizes are shown in Fig. 1. By altering the shapes of the clusters while keeping the total surface area in contact with the continuous layer constant, it was found that the pinning fields remained the same, but the location at which the domain wall was pinned changed depending on the shape of the cluster. For example, when the domain wall encountered a triangular-shaped cluster, first crossing the vertex of the cluster, the domain wall was pinned at the centre of the triangle. However, when the domain wall was parallel to the edge of the triangle then, depending on the field strength, it would become pinned at that edge. The pinning fields for various shapes and sizes of clusters are summarized in Fig. 2.

To test how the cluster density affected the pinning field, the cluster density was increased by creating smaller clusters at a pitch of 12.5nm, while maintaining a constant total surface area. It was found that a layer of dense, smaller clusters had a weaker pinning field of 1950 Oe, whereas a layer of larger, lower density clusters exerted a pinning of field 2250 Oe. Moreover, elongated clusters (20nm \times 10 nm clusters) with lower density but the same surface area (9600nm²) were found to have a larger pinning field of 3350 Oe.

In conclusion, the factors controlling the pinning fields of CPR media are: the cluster size, thickness of the continuous layer, cluster M_s and cluster density.

When recording on CPR media, the shape and density of the clusters plays a part in defining the sites where the domain wall is pinned.

Effects of exchange and dipolar interactions on the determination of intrinsic switching field distributions in perpendicular recording media.

Y. Liu¹, K. A. Dahmen¹, O. Hovorka², A. Berger²

1. Department of Physics, University of Illinois at Urbana-Champaign, Urbana, IL; 2. CIC nanoGUNE Consolider, Donostia - San Sebastián, Spain

It is believed that perpendicular magnetic recording (PMR), which is nowadays the dominating hard disk drive technology, has the potential for a 10-fold increase of achievable storage densities [1]. Any progress in the development and optimization of PMR materials however relies on the availability of accurate characterization methodologies capable of extracting crucial material information such as the intrinsic switching field distribution of recording media, for example. One of the recently developed methods for this purpose is the $\Delta H(M, \Delta M)$ method [2]. Among its main advantages is the fact that it relies only on a relatively simple set of macroscopic hysteresis loop measurements and that its reliability can be verified by a straightforward redundancy test of the experimental input data [3]. However, this methodology is based on a mean-field approximation of the inter-granular interactions, and its accuracy is considerably reduced in systems with pure exchange interactions [3,4]. A systematic analysis of the reliability of the $\Delta H(M, \Delta M)$ method in the presence of both, the exchange and dipolar interactions, has not been done previously and is the main subject of the present work. Our computational study is based upon the coupled hysteron model [4,5]. In this model, PMR media are viewed as an assembly of bistable magnetic grains distributed on a two-dimensional square lattice. Magnetization reversal of each grain is described by a hysteron having a rectangular hysteresis loop with symmetric switching thresholds $\pm H_S$. The switching field magnitudes, H_S , vary randomly from grain to grain according to a probability distribution $D(H_S)$. In addition, every hysteron interacts with its nearest neighbors via ferromagnetic exchange J_{ex} and with every hysteron in the entire lattice via dipolar interactions J_{dp} . For the present analysis, we will assume a Gaussian switching field distribution $D(H_S)$ having a mean of 5 and a standard deviation $\sigma=1$. Using this model, we now mimic the usual scenario for determining the switching field distribution $D(H_S)$ by the $\Delta H(M, \Delta M)$ method. For a given set of parameters (J_{ex}, J_{dp}) , we first compute a set of recoil curves that start at various distances ΔM from saturation. Subsequently, we calculate the field difference ΔH between each recoil curve, classified by its corresponding ΔM -value, and the major hysteresis loop as a function of magnetization M . This $\Delta H(M, \Delta M)$ -data set is then analyzed by means of a least-square fit to the corresponding mean-field approximation formula [2]. The quality of the fit for every (J_{ex}, J_{dp}) set is then determined by: a) calculating the square of the multiple correlation coefficient R^2 and b) calculating the difference P_d between the input value of σ and the ‘recovered’ variance σ_r extracted from the simulation data analysis. For an exact solution, we expect $R^2=1$ and $P_d=0$. The obtained results are shown as contour plots in Fig.1. As can be seen from these figures, in the absence of dipolar interactions the method remains accurate only for $J_{ex} < 0.2$. The situation improves substantially for non-zero dipolar interactions. However, a simultaneous presence of both interaction types enhances the method’s performance only for (J_{ex}, J_{dp}) sets inside the tilted-ellipse-like region embedded in the square $J_{dp} < 1$ and $J_{ex} < 1$. In this region $P_d \sim 0$ and $R^2 \sim 1$, indicating that the method indeed remains accurate. This behavior results from a partial compensation between the opposite correlation tendencies of the short-range ferromagnetic and the long-range dipolar interactions (which are antiferromagnetic in nature). For example, when J_{ex} increases for a fixed J_{dp} of sufficient strength, the system gradually shifts from ferromagnetic to antiferromagnetic correlation dominated parameter space, proceeding via a nearly mean-field like regime when both competing tendencies mutually compensate. This cancellation, which we refer

to as the ‘correlation compensation effect’, is responsible for an enhanced reliability of the $\Delta H(M, \Delta M)$ technique for realistic values of dipolar interaction (illustrated by dashed lines in Fig.1). In addition, we find that due to this correlation compensation effect and the re-emergence of true mean-field behavior, inter-granular interactions are indeed removed from the data sets with very high accuracy. As a consequence, $\Delta H(M, \Delta M)$ -data contain no or only very limited information about these very interactions and are therefore fundamentally unsuitable for determining the individual levels of simultaneously present interactions, independently of the type of approximation used for the data analysis. Fig.1: Contour plots of the fit quality measures as functions of J_{ex} and J_{dp} . (a) P_d . (b) R^2 .

Introduction

An important issue in perpendicular recording is to reduce the spacing between the soft underlayer (SUL) and the recording layer while retaining an effective seed layer to promote good recording layer growth. Recently, new approaches have been proposed to reduce the effective magnetic thickness of this layer [1]. In an effort to quantify the benefit, a hybrid SUL media consisting [2] of an amorphous SUL, non-magnetic seed layer and crystalline SUL has been studied using micromagnetic simulation. By comparing the write fields and gradients in the hybrid SUL structure with those in the conventional structure, equivalent performance is obtained with a suitable combination of non-magnetic seed layers and crystalline SULs. Our simulation indicates that the hybrid SUL structure can support a thicker seed layer than conventional structure while maintaining high write field and gradient at the center of the recording media.

Hybrid Soft Underlayer Structure

The layer structure of the media in the micromagnetic modeling was amorphous SUL, seed layer, crystalline SUL, non-magnetic interlayer (non-MIL) and single-pole head. Fig.1 illustrates the conventional medium with amorphous SUL and the hybrid SUL structure. It is noticed that while additional intermediate layers such as Ru_1/Ta (15-20 nm) have to be deposited on the amorphous SUL in the conventional media, the hybrid structure is expected to need a thinner intermediate layer (5 nm Ru_2) owing to the presence of the crystalline SUL, thereby generating less reluctance in terms of a magnetic flux circuit.

Results and Discussion

Saturation magnetization of the write pole and amorphous SUL is 1910 emu/cm^3 ; Saturation magnetization of the crystalline SUL is 1170 emu/cm^3 . The anisotropy field of the write pole and amorphous SUL is 10 Oe in plane, write pole width and length are 50 nm and 150 nm; Fly height is 5 nm; Recording media thickness is 15 nm; Crystalline SUL thickness is 20 nm; Non-MIL thickness is 5 nm. The seed layer thickness (t_{SL}) and crystalline SUL permeability (μ_{C-SUL}) are varied to investigate their effect on effective field and gradient. The conventional structure with different non-MIL thicknesses ($t_{non-MIL}$) is also analyzed and compared with the new structure. For studying effects of underlayer on writability, computations were performed without any recording layers. The Landau Lifshitz Gilbert equation was used to calculate the vertical component of effective field and gradient at 12 nm below the air bearing surface of the head, i.e., middle of recording layer.

By varying the crystalline SUL permeability and seed layer thickness, field and gradients comparable to specific conventional seed layer thicknesses are obtained in the new structure. Comparative results are presented in Figure 2. When the μ_{C-SUL} is 24 and t_{SL} is 6 nm, the effective field and gradient in the hybrid SUL is comparable to those in a conventional structure with non-MIL 13 nm thick. Table 1 shows a variety of conventional structures and hybrid SUL structures. It is noted that when $t_{non-MIL}$ in conventional media is 15 nm, comparable field and gradient can be obtained in the hybrid SUL structure for t_{SL} from 6 nm to 18 nm and μ_{C-SUL} from 10 to 28, respectively. For $t_{non-MIL}$ of 10 nm, magnetic equivalence requires a permeability of 38 if the seed layer thickness is 18 nm. In other words, the hybrid structure can allow 43 nm of crystalline material to seed the recording layer yet be magnetically equivalent to 10 nm of seed layer in the conventional structure. From these results, it can be concluded that the hybrid SUL improves the writability of perpendicular

recording media. With a suitable combination of crystalline SUL permeability and seed layer thickness, the hybrid SUL structure can reduce the effective magnetic spacing between SUL and recording head, or maintain comparable field and gradient with even thicker seed layer.

Recently composite media and exchange spring media were introduced to postpone the superparamagnetic limit to higher areal densities [1],[2]. It was shown that the required write field decreases by about a factor of two and four in composite media and exchange spring media, respectively. If the number of layers is increased the coercive field can be reduced even further.

The limits of the coercive field reduction mentioned above were investigated in a quasi static limit, where the external field is applied infinitely slow. However, the field rise times in magnetic recording are in the order of several hundred picoseconds. These fast field rise times together with small damping constants in the media allow for precessional switching in exchange spring media. The effect of precessional switching on switching times on exchange spring media was investigated in Ref [1]. It is shown that precessional switching is more pronounced in exchange spring media compared to single phase media. Reversal is reported for field pulses shorter than 25 ps [1]. Livshitz et al. investigated in detail the reduction of the switching field in exchange spring media due to precessional switching [2]. It is found that precessional switching occurs in exchange spring media for slower field rise times than in single phase media [1],[2]. Furthermore, due to precessional switching the angular dependence of the switching field is significantly modified [2].

In Fig.1 phase diagrams are presented which show the regimes of switching and not-switching for a magnetic trilayer. The phase diagram is plotted as a function of the external field pulse strength $\mu_0 H_{\max}$ and the field pulse time τ . Within a field rise time t_r the field is increased linearly until the maximum field $\mu_0 H_{\max}$ is reached. The maximum field is kept constant for a time τ . After this time the field is decreased linearly to zero within the time t_r .

In Fig 1 the phase diagrams are shown for different angles θ , which denotes the angle between the external field and the easy axis. Furthermore, the plots are done for different values of the field rise time t_r . The material properties of the investigated trilayer can be found in the figure caption of Fig 1. The dotted lines in the phase diagram show the static limit of the switching field, which is given by the coercive field of the trilayer if the external field is applied infinitely slow.

For fast field rise times of $t_r = 0.01$ ns and small angles $\theta = 10^\circ$ it is interesting to note that the particle can be reversed with the shortest field pulses if the external field is just large enough to reverse the particle et all. The trilayer can be reversed at a field of $\mu_0 H_{\max} = 1.15$ T, whereas the static coercive field is $\mu_0 H_c = 1.3$ T. If the strength of the field pulse is increased, longer field pulses are required to guarantee switching. These fastest switching modes for small external fields was also found in single phase media as well [1].

If for a field rise time of $t_r = 0.01$ ns the angle $\theta = 10^\circ$ is increased to $\theta = 45^\circ$ precessional switching is more pronounced. The switching field ($\mu_0 H_{\max} = 1.4$ T) is 30% smaller than the static coercive field ($\mu_0 H_c = 1.9$ T).

If the field rise time is increased to $t_r = 0.3$ ns precessional switching still occurs for $\theta = 10^\circ$. Interestingly the switching process is faster than for the case of the fast field rise time of $t_r = 0.01$. This effect was also reported for magnetic single phase media and magnetic bilayers [1]. For $t_r = 0.3$ ns, $\theta = 10^\circ$ and for external fields about $\mu_0 H_{\max} = 1.2$ T the particle can even be switched with field pulses with a duration of $\tau = 0.49$ ns, whereas the switching time in the same field interval for the fast field rise time of $t_r = 0.01$ ns is 1.25 ns.

If the field angle is increased to $\theta = 45^\circ$ no longer switching below the static coercive field occurs. However, the switching process occurs very fast. The particle can even be switched for $\tau = 0$. Hence, the particle is already reversed during the time when the field is increases from zero to $\mu_0 H_{\max}$ within the time t_r .

If the field rise time is increases to $t_r = 0.3$ ns the effect of reversal below the static coercive field also vanishes for $\theta = 10^\circ$.

Phase diagram of the switching event for a magnetic trilayer with a total thickness of 25 nm. In all layers the same value of the intra-granular exchange constant and the magnetization is assumed ($A=10^{-11}$ J/m, $J_s = 0.5$ T). The thickness of the softest layer is 11 nm with $K_1 = 0.125$ MJ/m³. The layer in the centre has a thickness of 7 nm with $K_1 = 1$ MJ/m³. The bottom layer with thickness 7 nm is the hardest with $K_1 = 2$ MJ/m³. The damping constant is $\alpha = 0.02$.

Co-rich Co-Pt films with low ordering temperature and high perpendicular hard magnetic properties for high-density magnetic recording media.

S. Chen^{1,2}, P. Kuo³, C. Shen³, Y. Fang³, S. Hsu³

1. Department of Materials Engineering, MingChi University of Technology, Taipei, Taiwan; 2. Center for Nanostorage Research, National Taiwan University, Taipei, Taiwan; 3. Institute of Materials Science and Engineering, National Taiwan University, Taipei, Taiwan

Materials having high magnetocrystalline anisotropy constant (K_u) are generally attractive for ultrahigh density magnetic recording applications due to they allow smaller grains to keep thermal stability. Although K_u of L10 FePt and L10 CoPt films are as high as 7×10^7 erg/cm³ and 5×10^7 erg/cm³ respectively, the ordering temperature of FePt and CoPt films is usually higher than 500 °C [1, 2], which is too high for the manufacture process of hard disc. On the other hand, K_u of hcp Co₃Pt alloy film is also as high as 2×10^7 erg/cm³, and the temperature for obtaining high perpendicular magnetic anisotropy and high saturated magnetization (M_s) is only 300 °C [3], which is consistent with the current manufacture temperature of hard disc. Therefore, Co₃Pt alloy film has significant potential to be applied in ultra high density magnetic recording media. In this study, the Pt underlayer with 200 nm thickness is deposited on corning glass substrates by conventional magnetron sputtering at ambient temperature. Co₃Pt magnetic layer with thickness of 14 nm is deposited sequentially on the Pt underlayer. The as-deposited films are annealed at various temperatures for 30 min in a vacuum of 1 mTorr.

Figure 1 shows the dependence of (a) coercivity H_c and saturation magnetization M_s , and (b) squareness S on annealing temperatures for Co₃Pt(14 nm)/Pt(200 nm) films. The perpendicular coercivity ($H_{c\perp}$) increases with increasing annealing temperature and reaches a maximum value at 300°C. The trend for perpendicular squareness (S_{\perp}) is similar to that for $H_{c\perp}$. The HRTEM cross-sectional lattice image shows that a well epitaxial growth of hcp (002) Co₃Pt on (111) Pt underlayer, which leads to present excellent perpendicular magnetic anisotropy of Co₃Pt film at 300°C. When the annealing temperature is higher than 350°C, the transformation of hcp Co₃Pt to fcc Co₃Pt results in the drastically decrease of magnetic properties. Figure 2 (a) shows the perpendicular coercivity, perpendicular squareness and saturated magnetization of Co₃Pt(14 nm)/Pt(200 nm) film annealed at 300°C are 3800 Oe, 0.93 and 650 emu/cm³ respectively. After depositing Co₇₀Tb₃₀ (85 nm) onto Co₃Pt (14 nm) film, the $H_{c\perp}$ value increases from 3800 to 6560 Oe due to interfacial exchange coupling between Co₇₀Tb₃₀ and Co₃Pt films, as shown in Fig. 2 (b). These magnetic properties obtained at low temperature of 300°C reveal its promising potential to be applied as magnetic recording media for high-density recording.

Nowadays, the FePt with $L1_0$ phase has received significant attention owing to its excellent magnetic and magneto-optical properties, such as large saturation magnetization, high perpendicular magnetocrystalline anisotropy, high Curie temperature, and high environmental stability [1]. In pursuit of patterned recording media, magnetic nanomaterials fabricated through porous anodized aluminum oxide (AAO) have been widely investigated [2]. Recently, the percolated recording media has been investigated because of its high thermal stability [3,4]. In this study, FePt films were prepared on the AAO membranes with pore diameter of around 20nm and 200nm by a DC magnetron sputtering system. The thickness of FePt films was ranged from 15nm to 50nm. After deposition, a post annealing procedure with temperature ranged from 400°C to 650°C for one hour was taken to obtain the hard phase of FePt. In order to prevent the interdiffusion, a 10nm thick Au buffer was grown on AAO templates prior to FePt layers.

From x-ray spectrum, we found that the FePt films grown on both templates, with or without Au buffer, were polycrystalline after a high temperature annealing. Interestingly, the $L1_0(001)$ phase was obtained while the FePt grown on the 20nm pore diameter AAO templates with Au buffer layers, as shown in Fig. 1(a). For the samples without Au buffer layers or grown on the AAO templates with larger pore diameter, one can not obtain the $L1_0(001)$ phases, as shown in Figs. 1(b) and 1(c), respectively. Detail investigation on the XRD spectrum showed that the 20nm pore diameter AAO template can assist the formation of Au(100) phase that resulted in the formation of FePt $L1_0(001)$ phases under 600°C annealing. For all samples, the coercivity of FePt increased as increasing annealing temperature. However, the coercivity decreased while annealing temperature higher than 650°C. A large perpendicular coercivity, namely 11000 Oe and 9000 Oe, was obtained in 600°C annealed FePt samples grown on 20nm and 200nm pore diameter AAO templates with Au buffer layers, respectively, as shown in Figs. 2(a) and 2(b). It is in a good agreement with the observation of FePt $L1_0(001)$ phases. And a relative lower perpendicular coercive value, namely 6500 Oe and 1000 Oe, was observed in FePt films directly grown on 20nm and 200nm pore diameter AAO templates, respectively, as shown in Figs. 2(c) and 2(d). That resulted from the interdiffusion between FePt and alumina. From these magnetic investigations, we concluded that a template with small pore diameter (or with large pore density) will enhance the coercive force (or domain wall pinning effect). For the experiments on thickness variation, the coercivity was almost the same for 15nm and 30nm thick FePt samples, as depicted in Figs. 3(a) and 3(b), respectively. But a relative lower coercivity was observed in 50nm thick FePt samples, as depicted in Fig. 3(c). The decreasing of coercivity in thicker films after annealing was probably due to the grain growth [5]. In summary, we have observed experimentally the first time the structure and magnetism of FePt on AAO template. The Au (100) buffer layers and AAO templates will enhance the coercive force of FePt films through assisting the formation of $L1_0(001)$ phases and providing extra pinning sites, respectively.

Introduction

(001) textured $L1_0$ FePt is commonly accepted as a promising material for perpendicular magnetic media with ultra high recording density exceeding 1 Tbit/inch². In order to enhance the recording performance, the medium with granular microstructure is necessary. In such a microstructure, magnetic grains or particles are surrounded and isolated with non-magnetic phase, which effectively decouple the grains and promote the independent magnetic reversal. Many attempts have been made to create this microstructure in $L1_0$ FePt film using various non-magnetic materials. Among these isolation materials, MgO have received great deal of attention because it can induce strong (001) texture of $L1_0$ FePt [1, 2]. It have been reported that large amount of MgO in the FePt-MgO two-phase mixture segregates and surrounds the $L1_0$ grains uniformly after annealing [3]. A microstructure similar to currently used media has been achieved. Apart from the formation of granular film, the addition of MgO has been also reported to change the magnetic properties and domain structure of (001)-textured FePt film [4]. However, the effect of incorporating small amount of MgO is not extensively investigated. In this presentation, the effect of MgO doping on structural and magnetic properties in (001)-textured $L1_0$ FePt grown on MgO underlayer will be discussed.

Experimental

Composite Magnetic (FePt)_{100-x}-(MgO)_x films ($x = 0\sim 10$ vol.%) were magnetron sputtered on MgO(200) underlayer at 530 and 580°C with glass substrates in an ultra-high vacuum sputtering chamber. The thicknesses of the FePt-MgO film and MgO underlayer were set to 20 and 10 nm, respectively. The crystalline structure and microstructures of the films were identified by X-ray diffraction and transmission electron microscopy, respectively. The chemical composition of FePt analyzed by energy dispersive spectroscopy was Fe₄₈Pt₅₂. Since MgO is immiscible with the magnetic FePt phase, the MgO content of the magnetic FePt matrix was determined by calculating the formula $[R_{MgO}/(R_{FePt}+R_{MgO})]\times 100$ vol.%, where R denotes the sputtering rate. Magnetic properties were investigated with a vibrating sample magnetometer at room temperature with a maximum applied field of 1600 kA/m.

Results and discussion

Figure 1(a) shows the dependence of order parameter, S_{ord} , on the content of MgO. The samples with MgO less than 2 vol.% deposited at two different temperatures exhibit high S_{ord} value of 0.95~1. As MgO was increased gradually from 2 vol.% to 10 vol.%, the value of S_{ord} decreases to 0.67. Figure 1(b) displays the variation of lattice parameter of c -axis with MgO content. A compression of c -axis appeared in both 530 and 580°C deposited films. When the amount of MgO exceeds 2 vol.%, a drastic expansion was observed. At low MgO content region, the 580°C deposited films exhibit higher coercivity as indicated in Fig. 1(c), which can be related to its higher S_{ord} . The results of squareness ratio indicate that the 580°C film exhibit better alignment of c -axis as shown in Fig. 1(d). In Figs. 1(e) and 1(f), it is interesting to note that both samples present a peak in the dependence of anisotropic field (H_k) and anisotropic energy (K_u) on MgO content.

The increment of H_k and K_u can be related to the lattice compression as shown in Fig. 1(b). The fact that MgO is immiscible to FePt implies that the shift of (002) peak is resulted from other origins such as internal strain or stress. It have been reported that in a fully ordered FePt film, the residual strain by phase transformation will elongate the c -axis and compress the a -axis of a $L1_0$ lattice [5]. The addition of small amount of MgO may facilitates the relaxation of residual tensile strain along c -axis and thus enhance the values of H_k and K_u . However, as MgO is overdoped, in-plane compressive stress/strain may increase rapidly, resulting in expansion of lattice parameter c and reduction of H_k and K_u . In summary, the addition of MgO with a small proper amount was found to improve the magnetic properties of the FePt $L1_0$ phase without degrading the ordering and alignment of (001)-orientation, helpful to employ FePt medium in the future magnetic recording.

Introduction

(001) preferred orientation should be developed during $L1_0$ phase ordering reaction of FePt for perpendicular magnetic anisotropy applications. The (001) texture of $L1_0$ FePt is usually induced by sputter deposited on heated MgO (001) substrates [1], or using various composite materials [2,3], or using proper bufferlayers.[4] However, there is a thickness limitation of the films to develop the nearly perfect (001) texture of $L1_0$ phase during ordering reaction.[3,5] The reason for the dependence of film thickness on the (001) texture evolution is not clear yet. In this study, we analyzed the dependence of film thickness on the (001) texture development, degree of ordering reaction, and magnetic properties of the FePt:MgO nanocomposite films.

Experiments

[FePt 2.8/MgO 3.2 nm]_n multilayers were deposited at room temperature on thermally oxidized Si (100) substrates using a magnetron sputtering system with equiatomic FePt and MgO targets. The FePt and MgO sublayer thickness was varied from 2.4~3.4 and 0.4~3.2 nm, respectively. The samples were annealed in a vacuum furnace at 600 °C in a 4×10^{-6} Torr vacuum. The magnetic properties of the as-deposited and post-annealed samples were measured by using a vibrating sample magnetometer (VSM) in fields up to 12 kOe and a superconducting quantum interface device (SQUID) in fields up to 50 kOe at room temperature. The microstructures of the films were observed using transmission electron microscopy (TEM) and the crystal orientations were analyzed using X-ray diffractometer (XRD) in θ -2 θ scan mode.

Results and Discussion

Figure 1 shows the variation of in-plane and out-of-plane coercivity (H_c), texture coefficient (T.C.) of (002) plane, ordering parameter (S), and tetragonality (c/a) of $L1_0$ phase as a function of number of bilayers (film thickness). Out-of-plane coercivity and ordering parameter approach the maximum value at $n = 6$, film thickness of 36 nm. However, T.C. of (002) and ordering parameter degraded from above 6 bilayers, and hence the coercivity decreased. Figure 2 shows XRD patterns of the [FePt 2.8 / MgO 3.2 nm]_n films with n varying from 4 to 9, corresponding to film thickness ranging from 24 to 54 nm. When the n is 6, only FePt (001) and (002) peaks can be clearly seen and any other peaks don't exist. This means that a heteroepitaxially grown nearly perfect $L1_0$ face-centered-tetragonal (fct) (001) texture were obtained for annealed [FePt 2.8 nm / MgO 3.2 nm]₆ films. As the number of bilayer (film thickness) increases, the relative intensity of (111) peak slightly increase and (00n) peak decrease. Compared with the T.C. in Fig. 1(b), it is obvious that (001) texture developed in thinner films. In Fig. 1(a), thicker films have small out-of-plane coercivity comparable to in-plane coercivity. This may be because randomly oriented fcc FePt grains are mixed in thicker films as can be seen in Fig. 2. Hence the ordering parameter S decreases as the film thickness increases [Fig. 1(b)] and tetragonality slightly increases as can be seen in Fig. 1(c). The dependence of bilayer number (film thickness) on the texture evolution, degree of ordering, and the magnetic properties has a similar effect of the film thickness.[3,5] In the previous study [6,7], it was found that the anisotropic strain due to the $L1_0$ ordering was key factor to develop the (001) texture. Accordingly, we presumed that there should be a thickness limitation to satisfy the plane-stress condition [7] for the evolution of (001) texture and the $L1_0$ ordering.

L1₀ ordered FePt thin films have been intensively investigated in recent years for their potential applications for perpendicular magnetic recording. For practical use, it is necessary to obtain out-of-plane magnetic anisotropy with suitable crystalline orientation. There are two ways to get (001)-oriented L1₀ FePt films. One is the epitaxial growth [1-3], in which single crystal substrates (MgO and SrTiO₃, etc.) or assembled textured underlayers (CrRu, Pt etc.) have been used. The other is so-called non-epitaxial growth [4, 5]. The disordered (A1) FePt films which are soft magnetic, are deposited onto Si or glass substrates with or without underlayers at room temperature, and the L1₀ ordered structure is formed after post-annealing at a high temperature (T_A = 550°C or above). Then it is interesting to investigate the ordering kinetics in the two cases.

We have prepared three kinds of Fe₅₁Pt₄₉ alloy films with nominal thickness about 8 nm, by dc magnetron sputtering. Sample A, B, and C are films which are deposited at room temperature on SrTiO₃ (100), MgO (100) mono-crystalline substrates and 2-nm-thick FeO_x covered Si wafer, respectively, and then annealed for 10 minutes at temperatures from 300 to 750°C in vacuum. The structure is studied by x-ray diffraction (XRD) with Cu K_α radiation. The magnetic property of the films is measured by vibrating sample magnetometer (VSM).

Fig. 1 is the chemical ordering parameter S and the c-lattice parameter of samples A, B, and C as a function of annealing temperature, which are calculated from the XRD data [6]. It can be seen that the chemical ordering parameter S of FePt thin films on the FeO_x underlayers is larger than that of films on the mono-crystalline substrates and the c-lattice parameter is smaller than that at the same annealing temperature. The FePt films on the FeO_x underlayer are completely ordered with perfect (001) orientation after 600°C post-annealing (XRD not shown here), while for the ones on MgO and SrTiO₃ substrates the chemical ordering parameter S is still 0.96, 0.95 even after 750°C post-annealing. Furthermore, the FePt film deposited on Si with FeO_x underlayers begin to order at 400°C, and finish at 600°C. On the contrary, the epitaxial films begin to order at 500°C, and nearly finish at 750°C. The difference of temperature of the L1₀ phase formation is about 150°C. Then the phase transition from fcc to fct phase of the epitaxial FePt thin films is more difficult than that of the non-epitaxial ones on the FeO_x layers.

Fig. 2 indicates the dependence of coercivity of FePt alloy films on annealing temperature. For the films deposited on MgO and SrTiO₃ substrates in Figs. 2(a) and (b), the trends of coercivity are the same, increasing firstly and then decreasing with the annealing temperature. It is noticeable that the coercivities after 600°C post-annealing become smaller than those at 500°C. This may result from the decreasing of pinning sites of domain wall motion. On the other hand, for the FeO_x-FePt thin films in Fig. 2 (c), the out-of-plane coercivity increases with the annealing temperature. This implies that its magnetization reversal is rotational mode.

In summary, the different ordering kinetics of FePt films is observed and the ordering temperature of non-epitaxial thin films on FeO_x underlayer is around 150°C lower than that of epitaxial ones on mono-crystalline substrates for the 8-nm-thick FePt alloy films.

Domain reversal behavior of ultrathin FePt:C films.

H. Ko¹, P. Alagarsamy¹, S. Shin¹, W. Byun², S. Kim²

1. Physics, KAIST, Daejeon, South Korea; 2. Material Science, KAIST, Daejeon, South Korea

Introduction

Recently, researchers have attempted to solve various issues regarding the microstructural irregularities in ultrathin FePt films. Interestingly, Carbon doping in FePt thin films has been found to be one of the most effective ways to control L10 ordering and to reduce the average FePt grain size down to < 5 nm [1]. However, no detailed study has been reported on the magnetic domain patterns and domain reversal behavior of nanogranular FePt:C thin films. It is well-known that the domain patterns and domain reversal behavior of perpendicular recording media play an important role in the transition noise, and can be a serious limiting factor on the areal recording density. In this work, we report the study of time-resolved domain reversal patterns in the Carbon-doped equiatomic FePt films.

Experiment

7-nm thick FePt:C films were prepared on MgO(100) substrates using dc magnetron cosputtering of composite FePt and C targets. The volume concentration of the Carbon was varied up to 10 %. All the samples were prepared at a constant substrate temperature (350 °C). The crystal structure and microstructure of the films were characterized using X-ray diffractometry (XRD) and Transmission Electron Microscopy (TEM). Real time domain reversal patterns were obtained by means of a Magneto-Optical Kerr Microscope Magnetometer (MOMM) system capable of time-resolved domain observation with a spatial resolution of 0.4 μm and Kerr-angle resolution of 0.2°.

Results and Discussion

To reveal the effect of magnetic field and Carbon doping on the domain reversal behavior, direct observation of domain reversal patterns in real time was carried out in the MOMM system. The observed domain evolution patterns are illustrated in Figure 1 for various Carbon-doped FePt thin films. The areal expansion by domain wall-motion dominant process is clearly observed in the pure FePt film. As the amount of Carbon doping increases, time-dependent domain reversal pattern changes to nucleation-dominant reversal process at 10 vol. % Carbon-doped FePt film. To reveal the origin of domain reversal behavior with increasing Carbon doping in FePt thin films, we have considered the lowest energy state resulting from the sum of magnetostatic and domain wall energies. From the energy calculation, it was found that the change of the magnetostatic energy and the domain wall energy in our FePt:C films prefer wall-motion dominant process and nucleation-dominant process, respectively. Therefore, it would be difficult to clearly distinguish the actual contribution to the control of observed domain reversal patterns.

On the other hand, the effect of spatial anisotropy fluctuation coming from local structural variation on the domain reversal behavior was already simulated and proved as one of possible origin [2]. Therefore, to correlate the observed domain reversal behavior with the local structural variations in the Carbon-doped FePt films, TEM micrographs of the FePt:C films were obtained and analyzed. Figure 2 (a-c) shows the TEM micrographs of FePt:C thin films deposited at 350 °C with different Carbon concentration, while Figure 3(d) displays the average FePt grain size obtained from the TEM microstructure and calculated from the corresponding histogram, and the total number of available grains in the 150 \times 150 nm² area of TEM micrograph. With increasing Carbon concentration to 10 vol. %, the number of grains available in 150 \times 150 nm² was increased about 4 times with the average grain size of 4.3 nm. These results suggest that the Carbon doping plays an important role on building up the grain-grain boundary structure and leading to a uniform nanogranular

structure from the continuous film structure. The increased number of grain-grain boundary pairs with increasing Carbon doping in FePt film leads to a large increase in spatial anisotropy fluctuation due to the separation of uniform FePt film into grain (magnetic)-grain boundary (non-magnetic) structure. Hence, such a large discrepancy of spatial anisotropy fluctuation is the main origin of different domain reversal behavior

Fabrication of easy-axis-aligned ultrahigh-density FePt nanoparticles.

Y. Wu, L. Wang, C. Lai

Materials Science and Engineering, National Tsing Hua University, Hsinchu, Taiwan

The ultra-high-density perpendicular recording media demand excellent thermal stability, good magnetic isolation, and a narrow-distribution of easy axis. Many researches focus on the fabrication of FePt nanoparticles (NPs), by chemical syntheses [1] or physical vapor deposition [2], to fit those requirements. Although well-separated fine FePt particles have successfully been fabricated, it is quite challenging to align the magnetic easy axis of those NPs. Highly ordered FePt NPs with well-aligned easy axis have been fabricated by alternate deposition of FePt (at 780 °C) and MgO (at R.T.) on a MgO (100) substrates [3]. However, MgO single-crystal substrates may not be suitable for commercial products. In our previous study, we demonstrated that the well-aligned (001)-oriented FePt NPs on SiO₂ substrates can be obtained by combining agglomeration and atomic-scale depositions of [Fe/Pt/SiO₂]_n MLs [4]. In this work, we demonstrate the tunable particle size of FePt NPs by adjusting layer numbers of Fe/Pt/SiO₂. Eventually, fully isolated FePt NPs possessed a particle size of as small as 3.5 nm and a large out-of-plane coercivity ($H_{c,\perp}$) of 30 kOe were attained.

Sequential planetary sputtering of atomic-scale [Fe/Pt/SiO₂]_n (n = 3 to 18) MLs were performed on SiO₂/Si substrates at an ambient temperature. The corresponding thickness of Fe, Pt, and SiO₂ in each layer is 0.16 nm, 0.18 nm, and 0.28 nm, respectively. All samples were annealed in vacuum (1×10^{-5} Torr) at 700 °C for 2 s. The TEM plane-view images of samples (n = 3, 9, and 18) after annealing were shown in Fig. 1. All samples showed a clear particulate film structure, indicating that fully isolated FePt NPs were fabricated by agglomeration, a process that uncovering of a substrate or dewetting of an initially continuous film. The driving force of agglomeration was the divergence of surface/interfacial energy between films and substrates [5]. As the n value was equal to 18, all NPs presented an octagonal shape with the average particle size around 100 nm. The thickness of NPs was 22.5 nm, confirmed by TEM cross-section images, implying the particles were flatten-truncated octahedral shape. As reported in Ref. 4, the equilibrium flatten truncated octahedron shape of FePt NPs on an amorphous SiO₂ substrate was due to the lower interfacial energy of FePt/SiO₂ [4]. By reducing the n value to 9, NPs showed the reduced particle size of 10.1 nm and the clear octagonal shape in TEM plane-view image. In Ref. 2, it was reported that the equilibrium shape of FePt NPs tended to become an octahedron as the particle size was smaller than 10 nm, because the (111) surfaces were favorable in f.c.c/f.c.t system [2]. In our study, however, the flatten-truncated octahedral shape was kept even the particle size was reduced to 10 nm, which may be ascribed to the stabilizing effect on the particle shape due to the lower interfacial energy of FePt/SiO₂. Further reducing the n value to 3, NPs possessed the particle size of as small as 3.5 nm, and the areal density up to 1.4×10^{13} #/inch² were obtained. The shapes of these particles were sphere-like, implying the size may be too small to keep the flatten truncated octahedral shape of FePt NPs. The in-plane and out-of-plane hysteresis loops, shown in Fig. 2, were obtained by a superconducting quantum interference device. FePt NPs exhibited a well-aligned easy axis along [001] and possessed the high perpendicular anisotropy with a $H_{c,\perp}$ value larger than 45 kOe, which was attributed to the strong (001)-preferred orientation, confirmed by XRD, and high ordering factors as the particle size larger than 10 nm. In contrast, NPs with a size of 3.5 nm showed the poor perpendicular anisotropy and a small $H_{c,\perp}$ after annealing for 2s, which originated from the relatively low ordering factor due to the kinetic limit in small particles [6]. To beat the kinetic limit, these NPs were annealed at 700 °C for 6 hr. A large $H_{c,\perp}$ of 30 kOe was attained without obvious

change of particle size. The coarsening of FePt NPs may be restricted by a large diffusion barrier due to the sinking of FePt NPs into SiO₂ substrates during annealing. The kink in the hysteresis loop implied the existence of a soft phase, which might result from some NPs with too small particle sizes.

In summary, the particle size of FePt can be controlled by tuning the n value of [Fe/Pt/SiO₂]_n MLs. As decreasing the n value, the particle size reduces from 100 nm to 3.5 nm. The NPs show a flat-truncated octahedral shape and well-aligned easy axis along [001] even as the particle size was reduced to 10 nm. The NPs with a size of 3.5 nm exhibit a large $H_{c,\perp}$ of 30 kOe after a 700 °C annealing for 6 hr.

Structural and magnetic properties of textured Fe/FePt bilayer.

S. H. He, B. Ma, C. L. Zha, Z. Z. Zhang, Q. Y. Jin

Department of Optical Science and Engineering, Fudan University, Shanghai, China

Introduction

L10 ordered (FCT) FePt is a promising candidate for ultrahigh density recording media due to its high magnetocrystalline anisotropy. However, its coercivity is too high to be written by a real single pole head. New media designs are required. Recently, composite media and exchange spring media were introduced theoretically [1-3], and composite media effects were observed experimentally [4]. In exchange spring media a magnetic hard layer and a magnetic soft layer are strongly coupled. The switching field of the bilayer is far below the coercivity of hard magnetic layer due to the exchange interaction between them. Then a soft magnetic layer, such as Fe, can be utilized to promote the magnetization reversal of the ordered FePt layer.

We present here the structural and magnetic properties of Glass/Fe/(L10 FePt) bilayer. The Fe underlayer is a (002) textured film, on which an (001) textured FePt layer is prepared by epitaxial growth. The magnetic behavior of the bilayer has been studied.

Experimental

The Glass/Fe/FePt(7 nm) magnetic bilayers were fabricated in a dc magnetron co-sputtering system from individual Fe and Pt targets. The Fe layer was first deposited at room temperature, and then annealed at 600 °C in vacuum for 15 min. After that, perfect (002) textured Fe underlayer can be formed [5]. Then FePt layer was co-sputtered under the substrate temperature of 500 °C.

The crystallographic structure of the samples was examined by x-ray diffraction (XRD) with Cu K α radiation. Magnetic properties were measured by a vibrating sample magnetometer (VSM) and magneto-optical Kerr magnetometer (MOKE).

Results and Discussion

Figure 1 shows the θ -2 θ XRD patterns of the Glass/Fe/FePt samples as a function of the Fe layer thickness. For the sample with 6-nm-thick Fe layer, there is no Fe related XRD peak. The FePt (002) peak is clearly observed at 48.53°, an angle between the (200) and (002) peaks of bulk materials. This indicates that the film is still in the intermediate stage of an fcc-fct transformation. When the Fe thickness increases beyond 8 nm the Fe (002) peak shows up. Furthermore, both (001) and (002) peaks of FePt appear. Their intensities become apparent and the (002) peak approaches the very position with the increase of Fe thickness. FCT structure is formed. Simultaneously, the intensity of FePt (111) peak turns weak, and is invisible when Fe thickness increases up to 20 nm. This indicates that (001)-textured FePt layer are prepared on Fe underlayer with (002) orientation by epitaxial growth, since the mismatch between FePt (001)[100] and Fe (001)[110] lattice is 4.29% in our experiment.

The dependence of magnetic hysteresis and coercivity on the thickness of Fe layers is indicated in Fig. 2. Three kinds of magnetic behaviors can be observed. The first one is the Fe/FePt bilayer with 6-nm-thick Fe underlayer, which behaves as a single magnetic film as shown in Fig. 2(a). The second one is the exchange spring structure in which FePt and Fe layers interact in the way of exchange coupling as we can see in Fig. 4(b) and (c), when the Fe thickness is in the range between 8 – 12 nm. With further increasing of Fe layer thickness beyond 12 nm, there is a part of Fe layer which is uncoupled with FePt layer and keeps its own easy axis along film plane as the thickness is beyond the exchange length. This is the third kind. The hysteresis loops in Fig. 4(d)-(f) show the combination of soft magnetic phase and hard magnetic phase. This one is regarded as double-phase stage also.

Control of Curie temperature of FePt(Cu) films prepared from Pt(Cu)/Fe bilayers.

J. Ikemoto, Y. Imai, S. Nakagawa

Dept. of Physical Electronics, Tokyo Institute of Technology, Tokyo, Japan

Introduction

$L1_0$ ordered FePt alloy thin films with (001) preferential orientation are regarded as hopeful candidates for future high density perpendicular magnetic recording media because of their high uniaxial magnetic anisotropy energy. Besides, FePt is the center of attention as heat assisted magnetic recording (HAMR) medium because of the controllability of Curie temperature by adding third element such as Cu^[1]. Since the Curie temperature of FePt alloy is as high as around 500°C, it is required to control the Curie temperature around 250°C for application to HAMR medium applications. In our previous papers, we have found that Pt(100)[3nm]/Fe(100)[3nm] bilayered films deposited directly on crystallized glass disk substrates exhibited FePt highly ordered *fcc* alloy with (001) preferential orientation after annealing at 600°C in hydrogen atmosphere for 120 min^[2]. In this paper, we have attempted to control Cu addition into Pt top layer in Pt_{50-x}(Cu)_x/Fe₅₀ bilayered films and fabricated Fe-Pt-Cu films by the annealing process described above. We evaluated the controllability of Curie temperature of FePt(Cu) ordered films with (001) preferential orientation.

Experimental

Facing targets sputtering (FTS) method was employed to prepare Pt/Fe and Pt_{50-x}(Cu)_x/Fe₅₀ bilayers. Cu was added to Pt layers by placing the composite targets consisting of Pt and Cu. Fe bottom layer and Pt(Cu) top layer were deposited directly on crystallized glass disk substrates (OHARA:TS-CZ) at room temperature in Ar atmosphere. The atomic ratio of Fe:Pt:Cu was determined by ICP-OES analysis. All the specimen bi-layers were annealed at 600 °C for 120 minutes in hydrogen (1 atm) to enhance inter-diffusion and ordering to *fcc*-FePt. Crystallographic characteristics were evaluated by X-ray diffraction (XRD). Magnetic properties were measured by VSM at the maximum applied field of 15 kOe.

Results and Discussion

Prepared specimens can be categorized in 3-groups by the difference of Cu content, *i.e.* pure FePt(Pt[3 nm]/Fe[3 nm]), Cu-poor FePtCu(Pt₄₂Cu₈[5 nm]/Fe[5 nm]) and Cu-rich FePtCu(Pt_{32.5}(Cu)_{17.5}[4.5 nm]/ Fe[3 nm]). The atomic ratio of Fe:Pt:Cu of the Cu-poor and the Cu-rich FePtCu films were 50:42:8 and 37:41:22, respectively. Thickness of each layer was changed to maintain $L1_0$ crystalline structure, considering Cu atom was replaced in Fe site as described in later. All specimens indicated *fcc*-FePt(001) preferential orientation. Lattice constant *c* calculated from *fcc*-FePt(001) peak, magnetization of FePt, and Cu doped FePt films was plotted in Fig.1. Lattice constant *c* decreased as Cu percentile increases. This trend of *c* provided an evidence of the incorporation of Cu atom substituted for Fe or Pt in the *fcc*-FePt lattice. Additionally Cu atom seemed to be located in Fe site since magnetization of Cu doped FePt films decreased with Cu addition^[3]. Figure 2 showed changes of perpendicular coercivity and slope parameters $\alpha(=dM/dH)$ at H_c at the coercivity. Domain wall pinning effect by Cu addition resulted in large difference of α among pure FePt film and Cu doped FePt films.

Figures 3 and 4 showed the temperature dependence on saturation magnetization and perpendicular coercivity of FePt film and Cu doped FePt films, respectively. Pure FePt film held higher magnetization and coercivity at 300 °C than the Cu doped FePt films. By contrast with the pure FePt, the temperature dependence on the magnetization and perpendicular coercivity of Cu doped FePt films shifted lower. In particular, magnetization of Cu-poor FePtCu film, that is 8 at.% Cu doped FePt film, showed the steep decline at the temperature range from 150°C to 250°C and reached

down on 0 at 300°C. This was suitable for HAMR medium. Meanwhile, magnetization of Cu-rich FePtCu film, that is 22 at.% Cu doped FePt film, vanished at 100°C. Consequently, Curie temperature of *fcc*-FePt thin films was controlled from around 300°C to 100°C by adding Cu.

Exchange Coupling Assisted FePtC Perpendicular Recording Media.

J. Hu¹, J. Chen², Y. Ding¹, B. Lim¹, W. Phyoe¹, B. Liu¹

1. Data Storage Institute, Singapore, Singapore; 2. Department of Materials Science and Engineering, National University of Singapore, Singapore, Singapore

I. INTRODUCTION

Exchange coupling assisted (ECA) perpendicular recording has been proposed to decrease the writing field, which allows the application of high anisotropy materials as recording media. Relative insensitivity to c-axis dispersion is another advantage of this kind of recording media. In this paper, FePtC based ECA media was fabricated and the magnetic properties of the films were investigated.

II. EXPERIMENTAL DETAINLS

FePtC based ECA perpendicular media with the structure of Glass/CrRu/MgO/ L_{10} FePtC/fcc FePtC were prepared by an ultrahigh vacuum magnetron sputtering system. The CrRu and MgO act as the underlayer and buffer layer. Different deposition temperature was used to control the FePtC phases with soft (room temperature) and hard magnetic properties (350°C).

III. RESULTS AND DISCUSSIONS

The out-of-plane hysteresis loops of the ECA media and a single layer FePtC film were shown in Fig. 1. The coercivity H_c and saturation field H_s for the single FePtC layer (10 nm) were about 10 kOe and 24 kOe, respectively. After the introducing the top soft FePtC layer, the values of H_c and H_s reduced to be 8.3 kOe and 20 kOe (3 nm soft layer) and 7 kOe and 17.5 kOe (5 nm soft layer), respectively. No separated switching of soft and hard layers indicated that the two FePtC layers were exchange coupled with each other. Comparison of the loop steepness of the ECA media with that of the single hard layer indicated the increase of exchange coupling effect with the increase of the top soft layer.

The angle dependence of the coercivity and the remanent coercivity was measured for ECA media as shown in Fig. 2. To measure the angular dependence of the remnant coercivity, the sample was saturated at every angle by an applied magnetic field of -29 kOe, the field was then decreased to zero to measure the remanent moment. The remanent moment as a function of a magnetic field was measured for each angle by applying a positive magnetic field with a step of 400 Oe, until the applied field reached 29 kOe.

According to the Stoner-Wolfarth model, the switching field of the conventional perpendicular media is very sensitive to the angle between the easy axis and the applied magnetic field. In the ECA media in present work, the coercivity and the switching field demonstrated a less sensitivity on the angle between the easy axis of the hard layer and the external applied field, indicating by small variation when the angle increased from 0 to 15°. The insensitivity was attributed to the top soft layer. The angle dependences of coercivity and remanant coercivity are also consistent with the simulation results of Victora. [1]

Figure 3 shows the TEM images of the ECA media with different soft layer thickness. It can be seen that the ECA media was composed of two granular films. The grain size of the bottom hard FePtC layer is larger than that of the top soft layer. The grain size of top soft layer increases with the increasing layer thickness, which may explain the increase of the loop steepness with soft layer thickness. The grains of the soft layer located both on top of the bottom FePt grains and the grain boundaries.

IV. SUMMARY

In summary, the ECA media with structure of Glass/CrRu/MgO/FePtC (350°C)/FePtC (RT) were fabricated. The experimental results of angular dependence of the coercivity and the remnant coercivity are consistent with the simulation results.

Epitaxial thin SmCo₅ films with perpendicular anisotropy.

M. Seifert, V. Neu, L. Schultz

Institute for Metallic Materials, IFW Dresden, Dresden, Germany

Introduction

Hard magnetic thin films find important applications in nano and micro electromagnetic systems (NEMS, MEMS) and magnetic recording. SmCo₅ is a material with a high uniaxial magnetic anisotropy and therefore has the potential to be used as a high density recording media. Thus, in the last years, research focuses on the preparation of polycrystalline Sm-Co films with perpendicular anisotropy [1]. In our group we specialize on the realization of epitaxial growth and recent work led to SmCo₅ thin films with a perfect in plane texture [2]. Based on that knowledge, we developed epitaxial SmCo₅ films with strong perpendicular anisotropy by pulsed laser deposition, which can serve as test system for the study of perpendicular recording in high K_u materials.

Experiment

Films were prepared by pulsed laser deposition (PLD) at ultra high vacuum (UHV) conditions. At first, a buffer layer of 10 nm Ru was deposited onto an Al₂O₃ (0001) substrate, then 100 nm of SmCo₅ and finally 10 nm of Cr as an oxidation protection. The preparation temperature of the Sm-Co layer was varied systematically in a range between 550°C and 800°C. The texture of the films was analyzed with XRD and pole figure measurements. Magnetic properties were investigated using a vibrating sample magnetometer (VSM) and a magnetic force microscope (MFM). Additionally anomalous Hall Effect measurements were performed. Atomic force microscopy (AFM) was used to investigate the surface morphology. Thicknesses and composition of the layers were determined with EDX in a scanning electron microscope (SEM).

Results

Figure 1 shows the XRD pattern (CoK α) of the samples prepared at different temperatures. The (0006) peak of the Al₂O₃ substrate is clearly visible on which Ru grows with (0002) orientation. It can be seen that at 600°C the SmCo₅ (0002) peak appears for the first time and that the intensities increase up to 700°C. At higher temperatures additional Sm₂O₃ peaks are found.

To determine the orientation of the Sm-Co grains pole figure measurements were performed. We measured the (1 0 -1 4) pole of Al₂O₃ at $2\theta_{Cu} = 35.22^\circ$ and the (1 0 -1 1) pole of SmCo₅ at $2\theta_{Cu} = 30.5^\circ$. Because of the six-fold symmetry of the Sm-Co pole it was sufficient to measure a Φ range of 130° . The results of both measurements for the sample deposited at 700°C are displayed together in figure 2. It proves that the c-axis is oriented out of plane and reveals that there is an epitaxial growth with two different in plane orientations of the hexagonal unit cell, which are rotated 30° with respect to each other. The poles with the higher intensity (I) are rotated 30° with respect to the Al₂O₃ (1 0 -1 4) pole, the others (II) have the same orientation like the Al₂O₃. The peaks appear at a position of $\Psi = 44^\circ$, which agrees well with the theoretical value of $\Psi = 42^\circ$.

VSM measurements show, that already at low temperatures a SmCo phase with high uniaxial anisotropy is formed with coercivities of up to 2 T. However, these samples are macroscopically isotropic. Magnetic texture develops with increasing temperature. The sample prepared at 700°C possesses a square shaped out-of-plane hysteresis (squareness=0.81) with a coercivity of $\mu_0 H_c = 1.0$ T. (Fig. 3 (a)). For higher temperatures the samples become isotropic again. VSM measurements contain small steps around $\mu_0 H = 0$ T. To see if they arise from the film properties or are due to the substrate or measurement setup, additional Hall measurements were done. These measurements do not show any steps, but only the wanted square shape in the case of the 700°C prepared film (Fig. 3 (b)). For these films prepared at optimum temperature of 700°C the high uniaxial anisotropy of

the Sm-Co phase is obvious from the largely different hysteresis loops measured in different directions. From the intersection of the flat in-plane (hard axis) loop with the out-of-plane loop the uniaxial anisotropy constant is deduced to $K_u = 10$ MJ/m³.

Studies on $\text{Sm}(\text{Co,Cu})_5$ thin films with perpendicular anisotropy for extremely high areal density recording.

X. Liu¹, H. Zhao¹, Y. Kubota², J. Wang¹

1. The Center for Micromagnetics and Information Technologies, Department of Electrical and Computer Engineering, University of Minnesota, Minneapolis, MN; 2. Seagate Research, Pittsburgh, PA

SmCo_5 is well known as a hard magnetic material for its ultrahigh uniaxial magneto-crystalline anisotropy (10^8 erg/cm^3). Recently it is considered a promising candidate for future high areal density perpendicular recording media because of the demand of media with extremely small but thermally stable grains. Until now, SmCo_5 films with perpendicular anisotropy were only obtained on Cu underlayer or Cu sub-underlayer.¹⁻⁴ While Cu underlayer could induce the perpendicular anisotropy in SmCo_5 at relatively low deposition temperature, it also leads to large grain size in SmCo_5 magnetic layer. In this study, we successfully fabricated $\text{Sm}(\text{Co,Cu})_5$ film with perpendicular anisotropy on pure Ru underlayer (figure 1), instead of Cu underlayer, to control the grain size of SmCoCu film. And studies about the effect of deposition temperature, film composition and film thickness on the magnetic properties of SmCoCu films were performed.

The structure of SmCoCu films was $\text{Ta}(3\text{nm})/\text{Sm-Co-Cu}(10\text{nm})/\text{Ru}(20\text{nm})/\text{Ta}(4.2\text{nm})/\text{glass}$. The grain size of the $\text{Sm}(\text{Co,Cu})_5$ layer was reduced to 17nm, which can be further reduced. The deposition temperature was reduced to a relatively low value, 350°C. When the deposition temperature was lowered further to 250 °C and 150 °C, the perpendicular anisotropy in SmCoCu film could not be achieved (figure 2(a)). And the study of SmCoCu films' composition showed that the addition of Cu in the SmCoCu layer was another important factor for the perpendicular anisotropy (figure 2(b)). The SmCoCu film's out-of-plane coercivity was found to depend on film's thickness. A 2.2nm magnetic dead layer between SmCoCu and Ru layers was estimated by fitting the saturation magnetization vs. inverse of film thickness curve. The switching mechanism of the Sm-Co-Cu films was investigated by measuring the angular behavior of the remanent coercivity. A switching model involving the pinning sites that are related with Cu doping and grain boundaries was proposed and will be discussed in detail in the full presentation.

Second order anisotropy in exchange spring systems.

B. F. Valcu, A. Dobin, E. Girt
Seagate Technology, Fremont, CA

Exchange spring systems consist of a soft magnetic layer ferro-magnetically coupled to a hard magnetic layer [1]. When a reversal field is applied, the magnetization in the structure rotates incoherently, a partial domain wall being formed at the hard/soft interface. If the hard layer has large enough anisotropy, a relatively thin soft layer can be used as a write-assist, making the structure interesting for recording applications. The magnetic materials used for both the hard and soft layer have in general only first order anisotropy $Ku^{(1)}$. We report here experimental observation and micromagnetic studies of a change in the symmetry of the torque curve for exchange spring systems that leads to an apparent second order term $Ku^{(2)}$ in the anisotropy energy.

In torque measurements the magnetic film, whose moment was initially saturated, is rotated in a high field of constant magnitude. The magnetization direction deviates from the applied field, due to competition from the anisotropy field. The torque is proportional to the component of magnetization perpendicular to the field, measured for example using a vector VSM. When the applied field angle is varied, the torque follows a sinusoid curve, whose amplitude indicates the anisotropy energy constant.

The simplest way to analyze torque curves for a bi-layer system is to assume that the magnetic moments of the two layers are parallel with each other (rigid coupling). However, if one of the layers has much smaller anisotropy than the other—as it is the case with exchange spring systems—the validity of the assumption must be questioned. We built a spin chain model in which magnetization is allowed to rotate from the bottom of hard layer to the top of soft layer. The exchange stiffness values of the two layers control the extent of magnetization non-uniformity.

Energy minimization leads to a second order differential equation for the magnetization direction as a function of the distance to the hard/soft interface [2]. Since in the torque measurement the deviation of the magnetization from the field direction is small, we can expand linearly the magnetization angle around the field angle and solve the equation analytically. We arrived at a closed expression for the torque, parameterized by the magnetic properties of the two layers. In case there is only one layer, the magnetization direction is constant through the film and the torque expression simplifies to:

$$m_y(\alpha_H)/m_{\text{total}} = -(1/2 Hk^{(1)} \sin(2\alpha_H) + Hk^{(2)} \sin^2(\alpha_H) \sin(2\alpha_H)) / (H + Hk^{(1)} \cos(2\alpha_H) + 2Hk^{(2)} (\sin^2(2\alpha_H) - \sin^2(\alpha_H))).$$

In the above the perpendicular component of magnetization m_y is normalized by the total moment of the sample, α_H is the applied field angle, $Hk^{(1)}$ and $Hk^{(2)}$ are the first and second order anisotropy fields and H is the constant valued of the applied field.

For illustration, let us consider an exchange spring system in which the hard layer is 12 nm thick and the soft layer is 20 nm thick. The (effective) anisotropy field of the hard layer is 8 kOe, oriented perpendicular to the film surface, while the soft layer has no anisotropy. The largest deviation from the field direction is obtained when the external field ($=16$ kOe) is applied at 45 degrees with respect to the easy axis. In the case of rigid coupling, the magnetization is uniform through the film, and makes an angle of ~ 39 degrees with the easy axis (Figure 1). However, if the exchange constant in the film is finite, the magnetization in the exchange spring system rotates gradually from 33 degree to 45 degree. The resulting torque curves are also shown in Figure 1, for both rigid and non-rigid coupling cases. If we were to fit the two curves to sample-averaged $Ku^{(1)}$ and $Ku^{(2)}$, it is interesting to observe that in the non-rigid coupling case we would get a significant $Ku^{(2)}$ con-

tribution. Allowing magnetization to rotate non-coherently changes the symmetry of the torque curve.

Experimentally we sputtered a series of exchange spring films, in which the thickness of the soft layer (denoted by t_2 in Figure 2) was varied [3]. The torque curves were fitted using our micromagnetically-derived expression. The estimated anisotropy constant of the soft layer is independent of the film thickness. This ultimately proves the existence of the exchange spring effect.

Magnetic recording in patterned media at 5 - 10 Tbit/in²

S. Greaves¹, Y. Kanai², H. Muraoka¹

1. RIEC, Tohoku University, Sendai, Japan; 2. IEE, Niigata Institute of Technology, Kashiwazaki, Japan

<p>Introduction

Bit patterned media (BPM) are expected to be able to support ultra-high recording densities well in excess of 1 Tbit/in². In this paper we describe how micromagnetic modelling was used to determine the areal density limit for a shielded, single-pole write head and single phase magnetic dots, without the use of thermal or microwave energy sources.</p>

<p>Models

Head field distributions were calculated using a finite element model. The width of the main pole at the air bearing surface (ABS) was 10 nm and its length was 20 nm. Side and trailing shields were located 5 nm and 15 nm from the main pole, respectively. The ABS—soft underlayer (SUL) spacing was 8.5 nm and the recording layer was situated between the two.

The recording layer consisted of rectangular bit cells, with a single magnetic dot centered in each bit cell. The 10 Tbit/in² design was subject to the following constraints: Bit cell area = 65 nm², minimum non magnetic boundary between dots = 2 nm, $K_u V / k T = 60$ and $H_d + H_{adj} < H_k < H_{head}$, where H_d is the magnetostatic field in a saturated medium, H_{adj} is the adjacent track erasure field, which is the head field in an adjacent track, H_k is the anisotropy field of the dots and H_{head} is the maximum head field.

Based on these constraints the magnetic dot size was chosen to be 11 nm × 3 nm × 7 nm in a 13 nm × 5 nm bit cell. A dot thickness of 7 nm gives a maximum head-medium spacing of 1.5 nm, i.e. contact recording if an overcoat is used. The maximum head field in the centre of the dots was 13300 Oe with a maximum head field gradient of 711 Oe/nm. Dots were discretised into 1 nm cubes and media contained 11 tracks of randomly magnetised dots to determine the effect of the magnetostatic field. The magnetic properties of the dots were $M_s = 1380 \text{ emu/cm}^3$ and $K_u = 10.85 \times 10^6 \text{ erg/cm}^3$.</p>

<p>Results

Using the parameters listed above, simulations of recording were carried out at a temperature of 300 K. The head-medium velocity was 10 m/s and the head field rise time (zero - 90% of maximum field) was 0.12 ns. Even in the absence of geometric and material property distributions it was not possible to write error-free tracks, unless the temperature was reduced to zero. Despite the high head field gradient, the spacing between dots was too small to write to a selected dot without frequently over-writing the previous dot. Reducing the head-medium velocity to 5 m/s reduced on-track write errors, but increased adjacent track erasure.

Magnetostatic field distributions were calculated for media with randomly magnetised dots (up/down). The effective magnetostatic field distributions, taking account of the angle and assuming Stoner-Wohlfarth switching behaviour, are shown in Fig. 1. For a 13 nm × 5 nm bit cell the average value of H_d was 2570 Oe, with standard deviation, $\sigma = 900 \text{ Oe}$. For a dot subject to $H_d + 3\sigma$, the average interval between thermally induced magnetisation reversal would be around 5 seconds. Writing schemes to limit the maximum magnetostatic field would be required to ensure data integrity in such a medium.

The areal density of the patterned media was reduced and the dot volume increased to determine the maximum areal density that could be used with the given write head. Bit cells of 15 nm × 8 nm and dots of 11 nm × 4 nm × 7 nm were found to permit reliable recording of data tracks without

adjacent track erasure at a head-medium velocity of 10 m/s. The areal density of such a system is 5.38 Tbit/in² and long-term stability of dots is ensured. Fig. 2 shows a portion of such a medium. The central track was recorded with an alternating pattern and the magnetisation of the surrounding dots had a random up/down orientation.</p>

<p>Conclusions

The head and medium design outlined here could support areal densities in excess of 5 Tbit/in², a tenfold increase on current demonstrations. To achieve 10 Tbit/in² requires an extremely high head field gradient; improved head designs are currently being investigated to meet this target.</p>

1. RIEC, Tohoku University, Sendai, Japan; 2. IEE, Niigata Institute of Technology, Niigata, Japan

Introduction

The potential and characteristics of bit patterned media with an areal density of 2 Tbit/in², for use in future storage devices, were investigated using micro-magnetic simulations based on the Landau-Lifshitz-Gilbert equation. The influence of dot size and position dispersions on the signal to noise ratio (SNR) was clarified. The head-medium synchronisation tolerance (write margin) for error-free writing was calculated, and the feasibility of achieving 2 Tbit/in² recording with bit patterned media was demonstrated.

The model

The region containing a single dot and its non-magnetic boundary is called the bit cell. The bit cell length (down-track direction) and width (cross-track direction) correspond to the bit length and the track pitch, respectively. In this research, the bit cell length in the patterned media was 13 nm and the width was 25 nm, giving an areal density of 2 Tbit/in². Rectangular, magnetic dots, formed from a number of 2 nm cubes, were centered in each bit cell. The dots in adjacent bit cells were never in contact. The dot dimensions were 16 nm × 8 nm and 10 nm thick and had a saturation magnetization, M_s , of 860 emu/cc. The exchange coupling constant, A , temperature, T , and easy axis dispersion were 10 erg/cm², 300 K and 0 degrees, respectively.

The simulated media contained seven columns (tracks) of dots in order to bring the maximum magnetostatic field close to the value predicted for an infinitely wide medium. A 1/0/1/0... pattern was programmed into the middle track of each medium. The polarity of bits in the remaining tracks was set at random. The sensitivity function of a 20 nm wide magneto-resistive (MR) head with a 25 nm shield-to-shield spacing was calculated and used to evaluate the SNR of tracks in an ideal patterned medium, and in media with random dot displacements and dispersions of dot areas.

Subsequently, write margins were determined for 2 Tbit/in² patterned media. The write fields of shielded, single pole heads were calculated using a finite element model. The main pole width was 20 nm and the length was 30 nm. The head to medium spacing was 6 nm, with a 2 nm thick seed layer between the bottom of the dots and the soft magnetic underlayer. Side shields were placed 10 nm either side of the main pole and a trailing shield was located 30 nm behind the main pole. The maximum write field in the uppermost layer of the medium was 9.4 kOe. The uniaxial anisotropy, K_u , of the media was 3.88×10^6 erg/cc and was chosen to give high thermal stability ($K_u V/kT = 120$) and anisotropy fields, H_k , slightly lower than the maximum head field. Multiple simulations of recording single bits were carried out, each with random media magnetization configurations. The probability of successfully writing a bit was calculated for different initial write head positions.

Results

Random variations in the dot positions of up to 2 nm did not have a significant effect on the SNR. Fig. 1 shows the effect on the SNR of introducing dispersions of dot areas. The bit cell length of 13 nm equates to a linear density of 1954 kfc/i, resulting in a small output signal from the read head. Dot area dispersions lead to large fluctuations in the amplitude of the readback signal, significantly reducing SNR. Fig. 2 shows the write margin, defined as the range of offsets between the trailing edge of the write head and the dot centers for which error free writing could be achieved. For these media, the write margin was 2 - 3 nm.

Simulation Study of High Density Bit Patterned Media with Inclined Anisotropy.

N. Honda, K. Yamakawa, K. Ouchi

Research Institute of Advanced Technology, Akita Prefectural R & D Center, Akita-shi, Japan

1. Introduction

Bit patterned media is one of promising candidates which extend recording densities of perpendicular magnetic recording beyond 1 Tbit/in². However, when the packing density of the magnetic dots is increased towards 2 Tbit/in², some additional methods, such as use of exchange coupling [1] or in-plane anisotropy [2], should be introduced to reduce the enhanced effect of magnetostatic interaction between the dots. This paper proposes another simple technique of using inclined anisotropy, which is effective to realize high areal densities beyond 2 Tbit/in².

2. Simulation model of media and magnetic properties

Figure 1 shows modeled bit patterned media with an areal density of 2 Tbit/in² with an inclined anisotropy angle to the longitudinal direction, ϕ . The media consisted of three tracks with 51 dots for each with an analytic soft magnetic underlayer (SUL). Each 10x15x5 nm³-dot was modeled with 48 exchange coupled 2.5 nm-cube elements with $M_s=1000$ emu/cm³, $\langle H_k \rangle=13$ -18 kOe with 15 % standard deviation, and an orientation deviation of 2 deg. The $\langle H_k \rangle$ values were determined so that the magnetic energy estimated from the minimum reverse filed in each easy axis satisfies the thermal stability condition. The smaller the angle, the smaller H_k is required. Figure 2 shows simulated anisotropy angle dependence of remanence properties of the media for perpendicular applied field. The switching field width, $(H_{sr}-H_{nr})$, reduced with decreasing the anisotropy angle, especially for angles less than around 50 degrees, which indicated change in the effect of the interaction field between the magnetic dots. Increased down track shift margins for recording were expected from the decreased switching field width [3].

3. Recording simulation

Although the anisotropy axes of the media were deviated from the perpendicular direction, a shielded planar pole head [4] was used for recording at 2 Tbit/in². Recording simulation was performed using the optimum magnetomotive force (MMF) for each medium. When the switching timing of the recording field was properly chosen, a 2 Tbit/in² pattern was successfully recorded on the center track without affecting adjacent tracks for all the media. The write error rates for 51 recorded bits were investigated for the media by shifting the switching timing in the down track direction, and the down track (DT) shift margins were estimated as no error shift width. The write rates at the adjacent track when the head filed was shifted in the cross track direction were also investigated for the media, and the cross track (CT) shift margins were obtained. The results are summarized in Fig. 3. It was found that the shift margins in the down and cross track directions were increased for media with inclined anisotropy and the effect was significant for media with angles less than about 50 degrees. The increased CT shift margins were also caused by the decreased switching field width. It is expected that an areal density of 2.6 Tbit/in² with a reduced track pitch of 20 nm would be realized with shift margins of 8 nm in DT and 7 nm in CT for media with an inclined anisotropy angle of 30 degrees.

We would like to thank Dr. S. Iwasaki for his stimulating guidance. This work was partially supported by Akita Prefecture CREATE, JST and SRC.

Writability in Discrete Track Media.

K. Moon¹, C. Che¹, Y. Tang², M. T. Moneck², J. Zhu², N. Takahashi³

1. Samsung Information Systems America, San Jose, CA; 2. ECE Department, Carnegie Mellon University, Pittsburgh, PA; 3. Fuji Electric Advanced Technology, Nagano, Japan

Discrete track media, based on conventional PMR media, were prepared to get grooves and lands in the magnetic layer, defined by e-beam lithography and ion-milling processes. The bottom of milled groove reaches the interlayer. The interlayer and soft under-layer are continuous under the patterned magnetic layer. Discrete track zones and continuous zones are alternatively positioned within a limited portion on a track with each zone being 50 μm long in the down-track direction. Both discrete track zones and continuous zones are repeated 10 times. The patterned recording tracks are designed to have 150, 100, and 50 nm widths with groove widths of 200 nm. Since these patterned zones are formed on a small scale in a given track, the flying of R/W head was minimally disturbed by the groove features. To secure a stable trigger on the Guzik spin stand, a number of Guzik servo signals are reduced to let the whole pattern area be in one sector. It was well recognized that discrete track media could effectively reduce adjacent track erasure (ATE) which would be a hurdle to high areal density of more than 500 Gbpsi [1]. The edge of the discrete track is supposed to have a stable magnetization configuration due to reduced self-demagnetization [1]. This stable magnetization at the edge may generate an issue in writing performance even if it could reduce ATE. In this study, writability of discrete track media as well as of continuous media with various write currents is discussed. Writability here is gauged by the amplitude of output signal which is the root-mean-square (rms) of the fundamental harmonics for LF writing frequency (53 Mf/s). Write track width of the head was 169 nm while read width was 89.5 nm. From separate experiments, the output of discrete zones and continuous zones became saturated at 12 mA. Therefore, writing current was changed from 6 mA to 12 mA with 0.5 mA step. An initial 2T writing part (200Mf/s) in a given track is saved from LF writing during experiments and used for triggering, by controlling the gate in the spin stand controller. It was found that the output signal in the discrete zone was smaller than the one in the continuous part at a certain range of current if current is less than 12mA when discrete zone becomes narrower (Fig. (1)). That indicated that the discrete zones are not fully magnetized at low writing current whereas continuous zones are already magnetized. But, no amplitude difference was observed between discrete zones and continuous zones when current were more than 12 mA. From cross-sectional TEM study and simulation, it is recognized that shallow wall angle after ion-milling could be one of root causes for this under-magnetization of discrete media (Fig (2)). In a conclusion, the writability of the discrete zone is not so different from that of continuous zone when current is more than 12 mA.

Magnetization switching experiments on sub-micron Co/Pt multilayer dot with pulse field generator with nanoseconds duration.

N. Kikuchi, I. Atsuo, S. Okamoto, O. Kitakami
IMRAM Tohoku University, Sendai, Japan

I. Introduction

Bit patterned media (BPM) is one of the candidate solutions to overcome superparamagnetism limit of ultrahigh density magnetic recording. Understanding of dynamical switching behavior of the nanomagnet is one of the key issues to realize BPM, since the operation frequency is expected to be of the order of 1 GHz and comparable with the timescale of magnetization reversal itself. However, investigation of dynamical switching behavior of individual hard nanomagnet in a timescale of nanoseconds is still challenging due to the difficulties of generating a large pulse field to switch magnetization, although a few works has been reported on continuous films [1, 2]. In this work, we have developed a nanoseconds pulse field generator with the maximum field of several hundred oersteds in submicron area. Magnetization switching behavior of a single Co/Pt multilayer dot with sub-micron diameter in the pulse field has been investigated by combining with anomalous Hall effect (AHE) detection [3].

II. Sample fabrication

A multilayer of $[\text{Co}(1.3 \text{ nm})/\text{Pt}(2 \text{ nm})]_3$ was deposited on a glass substrate with Pt (2 nm)/ Ta (2 nm) underlayers. The multilayer was patterned into a dot of 400 nm in diameter by means of e-beam lithography and Ar ion etching. A 10 nm-thick Pt film was deposited on the dot and subsequently patterned into cross-shaped electrode for AHE measurement. A Cu stripline of 10 μm in width and 200 nm in thickness for pulse field generation was deposited beside the Co/Pt dot. The distance was designed as 5 μm from the edge of the stripline to the dot center. A SEM image of the sample is shown as Fig. 1. The direction of pulse field is perpendicular to the film plane with this sample geometry.

III. Results

The developed pulse generator consists of a power supply, a coaxial cable as capacitor and two relay switches for charging and discharging. The amplitude of the pulse field is proportional to the charged voltage V_p and the estimated maximum field of 740 Oe on the dot was obtained with $V_p = 400 \text{ V}$. The pulse duration is defined by the coaxial cable length with the rate of 10 nm/s and was fixed as 10 ns in this study. By careful adjustment of characteristic impedance of the whole system including the microfabricated sample, very rectangular shaped pulse with rise time of 0.4 ns was obtained. AHE measurement in a static field revealed that the switching field of the dot is 2.9 kOe. Since even the maximum pulse field is insufficient to switch the dot magnetization, all the measurements were carried out with the assistance of bias DC field H_{DC} . Figures 2 show switching probability after applying pulse field as function of H_{DC} . V_p was varied from 0 to 400 V. The direction of the pulse field was set to (a) anti-parallel and (b) parallel with the direction of H_{DC} . Significant reduction of required H_{DC} for switching (H_{DC}^c) is observed only when the pulse field direction is parallel to the direction of H_{DC} . H_{DC}^c depends on also V_p and decreases with increasing of V_p . These field amplitude and direction dependences indicate that the magnetization of the dot was switched by the generated pulse field, not by heating or eddy current. Moreover, these results suggest the possibility of real-time measurement of magnetization reversal of a single hard nanomagnets. The effect of pulse field becomes insignificant below $V_p = 200 \text{ V}$. This threshold can be explained qualitatively by considering thermal relaxation process both of in timescales of the pulse field and

measurement process, respectively. The origin of rather wide distribution of switching field found in Fig. 2 (b), which is apparently larger than experimental error, also will be discussed.

I. INTRODUCTION

Bit patterned media (BPM) is a promising candidate for high-density magnetic recording media because it can improve thermal stability and reduce media transition noise. We proposed the Artificially Assisted Self-Assembling (AASA) method a low-cost and large-area nanopatterning method for BPM [1]. For BPM applications, it is necessary to minimize the switching field distribution (SFD) of patterned dots. The origins of SFD in BPM are distributions of anisotropy, magnetization, exchange, magnetostatic coupling, dot size, and dot edge effects [2]. In our previous report, it is found that thick grain boundary and poor crystal orientation are the possible origin of the large H_c distribution [3]. In order to investigate the origin of the SFD, we made highly oriented CoPt dot arrays with different diameter and similar size dispersion using diblock copolymer.

II. EXPERIMENTAL METHODS

Highly oriented perpendicular magnetic films were fabricated by sputtering. Film stack was 2.5 in. glass disk/Ti seed layer 20nm/Co₈₀Pt₂₀ 15nm. These films were patterned by an Ar ion milling using self-assembled PS-PMMA diblock copolymer mask. PMMA dots were arranged in PS matrix with 45 nm and 60nm pitch. Each process step was optimized to give similar dot size distribution. Magnetic properties were measured by a vibrating sample magnetometer (VSM).

III. RESULTS AND DISCUSSION

Dot diameter and its dispersion were estimated from SEM images. Fig.1 shows the distribution of the dot diameter of (a) 60nm pitch and (b) 45nm pitch. The average diameter was 38nm and 24nm, respectively. However, one-sigma of the dispersion is similar for both samples (13-14%).

Fig.2 shows hysteresis loop (thick line) and DCD (dc-demagnetization) curve (thin line) for (a) 60nm pitch and (b) 45nm pitch. The hysteresis loop of 45nm-pitch has large amount of small coercivity region although the DCD curve is similar for both samples. This region is expected to correspond to the dots that have reversible magnetic property with relatively large anisotropy energy. Such dots could be damaged by oxidization at its side wall or physical etching process. This damage is emphasized for small dots in the 45nm-pitch sample.

From the hysteresis loops and the DCD curves, about a half of the 45nm-pitch dots changed into the reversible state. The critical diameter at which the accumulated area distribution reaches 50% is about 24 nm for the 45nm-pitch sample. This result indicates that dots whose diameter is less than 24nm are tend to have reversible nature.

In conclusion, it is found that smaller dot has large SFD even though the size dispersion is similar. The origin of the SFD is expected to be the change in the magnetic properties for small dots. The change seems to results in the reversible magnetic property and the critical size is around 24nm. Study on ferro-antiferromagnetic transition in $L1_0$ FePtRh film for bit patterning.

I. INTRODUCTION

Recently, with continually decreasing grain size, the magnetic thermal fluctuation has been one of the main problems for the high density magnetic storage. The $L1_0$ FePt film (fct structure) has a high magnetocrystalline anisotropy ($K_u \sim 7 \times 10^7$ erg/cm³), which is considered to be suitable for a high recording density of more than 1 Tbit/in.² due to its good thermal stability.

Bit patterned media which consist of the ferromagnetic (FM) dots regularly arranged in a non-magnetic matrix have been proposed as a possible solution to overcome the superparamagnetic effect and medium noise of continuous media. For the fabrication of bit patterned media, lithographic patterning, ion irradiation and various chemical methods have been reported so far^{1,2}). In the lithographic patterning and self-organizing method, removing material between the dots or assembling particles leads to variations in the height of the storage medium which cause the tribology problems in the near-contact recording scheme. In the ion irradiation patterning, magnetic properties of continuous films are modified by local ion irradiation and a difference in the height between irradiated and nonirradiated areas was found to be about 2–3 nm. The resolution of patterning using local ion irradiation, however, depends on the distribution of ions in lateral direction and sharpness of FM-paramagnetic (PM) transition of films.

FePtRh bulk alloys are known to show a discontinuous FM-antiferromagnetic (AF) transition³). A new type of bit patterned film which has sharp transitions between dots due to its discontinuous FM-AF transition could be realized by changing the composition locally by using ion irradiation or lithographic techniques. In this work, we report the influences of addition of Rh on the magnetic properties of a FePt film, and discuss the possibility of bit patterning by FM-AF transition.

II. EXPERIMENT

A function of $\text{FePt}_{1-x}\text{Rh}_x\text{-SiO}_2$ (19 vol%) (10 nm) films were prepared by using a sputtering method onto SiO_2 substrates at room temperature. The films were annealed at 973 K for 2 hours by a rapid heating furnace. SiO_2 was added for improving the [001] orientation of FePt film. The composition and the crystalline structure were detected by the energy dispersive X-ray spectroscopy and the X-ray diffraction (XRD), respectively. The alternating gradient magnetometer were used for studying the magnetic properties.

III. RESULTS AND DISCUSSION

Figure 1(a) shows the 2θ - θ scans from the XRD measurements for the $\text{FePt}_{1-x}\text{Rh}_x\text{-SiO}_2$ films annealed at 973 K. The intensity of the superlattice (001) reflection peaks from the $L1_0$ phase are quite larger than that of fundamental (111) peaks in the films with $0 < x < 0.40$. These intensity differences indicate that a [001] crystalline texture normal to the film plane is obtained. The magnetic properties are shown in Fig. 1(b). The films with $0 < x < 0.30$ have the $L1_0$ structure and [001] crystalline texture normal to film plane with large coercivity (H_c) of $3.5 < H_c < 16.8$ kOe. The small magnetization (~ 300 emu/cm³) is caused by the unsaturation due to its large H_c . At around $x=0.30$, an abrupt change from FM phase with high H_c to nonmagnetic phase appeared. This discontinuity seems to be caused by the FM to AF transition. In the case of $\text{FePt}_{1-x}\text{Rh}_x$ bulk alloy, it is known that the FM-AF transition is observed at around $x \sim 0.22$ at room temperature³).

The FM-AF transition needs to occur easily during the bit patterning process, for instance by annealing or ion irradiation. To confirm this point, an experiment in which Rh was added into a FM

FePtRh film to change the properties from FM to AF was carried out. Figure 2(a) and (b) show the magnetization curves of $\text{FePt}_{0.72}\text{Rh}_{0.28}\text{-SiO}_2$ film (10 nm) and $\text{Rh}(0.38\text{ nm})/\text{FePt}_{0.72}\text{Rh}_{0.28}\text{-SiO}_2$ (10 nm) bi-layer film annealed at 973 K, respectively. The film shown in Fig. 2(a) has a large H_c (~ 8 kOe). In contrast, the film in Fig. 2(b) shows nonmagnetic properties. It seems that the $\text{Rh}/\text{FePt}_{0.72}\text{Rh}_{0.28}$ bi-layer structure was mixed and changed to $\text{FePt}_{0.68}\text{Rh}_{0.32}$ within the AF region. These results suggest the possibility of realizing a bit pattern using a material with a critical composition of FM-AF transitions. The discontinuous FM-AF transformation between dots would make its boundary sharper than the FM-PM transformation, so local Rh or Pt addition into the $\text{FePt}_{1-x}\text{Rh}_x\text{-SiO}_2$ film ($x < 0.30$) can realize the bit patterned film consisting of high H_c dots ($x < 0.30$) and AF spacing ($x > 0.30$).

CoCrPt-SiO₂ is a granular material consisting of small magnetically decoupled grains and is commonly used for perpendicular magnetic recording applications. In this study, the system was deposited onto SiO₂ spherical particle arrays with diameters down to 10 nm to form arrays of magnetic nanostructures following an approach by Albrecht et al. [1]. It was shown that the deposition of Co/Pt multilayers on Polystyrene spheres leads to single-domain and exchange isolated caps with a radial symmetric spatial variation of the anisotropy orientation [2]. Combining this approach with the advantages of CoCrPt-SiO₂ is a promising way to realize “patterned media”.

Densely packed arrays of monodisperse SiO₂ particles are formed in a self-assembling process by the method of Micheletto et al. [3]. These particle arrays serve as a topographic pattern for the subsequent depositions carried out in the commercially available RACETRACK hard disk fabrication system. Two layer stacks, Carbon(4 nm)/ CoCrPt-SiO₂(12%)(15 nm)/ Ru(12 nm)/ Ru(8 nm)/ Ta(5 nm) and Carbon(4 nm)/ CoCrPt-SiO₂(12%)(10 nm)/ Ru(5 nm)/ Ta(5 nm) have been deposited onto SiO₂ particle arrays with diameters from 10 nm to 330 nm and for comparison onto planar SiO₂ substrates.

TEM studies reveal that the growth of CoCrPt-SiO₂ on the curved particle surface remains columnar with a substantial reduction of the lateral grain size down to 5 nm (Fig 1). The (0001) orientation of individual grains is pointing perpendicular to the particle surface.

By varying the growth conditions and the thickness of a Ru seed-layer, the degree of intergranular exchange coupling can be controlled, leading to pronounced differences in the magnetic domain structure and its magnetic reversal behavior.

A two-step Ru seed-layer with a thickness of 20 nm leads to magnetically exchange decoupled grains and strong perpendicular anisotropy. The variation of the orientation of the easy axis along the particle surface, as well as an increase in defects is leading to a reduction of the coercivity on particles compared to the coercivity on planar substrates (Fig 2 (a) and (b)). The domain structure remains nearly unaffected by the changes in topography, leading to multidomain magnetic caps (Fig 2 (c)).

Reducing the Ru thickness to 5 nm is leading to a substantial decrease in coercivity and to a narrow switching field distribution on planar SiO₂ substrates. On SiO₂ particles, however, single-domain magnetic caps are observed and the magnetic coercivity field is increasing for smaller particle sizes (Fig 2 (d) – (f)).

<P>Introduction

Fabrication of magnetic nanostructures has been of considerable interest both for fundamental studies of nanomagnetism and various applications such as bit patterned media [1]. Typically, lithographic patterning in a resist layer is subsequently transferred to a magnetic film in the nanofabrication process. However, especially when fabricating nanostructures on a scale of tens of nanometers, the process suffers from pattern distortion and edge roughness caused by etching and/or liftoff that are generally applied to the pattern transfer. In this study, we show a simple route to formation of perpendicular magnetic nanostructures without any etching or solvent by directly exfoliating magnetic thin films sputter-deposited onto molds.</P>

<P>Experiments

We have prepared a Ni nanoimprint mold that has an array of cylindrical dots hexagonally arranged with 100 nm pitch in a macroscopically large circular patterned area of 18 mm in diameter. A thermoplastic polymer resist made of polymethylmethacrylate (PMMA) was spin coated on a Si substrate, and then the Ni mold was pressed onto the PMMA resist to create the pattern in the resist [2]. This nanoimprinted resist layer was utilized as a polymer mold for the following magnetic nanostructure formation.

Perpendicular Co/Pd multilayers were sputter-deposited onto the polymer mold at room temperature with the stacking structure of [Pd 1 nm/Co 0.2 nm]₈/Pd 50 nm. A flat glass substrate was then attached to the back surface of the deposited films using a liquid ultraviolet-curing adhesive agent. After ultraviolet curing, the front surface of the films was mechanically separated from the polymer mold.</P>

<P>Results and discussion

The surface topography and magnetic domain structures of the sample have been investigated by atomic force microscopy (AFM) and magnetic force microscopy (MFM), respectively. The AFM image (left figure) shows the hexagonally arranged nanodots made of Co/Pd multilayers indicating high fidelity of the pattern transfer in this sputter-deposition/exfoliation method. The dimensions of the nanodots are about 60 nm in diameter and 20 nm in height and quite similar to those of the concaves in the polymer mold. The MFM image acquired in the same area in the as-prepared state (right figure) clearly demonstrates that each nanodot is in a single domain state and that its magnetization direction is either up or down. The image also suggests that the nanodots are exchange-isolated because of little magnetization at the boundaries between nanodots and trenches; the deposited Co/Pd multilayer probably has much thinner Co layers (below 1 ML) at the boundaries, which would greatly reduce their magnetization. Perpendicular coercivity measured by polar magneto-optical Kerr effect was 1.0 kOe in the patterned area of the sample, while that in the unpatterned area (flat film) is 0.6 kOe. The increase in the coercivity is also consistent with the nanodot formation in the perpendicular magnetic thin films [3].</P>

Design of Ni-Mold for Discrete Track Media.

K. Ichikawa¹, T. Usa², K. Nishimaki², K. Usuki¹

1. Recording Media Research Laboratories, FUJIFILM Corp., Odawara Kanagawa, Japan; 2. Production Engineering & Development Center, FUJIFILM Corp., Odawara Kanagawa, Japan

Discrete track media (DTM) [1-3] has been promised as the media for the next generation HDD. For DTM production, Nano Imprint Lithography (NIL) must be the indispensable technology- and the NIL mold plays the most important role in it. But the nickel (Ni) mold has been hardly reported except the field of optical storage disks such as CDs and DVDs. Therefore, the DTM Ni-mold with narrower track pitch than present HDDs has been studied.

We designed and made two Ni molds with different patterns. One contains land-and-groove pattern for discrete track and servo pattern with 150nm track pitch (169kTPI) on 65mm whole area. This track density corresponds to the area density 100-150Gbps which is equivalent to that of the available HDD products. The other was designed for 300-450Gbps [2] and was fabricated discrete track and servo patterns with 90nm track pitch (282kTPI) in 200 to 500 μ m band at three radius positions ($r=15$ mm, 21mm, 29mm). The ratio of land to groove is set as 1 to 2, and the height of pattern is 60nm.

The dimension of the pattern on Ni-mold should be designed with taking the change of line width in NIL process and magnetic property of finished DTM into consideration. [4] In particular, the fluidity of imprint polymer used in NIL process and the etching behavior may expand the line width of grooves. Therefore the land width of Ni-mold should be designed more narrowly.

Ni-mold was fabricated with the following process. 1) The EB resist was coated on Silicon wafer. 2) The designed patterns were drawn on the resist by electron-beam recorder with an R-theta stage. [5] 3) Silicon was patterned using reactive ion etching method. 4) Nickel was deposited on Silicon master by electroplating. 5) The Ni-mold was taken off.

Fig.1 shows SEM image of discrete track and servo area. The sample was tilted to show mold surface and the height. The defects were not found in observed surfaces. The unevenness of discrete patterns were replicated by electroplating.

Table.1 shows the result of measured line width and line width roughness (LWR). The line width and LWR of the trench pattern on etched Si were measured by Critical Dimension SEM. The measured position is full width at half maximum on Ni-mold. The line width is 30nm at 282kTPI, and is 44nm at 169kTPI. LWRs were a range from 6 to 7nm, and did not have the significant difference in each track pitch. It can be important to reduce LWR since the ratio of LWR to line width is increasing for a smaller pattern below 30nm line width. The difference of line width between each radius was within 10%.

Fig.2 shows AFM cross section at Ni-mold with 282kTPI. The pattern height is 60nm with standard deviation of 0.8nm. There is little height change.

We proved the feasibility to fabricate Ni-mold with the uniform line width and pattern height at 282kTPI.

Integrated on-chip microstrip lines with Co-Ta-Zr magnetic films.

P. Khalili Amiri¹, B. Rejaei¹, Y. Zhuang¹, M. Vroubel¹, D. Lee², S. Wang², J. Burghartz^{3,1}
 1. Delft Institute of Microsystems and Nanoelectronics (DIMES), Delft University of Technology, Delft, Netherlands; 2. Department of Materials Science and Engineering, Stanford University, Stanford, CA; 3. Institute for Microelectronics Stuttgart (IMS CHIPS), Stuttgart, Germany

Introduction: Integrated passive devices such as transmission lines and inductors are indispensable components of contemporary radio frequency (RF) integrated circuits (IC's), being used for impedance matching, filtering, and RF signal transfer. These on-chip passives, however, typically suffer from high loss (low quality factor Q) and small inductance per unit area. In order to address those issues, monolithic integration of IC-compatible metallic magnetic films (e.g. Ni-Fe) has been increasingly studied in recent years [1-6]. Nevertheless, the high loss brought about by parasitic currents in the metallic magnetic films and the limited frequency range of operation due to ferromagnetic resonance (FMR) have thus far impeded the integration of magnetic RF devices in a practical setting. For example, while the use of thick magnetic films can bring about a significant increase in inductance, measurements for microstrip lines with Ni-Fe cores show that an increase of magnetic film thickness from 200nm to 500nm reduces the Q factor by a factor of ~2 due to enhanced eddy current loss, essentially rendering thicker Ni-Fe films useless [5, 6]. Moreover, for typical Ni-Fe layers, FMR limits the useful operation frequency to below 2GHz. Improved materials with higher resistivity (i.e. larger skin depth, thus enabling the use of thicker films) and increased FMR frequency (i.e. large anisotropy and saturation magnetization) are thus highly called for in order to better realize the potential benefits of integrated magnetic RF components. This work presents results on microstrip devices based on such a candidate material.

Experimental results: We deposited by RF diode sputtering a set of amorphous Co-Ta-Zr films with a resistivity of $\sim 100\mu\Omega\text{-cm}$ (~ 6 times higher than Ni-Fe), and an internal anisotropy field of $\sim 18\text{Oe}$ (induced by an external field during deposition) [4, 7]. The films were patterned into $100\mu\text{m}$ -wide, 1mm -long stripes and incorporated into microstrip transmission line structures on a silicon wafer (fig. 1). When compared to non-magnetic control devices, microstrip lines with $50\mu\text{m}$ -wide aluminum signal lines and $1\mu\text{m}$ -thick Co-Ta-Zr magnetic cores showed an increase in inductance by a factor of ~ 11 which remained constant up to $\sim 4.5\text{GHz}$. The Q factor was increased by a factor of ~ 6 at 0.7GHz and remained higher than that of the control lines up to $\sim 3\text{GHz}$ (fig. 2). Propagation wavelength at 5GHz was shortened by a factor of ~ 4 , leading to significant size reduction on the chip (e.g. when used in distributed elements such as quarter-wavelength transformers). The effect of shape-induced demagnetization fields in increasing the frequency range of operation was also studied. The fairly high resonance frequencies in our Co-Ta-Zr devices are attributed to a combination of internal and shape anisotropies, and can be further increased by moving the signal line towards the edges of the $100\mu\text{m}$ -wide magnetic stripe. In this way, one can take advantage of the nonuniform shape anisotropy profile (which is larger near the edges [8]), increasing the maximum frequency for inductance enhancement from 6 to beyond 7GHz . In conclusion, device characteristics of the Co-Ta-Zr lines are dramatically improved with respect to both non-magnetic control devices and previous results with Ni-Fe films [6]. The high resistivity of Co-Ta-Zr allows for the incorporation of a relatively thick ($1\mu\text{m}$) magnetic film without inducing excessive conductive loss. This results in an order-of-magnitude increase in inductance, while simultaneously maintaining a reasonable enhancement of Q factor and improving the high-frequency behavior of the line by realizing a fairly large ($\sim 150\text{Oe}$) shape-induced anisotropy field.

Optimal Design of Microwave Absorbers Using Ferrite-epoxy and Iron-epoxy Composites.

R. Yang¹, S. Hsu¹, C. Lin², C. Tsay²

1. Aerospace and Systems Engineering, Feng Chia University, Taichung, Taiwan; 2. Materials Science and Engineering, Feng Chia University, Taichung, Taiwan

There has been a growing and widespread interest in radar-absorbing material (RAM) technology, e.g., radar-cross section reduction (stealth technology), electromagnetic interference reduction (EMI) and human health protection. These RAMs absorb microwave energy due to various interactive loss processes of magnetization and polarization in the materials. Polycrystalline ferrite is a class of material with appropriate complex permittivity and permeability which can be used for electromagnetic interference suppression and RAM coatings from centimeter to sub-millimeter spectrum. Iron powder is proved to be a suitable absorber and can be mixed with polymer to become an iron-epoxy composite. In this paper, the complex permittivity ($\epsilon' - j\epsilon''$) and permeability ($\mu' - j\mu''$) as well as microwave absorbing properties of ferrite-epoxy and iron-epoxy composites were studied in the gigahertz range. Different absorbing powders (NiZn-ferrite, MnZn-ferrite, iron particles) are added to epoxy resin to manufacture the composites for the microwave absorbers. The X-ray diffraction (XRD) patterns of iron particle and NiZn-ferrite are shown in Fig. 1. The presence of peaks of iron particle confirms the formation of body-centric cubic (BCC) while the NiZn ferrites are spinel cubic structures. Epoxy resins are used as a matrix material (binder). The mixing ratio is varied from 50% to 80% in weight. For the investigation of the electromagnetic wave absorption properties, we prepared samples with toroidal shapes with an inner diameter of 3.04 mm and an outer diameter of 7.00 mm. The mixture was molded in a coaxial die with the same dimensions. The composite specimens were cured at room temperature for about 12 hrs before testing. The complex permeability and permittivity were measured and determined by using Agilent N5230A network analyzer (10MHz~20GHz) with Agilent 85071E material measurement software. The frequency dependence of ϵ' , ϵ'' , μ' and μ'' for iron-epoxy with are shown in Fig.2 and Fig.3. Figure 4 shows the reflection loss in the X-band of microwave frequency as a function of frequency, composition and thickness of the composites adhered on the conducting plates. To obtain a broader frequency region of absorption, a genetic algorithm is adopted for the optimal design of wideband and multilayered radar absorbing coatings by using our own material database (not fictitious or adopted from other references). The synthesis of wideband absorbing coatings appears to reduce more than 20 dB in the frequency ranges of 8.0-12.0 GHz and the total thickness is less than 3 mm as shown in Fig. 5. The composition sequence of the multi-layered composite coating is Fe50%, MnZn, Fe80% and Fe60% with different thickness.

Strong Magnetoelectric Coupling at Microwave Frequencies in Metallic Magnetic Film / PZT Composites.

C. I. Pettiford, J. Lou, L. Russell, N. X. Sun
Northeastern University, Boston, MA

Magnetoelectric (ME) materials are the group of materials that are both ferro/ferrimagnetic and ferroelectric. Strong ME coupling has been successfully achieved in epoxy bonded bulk ME composite materials through a stress mediated ME coupling. These bulk ME composite materials and devices with strong ME coupling provide novel functionalities that are not able to be achieved by either magnetic materials or ferroelectric materials. Most recently a series of such electrostatically tunable microwave magnetic devices based upon glue bonded bulk ferrite/ferroelectric laminates [1-3]. These microwave ME devices provide great promise for electrostatically tunable microwave magnetic devices, which are much more energy efficient, compact, and light. However, all these demonstrated microwave ME devices use high quality yttrium iron garnet (YIG) single crystal as the magnetic phase in the ME composite materials and devices [1-3], which has a very low magnetostriction constant of 0.2ppm, which is not ideal for microwave ME devices. Plus the high cost and high process temperatures ($>700^{\circ}\text{C}$) for YIG single crystals put severe limit on the YIG based microwave ME devices. An alternative is metallic magnetic films. In order to achieve strong ME coupling at microwave frequencies, these magnetic films need to have a large saturation magnetostriction constant and a high permeability, i.e. a low saturation magnetic field and high saturation magnetization, and a narrow FMR linewidth. Metallic magnetic films with excellent magnetic softness and low ferromagnetic resonance linewidth, however, typically have very low magnetostriction constants. We have developed FeCoN [6], FeCoB [7] and FeGaB [8] films for microwave ME devices with saturation magnetostriction $>40\text{ppm}$. Most recently, we developed the FeGaB films, and achieved FeGaB films with narrow ferromagnetic resonance linewidth of 15 Oe at X-band (10 GHz), a low saturation field of ~ 20 Oe, and a large saturation magnetostriction constant of 70 ppm [7]. These FeCoB and FeGaB films with the combination of excellent soft magnetic properties and large saturation magnetostriction constant provide great opportunities for applications in novel microwave ME composite materials with metallic magnetic films. Magnetoelectric coupling at microwave frequencies was studied in metal magnetic film/ Pb(Zr,Ti)O₃ magnetoelectric composites. Both FeCoB/PZT and FeGaB/PZT multiferroic composite materials were studied (Fig. 1-2). Strong magnetoelectric coupling was observed in a FeGaB film / Pb(Zr,Ti)O₃ multiferroic composite material, in which the FeGaB film has a narrow ferromagnetic resonance linewidth of 20 Oe at 10 GHz and a saturation magnetostriction constant of 50 ppm. Large electrostatically induced ferromagnetic resonance frequency shift of 110 MHz at ~ 2.3 GHz was observed (Fig. 2). This large ferromagnetic resonance frequency shift provides great opportunities for integrated microwave magnetoelectric devices.

Nonlinear electrical tuning of ferromagnetic resonance in YIG film - PZT layered structures.

Y. Fetisov¹, G. Srinivasan²

1. Moscow State Institute of Radio Engineering, Electronics and Automation, Moscow, Russian Federation; 2. Physics Department, Oakland University, Rochester, MI

The ferromagnetic resonance (FMR) frequency f of a planar structure consisting of mechanically coupled ferrite and piezoelectric layers may be tuned by applying an electrical field E to the piezoelectric [1]. The field E creates a strain in the piezoelectric that is transmitted to the ferrite and resulting in a change in the internal magnetic field H in the ferrite and a shift in the FMR frequency. Past studies on a bilayer of yttrium iron garnet (YIG) film - lead-zirconium titanate (PZT) reveal a 25 MHz shift in FMR for E up to 8 kV/cm and a near-linear dependence shift on E [2].

Here we report results of investigations on nonlinear electric field tuning of FMR at high electrical fields E .

Figure 1 shows the bilayer structure used. An YIG film of dimensions $0.015 \times 1 \times 2.2 \text{ mm}^3$ grown on a gallium gadolinium garnet (GGG) substrate was bonded to a PZT plate of dimensions $0.5 \times 4 \times 4 \text{ mm}^3$ that was initially poled in an electric field. The bilayer was placed on a microstrip transducer of $50 \mu\text{m}$ width on an alumina ground plane. A bias magnetic field of $H=1.15 \text{ kOe}$ was applied parallel to the bilayer plane. The reflection coefficient S_{11} was measured in the frequency band of 3-8 GHz for voltages U up to 1000 V applied across the PZT plate.

Figure 2 shows FMR absorption profiles for $U=0 \text{ V}$ and 400 V . Figure 3 shows the dependence of the FMR frequency shift Δf vs U . For $U < 400 \text{ V}$, Δf is a near-linear function of U . The sign of the shift is reversed with the reversal of polarity of U . For $U \approx 550 \text{ V}$ ($E \approx 11 \text{ kV/cm}$), a discontinuous jump and a reversal in the sign of Δf are observed in Fig.3, resulting in a butterfly-like dependence. The data in Fig.3 qualitatively tracks electrostriction vs U for PZT, which was measured using a strain gage. The discontinuous changes in the frequency shift in Fig.3 are due to re-polarization of the PZT plate.

The research at Moscow was supported by a grant from Ministry of Education and Science of Russia. The work at Oakland University was supported by grants from ONR and ARO.

Generation of chaotic spin waves in magnetic film active feedback rings through four-wave parametric processes.

A. Kondrashov¹, A. Ustinov¹, T. Stemler², B. Kalinikos^{1,3}, M. Wu³, H. Benner²

1. *Physical Electronics and Technology, St.Petersburg Electrotechnical University, St.Petersburg, Russian Federation*; 2. *Institute for Solid State Physics, Darmstadt University of Technology, Darmstadt, Germany*; 3. *Department of Physics, Colorado State University, Fort Collins, CO*

Magnetic film active feedback ring systems (MFAFR) have proved to be useful in studies of non-linear wave dynamics. For the previous work in MFAFR systems, there are two focus areas: (1) stationary spin wave (SW) soliton excitations and (2) chaotic SW dynamics. The processes responsible for these phenomena may involve only four-wave parametric interactions or both four-wave and three-wave interactions. For (1), the work was done at relatively high frequencies where the three-wave processes were prohibited and one observed the generation of SW solitons and soliton fractals through four-wave processes [1,2]. For (2), the work was done at relatively low frequencies where both three- and four-wave processes were allowed and interacted to produce chaotic SW signals [3,4].

This work reports for the first time the self-generation of chaotic spin waves in a MFAFR system that allows only the four-wave processes. The experiments have been performed for both magnetostatic surface wave (MSSW) and magnetostatic backward volume wave (MSBVW) configurations. With increasing the ring gain, one observed in turn the self-generation of a continuous SW, the breakup of the continuous wave into a breathing wave, the breathing of the breathing wave, and the development of chaotic SWs. In the frequency domain, one observed the development of the power-frequency spectrum from a single mode to a comb-like spectrum, a multiple frequency comb, and a broadband chaotic spectrum. The measured chaotic signals show typical signatures of deterministic chaos.

Consider in more detail the studies performed with MSSW. The MFAFR system consists of a 6.8 micrometer-thick yttrium iron garnet film strip with input and output microstrip transducers, a microwave amplifier, and an adjustable attenuator for gain control. Detailed information on the experimental setup is given in Ref. [4]. A static magnetic field of 1200 Oe was applied in the film plane and perpendicular to the main axis of the film strip.

Figure 1 shows representative power-frequency spectra that demonstrate the development of chaotic SWs with ring gain. In order to prove the deterministic origin of the observed chaotic signals, we recorded also the time-domain data. The time series analyzed below were taken for ring gains close to the critical value of ≈ 15 dB. A quantitative measure of the strength of deterministic chaos is obtained by evaluating the largest Lyapunov exponent, which describes the rate of divergence of neighboring trajectories in phase space. The evaluation was done with the standard analysis program TISEAN [5]. As a first test to distinguish between a stochastic process and a deterministic process, one applied the method of surrogate data [6]. The test clearly proved the deterministic origin of the observed dynamic behavior. The respective Lyapunov exponents were obtained from the experimental time series with time steps ≈ 6.5 ns by means of delay embedding. This method allows the reconstruction of the strange attractor from the time series of a single variable accessible in the experiment. The delay coordinates, ... are considered to be independent components of an n -dimensional substitute phase space vector, where n is called the embedding dimension. Using a delay time and an embedding dimension between 7 and 10 we obtained the following values for the largest Lyapunov exponent (in units of $1/\tau$): ≈ 0.0028 , ≈ 0.0039 , and ≈ 0.0032 for ≈ 11 dB, ≈ 15 dB, and ≈ 22 dB, respectively. These values result in a time limit of about 2 microseconds for reasonable pre-

dictions of the system dynamics. Similar experimental and numerical data have been obtained for the MSBVW configuration. A detailed comparative analysis of the MSSW and MSBVW regimes will be presented in the conference paper.

Particle Effect of Electromagnetic Penetration in High Frequency in H Field and B Field application.

K. Fujisaki

1. Technical Development Bureau, Nippon Steel Corporation, Futtsu-city, Japan; 2. Graduate School of Environmental Studies, Tohoku University, Sendai, Japan

Introduction

High frequency magnetic field (H) and high frequency electrical field (E) are used for applying the materials, because chemical phenomena often changes such as higher speed reaction and lower temperature reaction at the two points [1]. At the first point, bulk materials applied and particle materials applied in high frequency electromagnetic field are different in chemical reaction. At secondary point, chemical reaction in H field application only and E field application only is different especially in case of metal particle samples [2]. To make clear the chemical phenomena in electromagnetic field application, electromagnetic numerical calculation is often used. The chemical reaction difference is considered to be derived from the electromagnetic characteristics difference. However, calculation data are possible to explain the chemical reaction difference neither in H field application and E field application nor in bulk material applied and particle material applied by means of macro level (meter-size) calculation as well as nano-meter-size level calculation [3, 4]. To solve the problem, electromagnetic field calculation in micro-meter-size level is shown in this paper to make clear the particle effect of electromagnetic penetration in high frequency.

Numerical model of H field and E field application to conductive particle

To make clear the electromagnetic characteristics difference in H field application only and E field application only, the numerical models of H field only and E field only applied to conductive particles are used as shown in Fig.1. In case of H field application, exiting coil is considered to apply the external H field to the particles. 2D-model with conductive and magnetized particles is considered, where the induced eddy current flows in vertical direction of this paper. In case of E field application, 3D-model is considered. In both cases, every particle is insulated electrically each other. Particle diameter and frequency are considered to be that the diameter of the particle is several times larger than electromagnetic penetration depth of conductive particle materials. For comparison, bulk materials with the same electromagnetic material constants as the one of the particles are also calculated instead of the particles. Displacement current and eddy current are considered in the electromagnetic field calculation. Because of small size calculation such as micro-meter-size which is large enough for electromagnetic wave length in high frequency operation, finite element method is used for calculation.

Calculation results

Induced eddy current distribution is shown to evaluate the electromagnetic penetration in Fig.2 and 3 as calculation results. In case of bulk materials, electromagnetic field penetrates in only penetration depth in both bases of H field only and E field only. In case of particles, electromagnetic field penetrates more deeply than the electromagnetic penetration depth in both cases of H field and E field. Induced current is considered to transmit to the near particles via induced magnetic field. The deep penetration of the electromagnetic field is expected to make increase the temperature of the particles which makes the chemical reaction of the particles increase. The penetration depth in case of E field application to the conductive particles is larger than the one of H field application. Therefore, chemical reaction change in particle application in high frequency electromagnetic field is considered to be derived from the deep penetration of electromagnetic field in particle application.

Multiferroic, combined with an intrinsic coupling of magnetization and polarization via magnetoelectric effect, has attracted a great deal of interest for novel applications in modern electronics. Up to date, some of studies on magnetic control of dielectric properties point to a high dielectric tunability related to the external magnetic field. In 2003, Kimura et al., reported an 4% to 10% dielectric tunability for TbMnO₃ under 9 T magnetic field [1]. Hemberger et al., found a near 500% dielectric tunability for CdCr₂S₄ in an external 5T magnetic field in 2005 [2]. Including these two reports, most of research focused on ferroelectric perovskites with magnetic orders and explained by a spontaneous polarization induced by magnetoelectric effect.

In this paper, we demonstrate the magnetic-control dielectric properties of micro-size iron particles dispersed in epoxy. The iron-epoxy composite is used to be a successful microwave absorption material. Comparing with research on ferroelectricity in a perovskite structure, the magnetic particles mixed with dielectric materials appealing attracted properties at microwave applications, provide a completely different aspect to the previous reports. In our study, the fraction of iron particles is fixed at 25 to 75 weight %, which means the 25g iron particles and 75g epoxy resin to make the 100g composite. In fabrication process, the iron particles and epoxy resin were mixed and stirred for 5-10 min and then poured onto a mold for 24 hour at room temperature. The 2 mm x 2 mm cylindrical samples are prepared for dielectric measurement.

A cavity resonator technique is utilized for permittivity measurements in the experiment. It is designed as a 7GHz to 13GHz resonator with a 6.5GHz cut-off frequency. In order to obtain a precise permittivity measurement, Teflon and Duroid/6010 materials are standard samples for calibration and adjustment in resonator cavity before the measurement. The testing sample is then placed into the cavity and the resonant frequency is obtained by the Network Analyzed (Agilent 8510C). The permittivity functions as a frequency is then obtained by the perturbation method. The magnetic biasing effect in permittivity is measured by applied the external magnetic field while the frequency swept shown above.

The sample is also examined by SEM. As can be seen in Fig.1, the iron particle with a 20 micrometer in diameter is formed in the testing composite. The XRD date show that a clear iron signal is seen in the sample. In permittivity measurement, as can be seen in Fig. 2, the Teflon sample provides a permittivity around 2.1 between 7 GHz and 13 GHz. Its permittivity decreases as the frequency increases. The permittivity does not change while the external magnetic field is on. However, we found that the iron-epoxy composites present a dielectric variation ranging from 2 to 5.4 by adding the iron particles in epoxy. The adding iron particles provide a more than 170 % enhancement in permittivity. Of interest are the permittivity is adjustable when the external magnetic biasing field is on. Comparing with Figs.3, 4 and 5, a clear dielectric tunability is observed for the iron particles fraction more than 50% . As it can be seen in Fig. 5, the tunability is up to 30% for iron was 75% in fraction at X-band (~12GHz) frequency. From our measurement, the iron-epoxy composites is tunable after an iron particle adding and also a high tunability is observed at high frequencies. In this paper, we will present the the experimental results and their details

High-frequency Magnetic Properties and Attenuation Characteristics for Barium Ferrite Composites.

Z. Li, G. Lin, Y. Wu, L. Kong

Temasek Laboratories, National University of Singapore, Singapore, Singapore

<p>This is a comprehensive report on high-frequency magnetic properties and attenuation characteristics for barium ferrite composites, based on work on Temasek Laboratories of National University of Singapore in the recent years.

All barium ferrites were prepared using conventional ceramic technology. The composites were prepared by mixing 50 % (by volume) of the barium ferrite particles and epoxy. To achieve low reflectivity and broad bandwidth at microwave frequency of 2-18 GHz, the composites should have large μ' matching with relatively large ϵ' , large imaginary permeability μ''_{\max} to significantly attenuate the incident electromagnetic (EM) wave and the appropriate resonance frequency f_r .

1. Control of resonance frequency f_r :

Ion substitution can significantly modify the magnetocrystalline anisotropy of ferrites. For barium ferrites, Co^{2+} ions lead to a decrease in c-axis anisotropy or a modification of anisotropy from c-axis to c-plane. It is found that, to a good approximation, the resonance frequency f_r is proportional to the out-of-plane anisotropy field H_0 for c-plane anisotropy or to H_a for c-axis anisotropy, as shown in Fig.1. Therefore, f_r can be controlled by the anisotropy field, which is closely associated with the substitution amount of Co ions.

2. Increase in real permeability:

Doping with small amount of oxides is another method for improving the high-frequency magnetic properties. Additives of CaO , CuO , Bi_2O_3 , MnO_2 , RuO_2 , IrO_2 , Nb_2O_5 and V_2O_5 oxides can significantly increase μ' . Fitting to complex permeability shows that the increase is mainly attributed to an enhancement of wall resonance.

The combined doping of IrO_2 and V_2O_5 can greatly increase μ'_0 and μ''_{\max} to 5.4 and 1.7, respectively, as compared to 3.0 and 1.2 for the undoped sample. The predicted frequency band for reflection loss $\text{RL} < -10$ dB covers from 3 to 12 GHz at the thickness of 0.35 cm. This is a potential EM attenuation material with low reflectivity and broad bandwidth at s, c and x microwave bands, as shown in Fig.2.

3. Enhancement of magnetic loss

In general, for natural resonance, μ''_{\max} is related not only to μ'_0 , but also to the effective damping coefficient λ by

$$\mu''_{\max} = (1/2)(\mu'_0 - 1)(1 + 1/\lambda^2)^{1/2}.$$

For $\text{Ba}_3\text{Co}_{2+x}\text{Ti}_x\text{Fe}_{24-2x}\text{O}_{41}$, λ is 1.43 for $x=0$ and decreases to 1.23 and 0.88 for $x=0.5$ and 1.0, respectively. The reduced λ leads to a significant increase in μ''_{\max} from 1.23 to 1.66 and 1.80, although μ'_0 remains almost the same for all composites. Due to the increase in μ''_{\max} , the relative bandwidth W for $\text{RL} < -10$ dB expands from 2.3 to 3.4 for composites with $x=0$ and $x=1.0$. Also, the thickness of composites decreases from 0.30 to 0.22 cm.

4. The effect of particle size and shape

The permeability is closely related to the size and shape of particles. The experiments show that composites with micro-particles have much larger complex permeability than those with nanoparticles. The difference is attributed to multi-domain structures for micro-particles. Besides the rotation permeability from natural resonance, the wall permeability is an additional and significant contribution.

On the other hand, the experiments indicated that, after the doing of V_2O_5 , the shape of particles is modified from cuboid-like to hexagonal-plate-like. Correspondingly, μ'_0 increases from 3.1 to 4.6 and μ''_{\max} increases from 1.2 to 1.7, due to different demagnetizing factors N_d . Based on Maxwell Garnett mixing rule, the permeability of composite is closely associated with N_d .

5. Two types of dispersions

In general, barium ferrite composites with c-axis and c-plane anisotropy exhibit the resonance-like and relaxation-like dispersions, respectively. Most of composites involved in this paper are the relaxation-like dispersion.

However, the composites with resonance-like dispersion have some important characteristics: relatively high f_r and low RL, as shown in Fig.3. For $\text{BaMn}_x\text{Ti}_x\text{Fe}_{12-2x}\text{O}_{19}$ composites, f_r can be controlled from 9 to 15 GHz, depending on the substitution x . The composite with $x=1.8$ shows good attenuation characteristics. The band for $\text{RL} < -15$ dB can cover from 8.6 to 14.3 GHz at thickness of 0.23 cm. The materials are good for use as EM materials in higher microwave bands (x and Ku bands).

Fig.1 Linear relationship between resonance frequency and anisotropy field Fig.2 Complex permeability and (insert) reflection loss for W-type barium ferrite composites undoped (grey) and doped with $\text{IrO}_2 + \text{V}_2\text{O}_5$ (black) Fig.3 (a) Complex permeability and (b) the corresponding RL-f curve for M-type barium ferrite composites with resonance-like dispersion.

High frequency property of polyol-derived FeCo nanoparticles for EWA application.

D. Kodama¹, K. Shinoda², R. J. Joseyphus³, Y. Shimada⁴, K. Tohji¹, B. Jeyadevan¹

1. Graduate School of Environmental Studies, Tohoku University, Sendai, Japan; 2. Institute of Multidisciplinary Research for Advanced Materials, Tohoku University, Sendai, Japan; 3. Department of Physics, National Institute of Technology, Tiruchirappalli, India; 4. Department of Electrical and Communication Engineering, Tohoku University, Sendai, Japan

Recent years, the popularization and use of various communication systems has begun to cause electromagnetic interference (EMI) to the electronic equipments. Though necessary measures are being taken on the side of electronic circuits to control the EMI, the measures on the development of electromagnetic wave absorber (EWA) materials have almost not advanced and new high frequency EWA is strongly required to absorb the interfering EM wave in the wide frequency range. On the other hand, the use of soft magnetic metal and alloy nanoparticles, which are well below the size that generates eddy current, has been proposed but yet to be tested. This paper reports the study undertaken to test the potential of polyol-derived FeCo nanoparticles with the particle size ranging between few hundred to few tens of nanometer as EWA.

The FeCo nanoparticles of various sizes have been synthesized by polyol process using the procedure described elsewhere [1]. The scanning electron microscope (SEM) image of FeCo particles used in the present study is shown in Fig. 1. The particles were cubic shaped and were about 100 nm in size. The magnetic properties of the particles such as saturation magnetization (M_s) and coercivity (H_c) were 209 emu/g and 193 Oe respectively. Though the M_s was lower and comparable to the bulk value of Fe, the H_c was larger.

The samples for high frequency property measurements were prepared as follows: First, the FeCo particles were colloid dispersed in isoparaffin and pasted on a glass substrate. Then, the specimen was heated to 373 K under an external magnetic field of 3 kOe to evaporate the solvent, which was used to assist the redistribution of the particles in the external magnetic field. Finally, an adhesive was introduced to inhibit the movement of the particles during measurements. The thickness of the sample ranged between 50 and 100 microns. The high frequency properties of plate-type FeCo samples were measured in the frequency range of 50MHz-9GHz using a shielded coil permeameter. Additional permeability measurements to obtain absolute values of real permeability were carried out using a ferrite yoke method.

The frequency dependence of real (μ') and imaginary (μ'') parts of permeability for FeCo sample is given in Fig. 2. The permeability begins to show an increase before the frequency reached 1 GHz and exhibits plural number of peaks in the GHz range. Since the variation in physical properties within the sample has been found to be low from the Mossbauer spectroscopic measurements, the appearance of plural resonance peaks are considered due to the exchange resonance mode caused by surface effect or presence of very thin oxide or organometallic layers [2]. However, it should be noted that the absolute value of μ' was low and practically demands a thicker layer.

Recently, appreciable enhancement in permeability has been reported through the formation of ferromagnetic particle composites formed of Fe and permalloy particles. The values obtained were larger than that of the individual components [3]. This has suggested that composites formed of ferromagnetic particles with different physical and magnetic properties could be a solution to develop EWA materials to suit the current demand. Thus, we attempted the preparation of a composite using submicron sized Fe particles and FeCo particles.

The high frequency properties of the composite synthesized by mixing Fe and FeCo particles in a weight ratio of 4:1 and that of Fe particles are also shown in Fig. 3. The composite exhibited a broad

single peak as against the plural peak shown by FeCo alone. Though μ' value dropped to 4.7 compared to 5.5 for pure Fe particle, the resonance peak shifted to 2.0 GHz as against 1.6 GHz for pure Fe. The above result is a consequence of the interaction between soft magnetic Fe and relatively hard (higher H_c) FeCo. Thus, it is speculated that varying the ratios between Fe and FeCo could control the resonance frequency of the composites. The resonance frequencies of composites with different Fe/FeCo ratio will also be reported and discussed.

Noise Suppression Effectiveness of Fe-Si-Al Magnetic Composite Thick Film on the Signal Transmission Cable.

K. Lee¹, D. Kang¹, I. Byun¹, I. Jeong¹, S. Kim²

1. R & D Center, Chang Sung Corporation, Incheon, South Korea; 2. Nano-Materials Research Center, Korea Institute of Science and Technology, KIST, Seoul, South Korea

Recently, in accordance with rapid progress of digital electronic equipment transmit high speed image data, the electro-magnetic interference (EMI) become a serious problem. Most of radiated emission noise is due to the common mode noise current in the data cables connected to digital equipment. To provide an effective solution for the problems, Mn-Zn or Ni-Zn soft ferrite bead cores are conventionally used as the common-mode noise filters.[1] As the ferrite core round data cable, magnetic wave caused by common-mode noise current in the MHz – GHz frequency range are absorbed by the bead core. However, permeability values of the ferrite materials are too small to fabricate a small bead core in quasi-microwave frequencies of gigahertz beyond Snoek's limit[2]. Several amorphous materials were proposed as a new material for EMI noise filter which is much smaller than ferrite core in the MHz - GHz.[3] This paper reports the higher permeability flexible thick film which is composite of Fe-Si-Al alloy flake and rubber to the noise filter.

The $\text{Fe}_{85}\text{Si}_{9.5}\text{Al}_{5.5}$ flake was fabricated by mechanical forging of spherical powders using an attrition mill. A soft magnetic paste made of Fe-Si-Al flakes and polymer solution was prepared. Magnetic composite thick film was fabricated by doctor-blade coating of the paste.

Fig.1 shows the noise current measurement system.[1] The current transmission characteristics of data cables were measured from 1 MHz to 1 GHz with network analyzer. We used 100cm twisted pair cables with a characteristic impedance of 100Ω. One end of the cable was connected to port 1 of a network analyzer via an impedance matching circuit and the other end was terminated with a resistance of 100Ω. A part of cable was wrapped with the magnetic composite thick film. The total volume of thick film was 0.187cc. A commercially available ferrite core (inner diameter 9.7mm, outer diameter 18.2mm, length 27 mm, volume 5.03cc) was also used for comparison. Common-mode noise current, which is equivalent to the transmitted power, S_{21} , was detected with a micro loop antenna.

From SEM observation of Fe-Si-Al flakes and cross-sectional view of magnetic composite thick film, it was found that the thickness and aspect ratio of the flaky particles are ranged 1-3μm and 15-25, respectively and thin flakes are well aligned parallel to the film plane. The magnetic property of the flake was measured with VSM. The M_s and H_c of the flake were 110 emu/g and 16.2Oe, respectively.

Fig. 2 shows the frequency dependence of permeability for magnetic composite thick film. As shown in Fig. 2, real part of permeability (μ_r') decreases with frequency above 30MHz and a high imaginary part of permeability ($\mu_r'' \approx 8$) is observed in range of 70MHz - 3GHz. The observed broad magnetic loss spectrum (70MHz - 3GHz) beyond Snoek's limit is attributed to the high saturation magnetization (110 emu/g) and low eddy current loss of the $\text{Fe}_{85}\text{Si}_{9.5}\text{Al}_{5.5}$ flake particles in magnetic composite film.

Fig. 3 shows the frequency dependence of S_{21} for the 100cm long cables on which the magnetic composite film and ferrite bead were wrapped, respectively. Because of the cable operates as an antenna for common mode noise current, the current power of S_{21} can be considered to radiation noise emission level. The radiated emission level increase in higher frequency range than 200MHz. Also, as shown Fig.3, it should be noticed that the emission noise level decrease average -4dB and -8dB in almost frequency of same range by attachment ferrite bead and magnetic composite thick

film, respectively. These results show that the Fe-Si-Al composite thick film can be a good material as the common mode noise filter on high speed data transmission cable.

Microwave absorption properties in Bi-substitute Yttrium Iron Garnet.

D. Hung¹, Y. Fu², Y. Yao³

1. Information & Telecommunications Engineering, Ming Chuang University, Taipei, Taiwan; 2. Department of Materials Science and Engineering, National Dong Hwa University, Hualien, Taiwan; 3. Department of Materials Engineering, Tatung University, Taipei, Taiwan

Introduction:

Yttrium iron garnet (YIG) materials possessing a high Q value over a broad-band frequency range make it to be widely used for various microwave components including magnetic filters, tunable oscillators, phase shifters etc., for years. However, from the past experience, YIG garnet is hardly used in multilayer communication chip, due to the sintering temperature is up to 1400oC that is higher than the melting temperature of most conductive metals. Bi-substituted YIG garnet has been known as the relevant ceramic materials that the sintering temperature is much lower than of pure YIG polycrystalline ceramics. In this study, Bi-substitute YIG was fabricated by sol-gel method. The experimental results show that the Bi-YIG sample allows a sintering temperature down to 900oC without change its garnet phase. Its microwave properties were examined by the FMR signal ranging from 45MHz to 20GHz. Of interest are that the FMR frequency is consistent to the different Bismuth contents in samples but its FMR absorption properties are modulated by substitution.

Sample preparation:

YIG:Bi having a stoichiometric composition of $\text{Bi}_x\text{Y}_{3-x}\text{Fe}_5\text{O}_{12}$, where $x=0.25, 0.5, 0.75, 1.00$ were prepared by the sol-gel method. In order to obtain a uniform and successful substitution of Bismuth to Yttrium in YIG structure, a coprecipitation method was proceed by mixing the raw solution. The nearly atom-level mixing provides a uniform and high-quality power that was calcined in the air at 700oC for 2 hours and then milled again for 1 hours. The resulting power was pressed as a disk with 3000N/m² and sintered in the air from 900-1200oC, respectively. All the samples have had at least 85% of theoretical density. Figure 1 shows the XRD patterns of successful samples for various Bismuth contents. From the XRD patterns, Bi-substituted YIG samples form a garnet phase at 900oC except the sample with $x=1$ substitute.

FMR absorption:

In this study, the YIG garnet substituted by the bismuth is concentrated on their FMR responses. Four different Bi-substitute samples ($x=0.25, 0.50, 0.75$ and 1.00) are fabricated by the sol-gel method and mold to 3mm x 4mm cylindrical shape. The samples are sintering to 900~1200 oC that is illustrated in section 2. A transmission line is designed for picking up the FMR signals in this experiment. The cylindrical samples are measured by the transmission line through the Network Analyzer (frequency from 45MHz to 20GHz). The magnetic field is applied along the microwave propagation. The FMR signals are observed by every 50Oe for a range from 50Oe to 3800Oe. Results demonstrate a series of FMR signals that are picking up from the $\text{Bi}_x\text{Y}_{3-x}\text{Fe}_5\text{O}_{12}$ samples with $x=0.25, 0.5, 0.75$ and 1.0 substitution. In the experiment, the FMR signal is found when the external magnetic field is around 200Oe for all four different bismuth contents. Increasing the magnetic field, the signal is shifted smoothly from 2.5GHz to 18GHz. Of interest is that the results demonstrates the similar FMR frequencies no matter of the difference in bismuth substitution, even the bismuth substitution for yttrium is up to 1.00. It can be concluded that the YIG garnet does not change the spin-precession behavior that responses to the ferromagnetic resonance by the Bismuth substitution. But in results, the 3db absorption bandwidth are various to the four different samples.

Preparation and characterization of nano-fiber nonwoven textile for electromagnetic wave shielding.

M. Sonehara^{1,2}, T. Sato², M. Takasaki¹, H. Konishi³, K. Yamasawa², Y. Miura²

1. Satellite Venture Business Laboratory, Shinshu University, Ueda, Japan; 2. Spin Device Technology Center, Shinshu University, Nagano, Japan; 3. Faculty of Textile Science and Technology, Shinshu University, Ueda, Japan

Introduction

The electromagnetic interference (EMI) has become extremely serious in various electronic equipments such as personal computers (a few GHz), cellular phones (0.8-2 GHz), electronic toll collection system (5.8 GHz), and others. Especially, the EMI at the medical equipment such as heart pacemakers is a hazardous problem because of the patient may have a risk of suffering severe damage when neglecting the EMI measures.

The authors developed a magnetic film for a noise filter in the electronic circuit [1]. In this study, a nanofiber nonwoven textile with an average diameter of about 600 nm spun by an electrospinning for electromagnetic wave shielding has been developed. Ni-Fe magnetic material was coated by sputtering unit on the textile surface for reflecting and absorbing electromagnetic wave. Because the functional textile is light, flexible and breathable, it will be versatile for the various electromagnetic wave shielding.

Fabrication

The raw material solution was made by stirring the mixture containing 12 wt.% of polyacrylonitrile (PAN) powder (Aldrich, mean molecular weight: 150,000) and 88 wt.% of N,N-Dimethylformamide (DMF) (Wako pure chemical industries) at 70 °C for 6 hours. The nanofiber nonwoven textile was prepared by an electrospinning system. A high voltage of 12 kV was applied to the nozzle which is separated at a distance of 100 mm from the grounded collector.

Metallic magnetic material, Ni-Fe, was coated on the nanofiber nonwoven textile with r.f. magnetron sputtering machine. Ni₈₃Fe₁₇ (at.%) was used for the metallic magnetic material at an Ar pressure of 0.5 Pa, and r.f. power of 100 W.

Measurement

EMI shielding effect defined as SE in the nanofiber shielding textile was measured using a vector network analyzer, a scattering parameters test set and waveguide components. When measuring, the nanofiber shielding textile was sandwiched between waveguide components.

SE was calculated with the following equations [2].

$$SE = (P_{\text{ref}} + P_{\text{loss}}) / P_{\text{in}} = 1 - 10^{(S_{21} [\text{dB}] / 10)} \quad (1)$$

$$P_{\text{ref}} / P_{\text{in}} = 10^{(S_{11} [\text{dB}] / 10)} \quad (2)$$

$$P_{\text{loss}} / P_{\text{in}} = 1 - (10^{(S_{11} [\text{dB}] / 10)} + 10^{(S_{21} [\text{dB}] / 10)}) \quad (3)$$

where P_{ref} is the reflective power, P_{loss} is the loss power, P_{in} is the input power, S_{11} is the input reflection coefficient and S_{21} is the forward transmission coefficient. Both S_{11} and S_{21} for the nanofiber shielding textile were obtained by the vector network analyzer and the scattering parameters test set.

Result and discussion

Figure 1 shows the frequency dependence of $P_{\text{ref}} / P_{\text{in}}$, $P_{\text{loss}} / P_{\text{in}}$, $P_{\text{thru}} / P_{\text{in}}$ where $P_{\text{thru}} / P_{\text{in}}$ means $1 - (P_{\text{ref}} + P_{\text{loss}}) / P_{\text{in}}$ in the nanofiber nonwoven textile (a) and the nanofiber shielding textile with Ni-Fe coating with sputtering time t_s of 15 min (b). In Fig. 1 (a), SE of the nanofiber nonwoven textile was about 10 % in measured frequency band. On the other hand, in Fig. 1 (b), SE of the nanofiber nonwoven textile with Ni-Fe coating was about 90 % in measured frequency band.

Figure 2 shows the relation between $P_{\text{ref}} / P_{\text{in}}$, $P_{\text{loss}} / P_{\text{in}}$, $P_{\text{thru}} / P_{\text{in}}$ and Ni-Fe sputtering time t_s at 5.8 GHz. In Fig. 2, when increasing the Ni-Fe sputtering time t_s , both $P_{\text{ref}} / P_{\text{in}}$ and $P_{\text{loss}} / P_{\text{in}}$ increased. The nanofiber shielding textile with Ni-Fe coating showed sufficient reflection and absorbance of the electromagnetic wave.

Along the last two decades we have witnessed considerable achievements related to the design of magnetic nanostructures, aiming both basic research and technological applications. Nanoparticles with super-paramagnetic properties have great potential to achieve such desirable properties. Various methods have been developed to synthesize iron oxide particles in nanometer size range [1-2]. These genuine improvements of fabrication techniques have not always been accompanied by a detailed comprehension of the relationships between structure, composition and magnetic properties in fine particle systems, even those composed of 'simple' materials as magnetite and maghemite whose bulk properties are well understood. Magnetite Fe_3O_4 is a ferrimagnet ($T_N=860$ K) with a cubic inverse spinel structure, that is, one third of the ions as Fe(III) , occupies all the available A sites, one-third also as Fe(III) , occupies half of the B sites, and one-third as Fe(II) occupies the other B sites. Maghemite $\gamma\text{-Fe}_2\text{O}_3$ has a nonstoichiometric spinel structure. There has been considerable controversy over whether Fe(III) occupies all the available tetrahedral sites with the vacancies being confined to the octahedral sites. For synthesis of magnetite initial molar ratios ranging from $\text{Fe}^{3+}:\text{Fe}^{2+}=1:1$ to $1.7:1$ have been used by various researchers [3-5]. Frequently, the particles thus obtained have not been completely characterized with respect to the phase(s) present assuming that the only phase present is magnetite. Magnetite and Maghemite are isostructural, with nearly the same lattice parameter, then X-ray diffraction (XRD) cannot differentiate between them, especially in the nanophase. Although Mössbauer spectroscopy in bulk material can clearly identify the two oxides, owing to the presence of divalent iron in magnetite, in the case of nanophase state, the spectrum displays broadened and asymmetric lines due to the surface contribution making their identification difficult. Then additional techniques are necessary in order to characterize the oxide nanoparticles.

Here, we report on the preparation and characterization of iron magnetic nanoparticles, where besides XRD and Mössbauer spectroscopy, Thermogravimetric (TG) measurements performed in the presence of a magnetic field (Termomagnetogravimetry, TMG) are used to identify the phases.

We have prepared iron oxide particles using various molar ratio of $\text{Fe}^{3+}:\text{Fe}^{2+}$ 2:1. The solution was stirred for 15 minutes with nitrogen bubbling. The above mixture was poured in aqueous ammonium solution (50 % v) and the solution was stirred for 2 hours and dried in a vacuum oven during about 12 hours. The main purpose of using molar ratios smaller than 2:1 is to compensate for the oxidation of Fe^{2+} to Fe^{3+} during the preparation to obtain the magnetite phase.

Their XRD patterns (not shown) are typical of an inverse spinel structure, meaning the formation of either magnetite or maghemite. Their ME spectrum (see Fig.1) presents the main characteristics of $\gamma\text{-Fe}_2\text{O}_3$: a symmetric spectrum with a mean isomer shift value of 0.33 mm/s, corresponding to Fe^{3+} . However the TMG measurement of this sample (see Fig.2) displays a main feature at 273 C which was observed in commercial magnetite but not in maghemite. From these results a reinterpretation of the Mössbauer spectrum was attempted. A hyperfine field distribution was simulated using a discrete set of 5 Voigtian contributions, one of them constrained to bear the 0.67 mm/s isomer shift value of the 2+ site of magnetite (Fig. not shown). The fit indicated that 13 % of the iron atoms could be in this environment. Assuming that magnetite 3+ Fe makes twice this contribution

(26 %) to the spectrum, a maximum magnetite content of 39% of the nanoparticles phase composition is inferred.

Magnetization reversal study in a permalloy wire with 3 dissimilar trenches by using real-time magnetic force microscopy.

K. Cheng^{1,2}, C. Yu¹, S. Lee¹, Y. Liou¹, Y. Yao³, J. Wu³, J. Huang²

1. Institute of Physics., Academia Sinica., Taipei, Taiwan; 2. Department of Materials Science and Engineering, National Tsing-Hua University, Hsinchu, Taiwan; 3. Department of Materials Engineering, Tatung University, Taipei, Taiwan

During the last few years, patterned magnetic wires have attracted much attention in both fundamental research and applications in storage media because of their bulk and nanostructure properties. In particular, study of the domain structure in submicro ferromagnetic elements using magnetic force microscopy (MFM) has attracted growing interest because of the potential for developing spin electronic devices as well as magnetic storage media. In situ scanning of submicro scale permalloy (Ni80Fe20) wire with an applied magnetic field could provide detailed insight into magnetization reversals[1-3]. In this report, we design trenches of three different depths to study their magnetic structures and the magnetic pinning force[4]. We also provide quantitative MFM analysis of the different trenches.

The permally wires were fabricated by electron-beam lithography and lift-off process. Using dc magnetron sputtering with a base pressure of 5×10^{-7} torr and a working pressure of 1×10^{-3} Torr. Figures 1a and 1b present atomic force microscopy (AFM) photographs of the wires and the AFM profiles of the three trenches. The width of the permalloy wire is $0.4 \mu\text{m}$ and the distance between the two extremities is $8 \mu\text{m}$. The pattern thickness is 30 nm, and the depths of these trenches, from left to right, are 15nm, 10nm, and 5nm. The main goal of this investigation was to measure the magnetic behaviour by real-time magnetic force microscopy (real-time MFM) while applying an extra magnetic field. The magnetic field change range was from +300 Oe to -300 Oe. In the experiment, the positive and negative field were applied in the in-plane longitudinal direction.

The real-time MFM measurement can be used to analyze the phase-shift of the tip oscillation during MFM scanning, which is related to the tip-sample interaction energy[5]. The phase-shift value is proportional to the force gradient of the stray field from the trench. Figure 2a presents a diagram showing the average mean-phase value analysis method for the pattern wire. From Fig. 2a, it can be seen that as the ion-milling depth increased, the magnetic switching field also increased. The switching fields of part A, part B, and part C are 25 Oe, 15 Oe, and 10 Oe, respectively. The mean-phase variation is also proportional to the depth of the trench. Fig. 2a implies that a deeper trench has a larger pinning force. The ability of the pinning force is like the energy of the switching field.

If we can quantitatively determine the pinning force, we might be able to use it in magnetic storage media. Figure 2b shows the depth of permalloy film versus switching field and mean-phase change value. When the permalloy wire has no ion-milling effect, the rate of the Hsw near 0 Oe, is roughly 1.6 Oe per nm of thickness of the trench. The magnetic film thickness appears to influence the domain wall magnetization direction.

In summary, the magnetization reversal behaviour in a permalloy wire with trenches is a typical hysteresis curve. We observed that a deeper trench has a larger switching field. The mean-phase variation is proportional to the depth of the trench. The thicknesses of these trenches are 15nm, 20nm and 25nm, and the switching fields are 25 Oe, 15 Oe and 10 Oe. This means that the deeper trench has the larger switching field, and its rate is roughly 1.6 Oe per nm thickness of the trench. In the same magnetic pattern, we could use the mean-phase value analysis method to determine the local area reversal process and the pinning force.

Diffraction magneto-optical Kerr effects of one-dimensional magnetic gratings.

J. Kim¹, G. Lee¹, Y. Lee¹, J. Rhee², C. Yoon³

1. Quantum Photonic Science Research Center and BK21 Program Division of Advanced Research and Education in Physics, Hanyang University, Seoul, South Korea; 2. BK21 Physics Research Division and Department of Physics, Sungkyunkwan University, Suwon, South Korea; 3. Division of Advanced Materials Science, Hanyang University, Seoul, South Korea

Magnetic photonic crystals (MPCs) are very interesting for the technical applications in information technology which requires the advanced solutions for heavy communication traffic, high-density storage and high-speed computing. By using external magnetic field, for instance, the properties of MPCs can be tuned [1]. The magneto-optical (MO) diffraction technique is a well-established method for the investigation on the micromagnetic properties of periodic structures based on magnetic/nonmagnetic media. There are several reports on the one-dimensional (1-D) array structures prepared by selective-area reactive ion etching or electron-beam lithography followed by ion milling. However, these fabrication methods for 1-D MPCs usually demand a great effort and time, and more simplified fabrication methods are required for the practical purpose. Recently, we have successfully fabricated 1-D MPCs by using a selective-area annealing of as-deposited Co_2MnSi film, and observed a great enhancement of the Faraday-like rotation of the first-order diffracted beam compared to the zeroth-order (undiffracted) one [2]. In this report, the MO properties of the 1-D magnetic-grating structure based on Co_2MnSi film were investigated. The longitudinal Kerr rotation of the first-order diffracted beam is also greatly enhanced, compared to the zeroth-order one.

Amorphous Co_2MnSi films were prepared by rf-magnetron sputtering on a glass substrate at room temperature. The as-deposited films exhibit no magnetic response at room temperature. By using the interference pattern of two femtosecond-laser beams, a selective-area annealing of the as-deposited Co_2MnSi film was achieved, and 1-D magnetic-grating structures were fabricated. The magnetic domain structure has been investigated using a magnetic-force microscopy system, which is basically a scanning-probe microscope (PSIA, XE-100) equipped with a magnetic tip (Nanosensors). The longitudinal Kerr rotation was measured at an incident angle of 45° by using a photoelastic-modulator method. A He-Ne laser light of 632.8-nm wavelength was used as a light source, and a detection system equipped with a photomultiplier tube was employed. For the polarizing optics, two MgF_2 Rochon polarizers were used. The external magnetic field was applied perpendicular to the incident plane using an electromagnet capable of applying a magnetic field up to ± 5 kOe.

Initially, the Co_2MnSi film was deposited onto a glass substrates at room temperature. The transmission-electron microscopy study revealed that the as-deposited film had a nearly amorphous structure and exhibited no magnetic response [2]. After the irradiation of interference pattern, the atomic-force-microscopy results showed regularly-spaced alternating lines with a periodicity of $2\ \mu\text{m}$, and the magnetic-force-microscopy images also revealed the similar periodic patterns of magnetic domains (not shown here). The hysteresis loops of the zeroth- and the first-order diffracted beams have been recorded by measuring the longitudinal Kerr rotation. The Kerr rotation was measured by using both p- and s-polarized incident beams. The magnetic field was applied perpendicular to the groove direction. The measured hysteresis loops imply that the sample is composed of magnetically inhomogeneous phases, which is indicated by a linear growth of the magnetization after a rather steep increase. It was also found that the longitudinal Kerr rotation of the

first-order diffracted beam turns out to be nearly 28 times larger as compared to the zeroth-order one.

Epitaxial ferromagnetic or ferrimagnetic (FIM) thin films on semiconductor have attracted much interests for spintronic devices [1]. The tetragonal Mn₂As, Mn₂Sb, Fe₂As, and Cr₂As materials had antiferromagnetic (AFM) orderings at 573, 550, 325, and 393 K, respectively. Here, we present that MBE-grown Mn₂As and Fe₂As films exhibited a ferrimagnetic orderings above room temperature, strongly supported by the hysteric magnetization, anisotropic magnetoresistance, and anomalous Hall effect data. However, the tetragonal Cr₂Sb thin film, which is newly synthesized, showed AFM ordering. The observed FIMs in Mn₂As and Fe₂As films were attributed to the strains due to the lattice mismatch and the difference in thermal expansion coefficients between the film and substrate, which will be discussed in detail. We have grown 1,000 Å-thick Mn₂As and Fe₂As thin films on Si(001) using a molecular beam epitaxy (MBE). The epitaxial growth was monitored by in-situ reflection high-energy electron diffraction (RHEED). The crystal structure and the growth direction of Mn₂As and Fe₂As thin films were tetragonal structures and (001) direction determined by x-ray diffraction (XRD) measurements. The c-axis lattice constant determined from the position of miller indices were $c=6.211$ (Mn₂As) and 6.168 Å (Fe₂As); this is smaller than that of bulk Mn₂As ($c=6.278$ Å) and larger than that of bulk Fe₂As ($c=5.973$ Å) lattice constant, which means that the strain due to difference of thermal expansion coefficients and lattice mismatch exists, which is consistent with the results of magnetic features for the Mn₂As and Fe₂As films observed by the magnetization measurements.

We have investigated the magnetic properties using SQUID measurements. The magnetic hysteric loops at different temperatures were obtained under the magnetic field parallel to the film surface. Figure 1(a) shows the temperature-dependent magnetization (M) of Mn₂As and Fe₂As film between the 10 and 380 K in the magnetic field of 1,000 G. The magnetization curve shows a long tail and an incline between 200 and 350 K, which is a typical FIM ordering rather than FM one. Figure 1(b) and (c) show the magnetic field dependence of the magnetization of the Mn₂As and Fe₂As films. The magnetizations and coercive fields were (b) 412 and (c) 72 emu/cm³; 803 and 1176 G at 10 K, respectively. The average magnetic moments per Mn and Fe atom determined from the saturated magnetization were 0.51 and 0.10 μ_B at 10 K for Mn₂As and Fe₂As films. In order to investigate the correlation between the magnetization and charge carrier transport, we have performed the magnetoresistance (MR) and Hall effect measurements.

Figure 2 shows the temperature dependence of the zero-field resistivity for Mn₂As and Fe₂As films. The distinct resistivity anomalies could be observed around 230 and 300 K. Moreover, for Fe₂As film has a slope change around 70 K. Figure 3(a) and (b) show the MR versus magnetic field curves of Mn₂As and Fe₂As films at 15 and 250 K. The applied field is perpendicular to the film plane. For Mn₂As film, at low temperatures below 250 K, MR was decreased with magnetic field due to the spin-related scattering. This negative MR was larger for the applied field parallel to the current, so called anisotropic magnetoresistance (AMR) effect [2]. However, for Mn₂As film, below 70 K, a monotonous resistivity increase with magnetic field is observed for all MR curves, which is due to the ordinary MR effect due to bending of the electron trajectories by the Lorentz force. We also observed the clear hysteresis and remanence of Hall resistance were observed below TC, which is consistent with the results of magnetization features observed by the SQUID measurements.

Electron paramagnetic resonance studies of diluted magnetic semiconductors $\text{Si}_{1-x}\text{Mn}_x\text{Te}_{1.5}$ crystals.

Y. Hwang¹, Y. Um¹, J. Choi¹, S. Cho¹, S. Na², J. Kim²

1. Physics, University of Ulsan, Ulsan, South Korea; 2. Physics, Pusan National University, Pusan, South Korea

Recently much effort has been devoted to achieve the ferromagnetism in IV-VI based diluted magnetic semiconductors. In this work, we have investigated the electron paramagnetic resonance (EPR) of the diluted magnetic semiconductors $\text{Si}_{1-x}\text{Mn}_x\text{Te}_{1.5}$ ($0.1 < x < 0.4$) as a function of temperature ($77 < T < 300$ K). The samples exhibited a ferromagnetic ordering about 80 K, strongly supported by the hysteric magnetization and EPR lineshape data. The EPR experiment was performed using a spectrometer (Bruker, EMX-300) operating with X-band microwave frequency. The X-ray photoemission spectroscopy (XPS) spectra of Mn 2p core levels measured from samples were shown in Fig. 1. The main peaks of the Mn 2p_{3/2} and Mn 2p_{1/2} doublet are located at 640.8 and 652.4 eV, respectively. These peak relative intensities were increases with increasing x. Since the Mn 2p_{3/2} core level spectra for elemental Mn is peaked at 639.0 eV, the present result reveals that the Mn atoms are bonded with other elements in our samples. This indicates that a portion of the Mn atoms chemically reacted with the host materials and become Mn²⁺. Fig. 1 XPS spectra of the Mn 2p core levels for the various Mn composition x.

Figure 2 show the EPR spectra for samples (a) at 300 K and (b) at 77 K. For the 300 K, main signal was observed at around 3480 G, those were the paramagnetic resonance signals. In addition, the effective g-factors were measured at the center of the resonance line. The g-factors at 3480 G were 1.98, 1.98, 1.99, and 1.99 for x=0.05, 0.11, 0.20, and 0.31, respectively. However, for the 77 K data, the other signals were observed between the 500 ~ 900 G. This change in line shape starts around 80 K. Since, considering the T_C of these samples have at around 80 K, this signals may corresponds to ferromagnetic resonance, which is consistent with the results of magnetic features of $\text{Si}_{1-x}\text{Mn}_x\text{Te}_{1.5}$ crystals observed by the magnetization measurements. The effective g-factors about 600 G were 4.92, 6.64, and 12.30 with x=0.11, 0.20 and 0.31, respectively. The magnetic structure for $\text{Si}_{1-x}\text{Mn}_x\text{Te}_{1.5}$ crystals shows a ferromagnetic transition at x=0.20 and 0.31 for low temperatures and a paramagnetic state for high temperatures where the g-factor shifts the most. In Fig. 2(b), the EPR lineshape was changed from fig 2(a) for x>0.2. This indicates that the spin-spin interaction is enhanced with the addition of Mn, which is consistent with the above behavior of the magnetic moment[1].

Fig. 2 EPR lineshapes of $\text{Si}_{1-x}\text{Mn}_x\text{Te}_{1.5}$ crystals measured at (a) 300 and (b) 77 K.

Figure 3(a) shows the EPR linewidth of the main signals (H~3480 G) as a function of temperature for x=0.11, 0.20 and 0.31. The linewidth was measured from peak to peak in the first derivative curves of the EPR absorption. The linewidth increased with the decrease of temperature. Webb et al. proposed the EPR linewidth increased with decreasing temperature because of the resonances due to inhomogeneously broadening [2]. Sayad and Bhagat described the unusual temperature dependence of the EPR linewidth in DMS [3] by the following relation; $\Gamma = \Gamma_0 + \Gamma_1 \exp(-T/T_0)$, where Γ_0 is the high-temperature linewidth and Γ_1 & T_0 are the empirical parameters associated with the freezing spins. Figure 3(b) shows the linewidth parameters (Γ_1 , T_0) obtained from the fit to the above relation. The EPR lineshape were broadened symmetrically and the linewidth increase with increasing Mn composition.

Fig. 3 (a) EPR linewidth of the main signals (H~3.48 KG) as a function of temperature for x=0.11, 0.20 and 0.31. (b) The linewidth parameters from the fit to Eq. for $\text{Si}_{1-x}\text{Mn}_x\text{Te}_{1.5}$

Metallographic Investigations of $\text{Co}_2\text{FeAl}_{1-x}\text{Si}_x$ Heusler-Compounds.

C. G. Blum, G. H. Fecher, B. Balke, C. Felser

Institut für Anorganische und Analytische Chemie, Johannes Gutenberg-University, Mainz, Germany

To get a deeper insight in the crystallisation process in $\text{Co}_2\text{FeAl}_{1-x}\text{Si}_x$ Heusler compounds, metallographic investigations were performed. Therefore discs were cut out of polycrystalline bulk samples (ingots), with respect to the cooling gradient applied during the preparation process. Each resulting ingot was cut in discs with cuts parallel to the cooling gradient and perpendicular. These discs were polished by hand in a multi-step process using 1 μm diamond-polishing paste in the final step.

After polishing, the surface of these discs were etched with 2 mol/L FeCl_3 in 10% HCl for 6-8 min, followed by washing with water and Toluene. The etched discs were examined with a light-microscope. The etching process was used to make the crystallite structure within each disc apparent. Different crystallites appear to be coloured after the etching process in different colours as green, red and grey scales. Using X-ray diffraction, it was found that single crystals within the polycrystalline disc show a surface of only one colour, when polished and etched this way. Thus, etching can be used as a first test to find single crystals.

Using this metallographic technique, the $\text{Co}_2\text{FeAl}_{1-x}\text{Si}_x$ Heusler compounds were found to exhibit two different types of crystallites: needle-like ones for $x > 0,8$ (fig1) and block-like ones for $x < 0,5$ (fig2). In the samples with x between 0,5 and 0,8 no crystallite structure was apparent using this technique.

As-melted $\text{Co}_2\text{FeAl}_{1-x}\text{Si}_x$ samples with $x < 0,8$ form immediately needle shaped crystallites, which are almost as long as the complete ingot and between 0,1 and 1 mm thick. They grow parallel to the cooling-gradient.

Figure 1a) shows the crystallites after etching. The disc was cut parallel to the cooling gradient. Figure 1b) shows a PEEM-Picture of a piece of the same ingot which was cut perpendicular to the cooling gradient.

These PEEM-images showed, that the needle shaped crystallites are surrounded by a Co-rich region, which is about 2 μm thick, as shown in Figure 1b). The structure, size and shape of these crystallites was not affected by annealing while small inhomogenities inside the crystallites vanish. In the as-melted $\text{Co}_2\text{FeAl}_{1-x}\text{Si}_x$ Heusler-compounds with $x > 0,5$ only a fine grain-structure was apparent using the etching process. Some of these grains grow while annealing at 1273 K, while some vanish. Figure 2 shows the growth process of the crystallites of a Co_2FeAl sample induced by annealing. No preferred orientation of these block shaped crystallites was observed.

Studies of the $\text{Co}_2\text{FeAl}_{1-x}\text{Si}_x$ Heusler-compounds with $x < 0,5$ lead to comparable results, but the crystallites found here were smaller for increasing Si content.

Background

Conventional gas-compression refrigeration offers low efficiency and the working with a harmful refrigerant such as freon leads to environmental concerns. In contrast, magnetic refrigeration offers considerable energy savings, mechanical stability, light weight, high efficiency and environment safe [1, 2].

Magnetic refrigeration is based on the magnetocaloric effect (MCE). The magnitude of this effect is given by the field-induced magnetic entropy change, $(-\Delta S_M)$. That is, when an external magnetic field is applied to a material, the magnetic spins in the material attempt to align with the magnetic field, thereby reducing the magnetic entropy of the spin systems. If the process is carried out adiabatically so that the total entropy of the system is conserved, then the magnetic entropy reduction is compensated by an increase in the lattice entropy of the system by the creation of phonons, resulting in a temperature increase. The reverse takes place when the field is removed [3, 4].

In this paper, we present the study of magnetic entropy change in $\text{La}_{0.5}\text{Nd}_{0.2}\text{Sr}_{0.3}\text{MnO}_3$ for magnetic refrigeration around room temperature.

$\text{La}_{0.5}\text{Nd}_{0.2}\text{Sr}_{0.3}\text{MnO}_3$ perovskite was prepared by a conventional solid state reaction method.

Results and discussion

Thermal property of raw materials of $\text{La}_{0.5}\text{Nd}_{0.2}\text{Sr}_{0.3}\text{MnO}_3$ have analyzed by TGA-DSC. The DSC curve shows one endothermic peak at around 587 K. The endothermic peak is related to the thermal decomposition of La_2O_3 into intermediate oxide phases. The endothermic peaks at around 1219 K can be related to the thermal decomposition of SrCO_3 . The endothermic peak can be considered as corresponding to the reaction forming a crystal structure of the perovskite at 1473 K.

The structural study was performed on an X-ray powder diffractometer. There is no evidence of an extra crystalline or amorphous phase being present. Each peak in the pattern can be indexed on a perovskite crystal structure.

Temperature dependence of magnetic moments was measured under zero-field cooled (ZFC) under 50 Oe. The magnetic ordering temperature, defined as the temperature at which the $|dM/dT|$ curve reaches a maximum, is found to be about 336 K.

Fig. 1 shows the magnetization curves measured at various temperatures of $\text{La}_{0.5}\text{Nd}_{0.2}\text{Sr}_{0.3}\text{MnO}_3$. A positive slope in the isotherm plots of H/M versus M^2 is a clear indication of a second-order magnetic transition from a ferromagnetic state to a paramagnetic one.

The magnetic entropy change in a magnetic system can be calculated from the M-H curves of $\text{La}_{0.5}\text{Nd}_{0.2}\text{Sr}_{0.3}\text{MnO}_3$ using the following equation :

$$\Delta S_M(T)_{\Delta H} = \int_{H_i}^{H_f} \left\{ \partial M(T, H) / \partial T \right\}_H dH \quad (1)$$

Equation (1) can be transformed into numerical integration form using the trapezoidal rule as follows [5]:

$$\Delta S_M(T_{av})_{\Delta H} = \delta H / 2 \delta T \{ \delta M_1 + 2(n-1 \sum_{k=2}^{n-1}) \delta M_k + \delta M_n \} \quad (2)$$

Fig. 2 shows the results of numerical integration of magnetization data in Fig. 1 using Eq. (2). This figure shows the temperature dependence of magnetic entropy change $(-\Delta S_M)$ under an applied field of 10 kOe for $\text{La}_{0.5}\text{Nd}_{0.2}\text{Sr}_{0.3}\text{MnO}_3$. The maximum magnetic entropy change $(-\Delta S_M)$ is 0.53 J/kgK for $\text{La}_{0.5}\text{Nd}_{0.2}\text{Sr}_{0.3}\text{MnO}_3$ sample in the field of 10 kOe. The maximum of magnetic entropy change $(-\Delta S_M)$ of $\text{La}_{0.5}\text{Nd}_{0.2}\text{Sr}_{0.3}\text{MnO}_3$ sample is at the around the magnetic ordering temperature.

The maximum magnetic entropy change $(-\Delta S_M)$ of $\text{La}_{0.5}\text{Nd}_{0.2}\text{Sr}_{0.3}\text{MnO}_3$ increases with the increase of the applied field. This property indicates that it could be a suitable candidate as working materials in magnetic refrigeration technology around room temperature.

Magnetic behavior and magnetoimpedance effect in Cobalt-based ribbons.

A. Rosales-Rivera¹, M. Gomez-Hermida¹, A. Velasquez¹, D. Muraca², H. Sirkin²

1. Laboratorio de Magnetismo y Materiales Avanzados, Universidad Nacional de Colombia, Manizales, Colombia; 2. Física, Universidad de Buenos Aires, Buenos Aires, Argentina

Cobalt-based amorphous magnetic alloy ribbons have attracted considerable attention since 1980, because of its applicability in electronic devices. Interest is also associated with the presence of GMI effect, as detected in the middle 1990s [1-4]. Cobalt-based amorphous magnetic alloy ribbons have interesting properties, among them high magnetic permeability and vanishing magnetostriction constant, which become them suitable to obtain high MI responses. In this paper a systematic study of the dc magnetization, ac susceptibility and giant magnetoimpedance effect, in amorphous alloy ribbons $\text{Co}_{80-x}\text{Fe}_x\text{B}_{10}\text{Si}_{10}$ with $x = 6, 8$ and 10 , is presented. The experiments were performed on samples of as-cast ribbons $\text{Co}_{80-x}\text{Fe}_x\text{B}_{10}\text{Si}_{10}$, prepared by the melt spinning technique. The dc field dependence of the magnetization, at room temperature, for all samples, for $-1 \leq H \leq 1$ kOe, is illustrated in Fig. 1. The curves in Fig. 1 are typical of an ultrasoft magnetic material, i.e., the loop is square shaped, having low coercivity; in addition, the saturation magnetization increases from 80 to 137 emu/gr with increasing x values. The dc field dependence of the real χ' ac part of the susceptibility, at room temperature, for the $x = 10$ sample at $f = 1000$ Hz is illustrated in Fig. 2. The χ' ac curve shows a peak at $H = \pm H_0 \neq 0$ which could be associated with the transverse anisotropy field. No observable shift in the peak field occurs as a function of frequency. The amplitude of these peaks increases with increasing frequency. It could be related with the soft magnetic character of the sample. Similar characteristics were observed in the χ'' ac curve (not shown here). The dc field dependence of the GMI ratio for the $x = 6$ sample, at room temperature, for the $0.5 \leq f < 10$ MHz is shown in Fig. 3. At low frequencies, $f < 2$ MHz, a single-peak (SP) behavior appears, typical for materials with vanishing magnetostriction [5]. For $2 < f \leq 10$ MHz, GMI results are no longer consistent with SP behavior. A two-peak (TP) behavior would be expected to occur for large f , as previously reported from magneto-impedance measurements in Co-based and Fe-based amorphous ribbons [5]. In our case, the TP behavior is also observed (GMI vs. H curves in Fig. 3, at $H = \pm H_k \neq 0$ where H_k is the transverse anisotropy field). The χ' ac peak at H_0 coincides quite well with the GMI peak at H_k , where GMI reaches its TP behavior.

In conclusion, all samples exhibit ultrasoft magnetic behavior, especially giant magneto-impedance effect, GMI. This behavior is consistent with the field dependences of the magnetization and ac susceptibility.

Correlation between surface magnetic field and Barkhausen noise in grain-oriented electrical steel.

S. Zurek¹, P. Marketos¹, S. Tumanski², H. V. Patel³, A. J. Moses¹

1. School of Engineering, Cardiff University, Cardiff, United Kingdom; 2. Institute of Electrical Theory and Measurements, Warsaw University of Technology, Warsaw, Poland; 3. Industry and Innovation Division, National Physical Laboratory, Middlesex, United Kingdom

Introduction

This paper shows a comparison of surface field and Barkhausen noise measured on the same grain-oriented (GO) sample. A single Epstein strip of conventional GO electrical steel, was tested at the Warsaw University of Technology (WUT) and the Wolfson Centre for Magnetism, Cardiff University (WCM). Prior to measuring, the domain structure was investigated with a static domain viewer to note the location of the grains (Fig. 1). The central part of the sample (40 mm x 20 mm) was examined with the use of two systems. The WUT used the Magnetivision system [1], which comprises a permalloy magnetoresistive sensor for the surface field investigation.

The surface of the sample was scanned in steps of 0.25 mm. The HS was measured at various values of peak flux density (B_{peak}) as measured by means of a search coil wrapped around the sample.

The WCM used a similar system, in which the surface of the sample was scanned with a BN sensor. The sensor comprised a ferrite rod (3 mm in diameter) with a 1000 turn enwrapping coil close to the surface of the sample. The sensor was positioned with spatial resolution of 1 mm. Figure 2 shows the distribution of peak values of HS acquired with the WUT system at 50 Hz and two levels of sinusoidal B_{peak} : 1.0 T and 1.5 T. The measured area is 140 mm x 30 mm and the values for each flux density shown in Fig. 2 were normalised to an arbitrary scale. A rectangle shows the area used for further analysis. Fig. 2 shows that the distribution of HS changes with B . It also shows that the overall topography remains similar at any B . However, this surface field activity does not seem to be directly connected to the grain structure, shown in Fig. 1 and Fig. 3. The comparison of results scanned for BN and HS from the two systems is shown in Fig. 3. The central area 40 mm x 20 mm (rectangle in Fig. 2) of the sample was scanned with the WCM system. The resultant rms Barkhausen noise distribution measured at 1.0 T, 50 Hz is shown in Fig. 3a. The results shown in Fig. 3a (BN) and Fig. 3b (HS) have a number of points with strong correlation. Lines A-A' and D-D' intercept at a grain over which there is very little activity for both BN and HS. On the right end of the D-D' line there is elevated activity (light grey or white) visible again in both cases. The intensity of HS and BN activities is clearly linked over around 50% of the tested surface area. However, this does not seem to be linked with the grain boundaries. It is therefore possible that the presented surface activity results from the grain-to-grain misorientation, which can take place at angles parallel to the surface of the sample, but also perpendicular to it. Such a misorientation would result in local demagnetising field, which would be dependent not only on the direction of a given grain, but also on the grains surrounding it.

Elevated HS and BN values are recorded in the vicinity of certain grains, whilst within other grains there is very little activity. Similar behaviour was observed at various flux density levels (from 0.5 T to 1.5 T) and magnetising frequencies (25 Hz and 50 Hz).

Conclusions

The measurements of the surface field and Barkhausen noise on the surface of a grain-oriented electrical steel sample show some correlation. On the other hand, there is a lack of clear link between the grain boundaries and the surface activity, which seems to be more affected only by cer-

tain grains. If Barkhausen noise is closely associated with hysteresis loss the results infer that this component varies spatially possibly independently of grain structure. More experimental work is required in order to understand and confirm the practical implications of these phenomena.

Comparison of properties of magnetoacoustic emission and mechanical Barkhausen effects for P91 steel after plastic flow and creep.

B. Augustyniak¹, M. Chmielewski¹, L. Piotrowski¹, Z. Kowalewski²

1. Gdansk University of Technology, Gdansk, Poland; 2. Polish Academy of Science, IPPT, Warsaw, Poland

Magnetoacoustic emission is introduced now as a new nondestructive technique of assessments of damage stage of ferromagnetic steels exploited at high temperature under stress [1]. This effect is closely related with abrupt displacement of mainly 90-deg magnetic domain walls [2,3]. The mechanical Barkhausen effect (MBN), the analogue of classical Barkhausen effect, deals with voltage pulses induced at pick-up coil when sample is loaded mechanically. This effect was used to evaluate internal stress distribution function [3]. It is thus not trivial existence of correlation between MAE intensity and MBE because both are due to displacement of the same type of DW. We like to test this correlation in the case of P91 steel at different stage of microstructure due to or plastic flow or due to creep performed at high temperature. The samples are plane specimens, as reported at [4]. Uniaxial tension creep tests was conducted under stress 290 MPa at temperature 773K. The tests were interrupted at certain times (up to 445 h) and the samples have the following creep plastic strains (%): C1 - 0.85, C2 - 1.85, C3 - 3.15, C4 - 4.6, C5 - 5.4, C6 - 7.9 and C7 - 10.0. Plastic flow was also applied at room temperature and the next set of samples had the following plastic strain levels (%): P1 - 2.0, P2 - 3.0, P3 - 4.5, P4 - 5.5, P5 - 7.5, P6 - 9.0, P7 - 10.5. There was also tested 'new' sample labeled as N. Magnetisation was made with coil using triangular like current (with frequency of 0.1 Hz). The MAE signal was detected with resonant PZT transducer, amplified and transformed to U_a voltage with rms integral circuit. The MBN signal was induced at the pickup coil wound directly on the specimen during free torsion like oscillation with frequency 2 Hz. The rms like value U_m of MBN intensity was also evaluated. The four representative plots of U_a and U_m (in function of driving current (denoted as H) and torsion strain (denoted as X), are shown in Fig. 1 and in Fig. 2, respectively. There is evident an decrease of MAE and MBN activities for all damaged samples. This effect is compared by means of integrals plotted in Fig. 3 as function of resulting plastic strain. These four plots reveal two main properties: analogous type of decrease of MAE and MBN effects (abrupt from the first stage of plastic strain) and much higher decrease of intensity of both effects for the case of plastic flow. There is also evident close correlation between MAE and MBN dependence on modification of the microstructure. It proofs the thesis about common source of these effects. Without detailed microstructural analysis one can argue, using the as presented MAE and MBN results, that effective internal stress level - for the same plastic strain - is higher at the case of plastic flow than of creep damage. These results roof again that the MAE technique is very suitable for nondestructive assessment of damage state of ferrite-pearlite as well as martensite steels.

The mechanical integrity of oil and gas pipelines is of major importance for the oil industry. The most effective method to detect local stresses and size defects in pipelines applies magnetic flux leakage (MFL) tools. The MFL signal is dependent, among other things, on the pipe wall magnetic properties and pipe wall stress. There exist several papers characterising the stress-state of pipeline steels [1–3], however, a systematic investigation correlating the microstructure with intrinsic magnetic properties of the material has not been reported. Therefore, in this paper three different types of steels API 5L (X52, X56, X60) obtained from out of service pipeline sections are investigated with respect to their microstructure, magnetic properties and magnetostriction.

The chemical compositions of the three steels under investigation were determined using the method included in the standard API-5L-2000. The microstructure was investigated using optical microscopy. As an example, Fig. 1 depicts the typical microstructure in the longitudinal direction of two studied steel samples. The steel X52 exhibits a ferrite/pearlite microstructure with both phases banding along the rolling direction. The mean planar grain diameter (d_m) was determined to be $22.5 \mu\text{m}$. The microstructure of the steels X56 and X60 consist also of ferrite/pearlite with incipient banding and $d_m = 11.5 \mu\text{m}$. The inclusion level of sulphurs, aluminates, silicates and globular oxides from the three studied steels were determined using the method in the standard ASTM E 45 [4]. The microstructure as well as the local composition of grains was studied also using a raster electron microscope (Quanta 3D 200) with EDX.

Two different sample geometries, rods and window-frames, were made of all steels taken from longitudinal and transverse directions. Fig. 2 shows minor hysteresis loops in the longitudinal and transverse direction of the steels X52 and X56, as obtained from the window-frame samples. The magnetic anisotropy is clearly visible, even though the materials are not fully saturated. This indicates that the bulk magnetic easy axis lies parallel to the rolling direction.

Using magnetic Barkhausen noise measurements Clapham et al. determined that the bulk magnetic easy axis in samples from steel API X70 is due to the strain induced during the cold-deformation stages of the pipe fabrication. They claimed that the presence of crystallographic texture and also the microstructure play no role in the origin of the bulk magnetic easy axis [1]. Magnetostriction is the most important intrinsic parameter of magnetic materials reflecting the stress influence on the shape of the hysteresis loop. Therefore, additionally magnetostriction measurements using strain gauge method and laser Doppler vibrometry were applied on all samples. The domain structure of the steel materials was observed using Magnetic Force Microscopy.

Pulsed field measurements were performed applying a maximum field of 5T in order to saturate the materials. However, in general stress states influence only the coercivity but not the saturation magnetization of ferromagnetic materials [5].

A Pulsed Field Magneto-optic Kerr Effect Magnetometer for Studying Magnetic Thin-Films and Nanostructures.

D. Atkinson, J. A. King

Physics, Durham University, Durham, United Kingdom

A magnetometer is presented that brings together highly-sensitive focused magneto-optic Kerr effect detection [1] with a pulsed field capability that allows the study of a magnetization switching behaviour in thin-film and nanostructured magnetic samples. Figure 1 shows a schematic overview of the system. The magneto-optics are based upon a high stability, low power diode laser. The laser beam is polarised with a high quality prism, collimated and focused on to a sample to a spot with a diameter of 5 micrometers (FWHM) as determined by scanning the laser spot across a 200 nm wide nanowire, see figure 2. The reflected light passes through a $\frac{1}{4}$ wave-plate and an analysing polarising prism and is focused onto a photodiode detector.

Low frequency magnetic fields are generated with a small electromagnet driven by a bipolar amplifier. Pulsed fields are generated by passing current pulses through micro-strip lines onto which thin-films and nanostructures are fabricated. Pulses of current are generated by a simple pulse-forming network that is rapidly switched using either a mercury-wetted relay at low voltages or a spark-gap switch at higher voltages. The duration of pulses is determined by the length of the pulse-forming network, with a shortest pulse width of 800 ps.

The time resolution of the system is currently limited to microseconds and therefore is suitable for investigating switching behaviour such as the stochastic behaviour of thin-films and nanostructures as a function of pulse duration rather time resolved GHz magnetization measurements. As an example, figure 3 shows the amplitude of the MOKE signal measured as a function of pulsed field amplitude for pulse lengths ranging from 1 microsecond down to 1 nanosecond. The sample consists of 20 nm thick permalloy (nominally Ni₈₁:Fe₁₉) deposited on top of a 30 nm thick aluminium strip-line. For a given pulse length the MOKE signal increases rapidly over a small field range. The field amplitude needed for switching increases for shorter pulse lengths as expected for thermally activated behaviour, and interesting when the switching curves are offset with respect to the field amplitude the curves follow the same field dependence indicating that the switching process is similar across three orders of magnitude from 1 microsecond down to 1 ns, see figure 4. A further point of interest in the switching of this sample is that with increasing field the MOKE signal reaches a peak and then reduces smoothly to a constant value as the field increases further. Further details of the MOKE system and example results will be presented.

A novel application of high resolution scanning electron microscopy for perpendicular recording media characterization.

E. T. Yen¹, L. Lee¹, B. Lu¹, O. Mryasov²

1. Seagate Technology, Fremont, CA; 2. Seagate Technology, Pittsburg, PA

One of the apparent challenges in designing perpendicular recording media (PRM) includes complexity in correlation between characteristics of multilayer PMR and recording performances [1]. Thus, recording performance gain or loss due to a given change in media layer is generally difficult to identify and rationalize. However, there is a number of magnetic, microstructure and materials characterization means that can be used to guide PRM development by studying correlations between given building block properties and recording performances. Currently, the most prevailing microstructure analysis tool is the high resolution transmission electron microscopy. However, the sample preparation difficulties, long turn around time and high capital expenses makes this tool not as desirable in industrial research environment. In the meanwhile, key inventions such as field emission gun and the in-lens secondary electron detector make today's high resolution SEM (HRSEM) to attain fine feature resolution of about 1nm and thus becomes a meaningful development tool for high resolution topography images but still is not enough to resolve the state of art PRM media's sub-nanometer grain boundary width as well as fine features such as precipitates, stacking faults and crystal orientation of which HRTEM can do.

Nevertheless, In this paper, we describe a novel characterization approach based on combination of high resolution scanning electron microscopy (HRSEM) and automated image analysis at interlayer of PRM. We demonstrate that HRSEM can be quite useful to characterize interlayer topography which in all considered samples can be successfully correlated with observed recording performances. Interlayer is known to be critical to grain size control of recording layer and which, in turn, tunes the magnetic performances as described in [1]. As a matter of fact, the lack of crystal orientation contrast in SEM micrograph actually turns into an advantage for automated high throughput quantitative IL grain size image analysis as described below. Besides, the lack of grain boundary width resolution does not affect the determination of the center to center distance (d) which is one of the major contributors in media SNR [2].

As illustrated in HRSEM pictures below, clear grain topography with rather uniform gray level can be achieved for a typical interlayer (see Fig. 1) while, for comparison, grain topography of recording layer is much less clear (see Fig. 2). The latter can be attributed in part to recording layer planarization effect rather than to SEM resolution artifact. The crisp HRSEM image in Fig. 1 can then be analyzed quantitatively with highly automated software procedure implemented based on a special image analysis software. This image analysis procedure features background equalization, noise filtering, defect removal, grain image separation and Voronoi polyhedra statistical construction [3]. Voronoi grain size and the center to center distance histograms (not shown here) can be obtained easily and accurately with a sample size of about thousand grains and done within in a minute using a desktop PC. The microstructure characterization using Voronoi construction help to minimize uncertainties due to lack of grain boundary contrast. Interestingly, the lack of grain crystal orientation contrast in Fig. 1 reduces grain to grain gray level variations and as we find here overall helps accurate grain image separation within the automated analysis procedure. Note, that this is in contrast with painful and time consuming efforts in obtaining similar grain size histograms by HRTEM plane view micrograph analysis.

With such innovative, powerful and convenient characterization method at hand, we proceed to investigate perpendicular media performance as a function of grain size changes in a series of

thickness ladder experiment. We observe strong media SNR and KuV/kBT dependencies upon variations in the center to center interlayer grain size. Due to space limitation, details will be discussed in the full paper.

Magnetic image detection of the stainless-steel welding part inside the multi-layered tube structure.

T. Hayashi^{1,2}, H. Yamada¹, T. Kiwa¹, K. Tsukada¹, M. Tamazumi³

1. Graduate School of Natural Science & Technology, Okayama University, Okayama, Japan; 2. Pulstec Industrial Co., Ltd, Hamamatsu, Japan; 3. Uno Kogyo Co., Ltd, Okayama, Japan

For the non-destructive evaluation of the weld, detection of the stainless-steel welding part inside the multi-layered tube was demonstrated by low frequency magnetic imaging. The magnetic images were obtained by a developed measurement system, which consists of the exposure coil, magnetoresistive (MR) sensor, measuring circuit, and lock-in amplifier, moving stage and personal computer (Fig. 1). A wide area of the stainless-steel sample was exposed to the magnetic field via an induction coil. The diameter of the induction coil was 0.8m, which was comparable to the sample size. The MR sensor measured the vector components of the generated magnetic field from the sample within the range of the low frequencies between 20Hz and 1kHz. The vector components of the generated magnetic field from the sample were measured by scanning the MR sensor on the sample surface. A cylindrical stainless-steel sample was fabricated as a tube by rolling a stainless-steel sheet (SUS304) and welding each edge by an arc welder with argon gas. The welds were made with a tungsten electrode (TIG308). The diameter of the cylindrical sample was 150mm, and the height was 500mm. The multi-layered tube was fabricated by putting one tube inside another. The distance between the sensor and the sample surface was kept to 3 mm during the scanning.

The obtained vector components were divided into normal components (B_z) and tangential components (B_x and B_y) to the sample surface. Each magnetic field vector was calculated from two parameters, signal amplitude and phase, obtained from the lock-in amplifier at the same frequency of the applied magnetic field. From the tangential magnetic field components, the induced current in the sample was reconstructed using formula $I_{xy}(t) = K(-B_y(t) \mathbf{e}_x + B_x(t) \mathbf{e}_y)$ where K is constant, and \mathbf{e}_x and \mathbf{e}_y are respective x and y unit vectors. Fig. 2 shows the obtained current images of the single and double layer tube sample. These maps were the contour plot of tangential magnet field strength ($B_{xy} = (B_x^2 + B_y^2)^{1/2}$) and superposed with the current I_{xy} by using arrows at each measuring point. The tangential magnetic field strengths of both sides of the welding part were stronger than that of the welding part, and the direction of the current was inversed across the welding area. Additionally, the welding part inside the multi-layered tube, which was not optically observed from the surface, was successfully imaged. Fig. 3 shows the normal component images of the single and double tube sample. The normal magnetic field strength was inversed across the welding part, which denoted the same tendency of the direction of the current images.

In summary, the magnetic imaging of the stainless-steel welding part was obtained by the developed system, which detects the normal magnetic field strength and the current distribution of the sample. By using a low frequency exposure magnetic field, detection of the stainless-steel welding part inside the multi-layered tube became possible.

Transient Eddy Current Measurement for the Characterization of Depth and Conductivity of a Conductive Plate.

W. Cheng

NDE Center, Japan Power Engineering and Inspection Corporation, Yokohama, Japan

Transient eddy current measurement rivals conventional single or multi-frequency eddy current technique for many of the common applications in non-destructive evaluation, such as the detection of defects, the estimation of thickness of a specimen itself or the coating, the measurement of electrical conductivity, and etc. Since the transient eddy current measurement signal is affected by both the plate thickness and the electrical conductivity, the interpretation of signal for the estimation of thickness and conductivity is studied. 3D transient eddy current simulation is carried out, and an optimization method to determine the conductivity and the thickness of a conductive plate is presented. A cylindrical air-cored coil is utilized for transient eddy current measurement. The coil is excited by transient current [1], and the normal component of the transient induced magnetic field flux density is detected by magnetic field sensors located on the coil axis. The period of the pulse wave is T , and current I_0 is turned off at time t_0 . Ideally the turn-off time should be 0. However, practically there is a time delay for current turn-off. The 3D transient eddy current problem is solved in three steps correspondently: a static study is carried out for $t < t_0$; the current is turned off at t_0 and a transient procedure starts, during which the current drops from I_0 to 0. The initial condition of the transient procedure is given by the solution of the static procedure. The eddy current, which concentrates in a small skin depth area close to the surface of the plate penetrates into the plate and decreases because of Joule dissipation, even after the current in the excitation coil is completely turned off at t_0 . The current in the excitation coil is described in Fig. 1. The normal component of magnetic flux density (B_z) along coil axis is calculated and the difference between two measurements, $\Delta B_z = B_{z1} - B_{z2}$, is utilized for depth and conductivity characterization.

The plate thickness is assumed to be 5, 7, 8, 9, 10, 15, and 20 mm respectively. And the conductivities used in simulation are respectively 0.5, 0.7, 0.9, 1.0, 1.1, and 1.5 MS/m. The current is 15 Ampere and turned off in 5 μ s.

The magnetic flux density at $Z=2$ mm and $Z=15$ mm above testing plate is calculated and ΔB_z is obtained. Fig. 2 shows the responds of magnetic field flux density with respect to time in the transient procedure, when the plate thickness changes. The conductivity is keep constant as 1 MS/m. Logarithm is taken for both time t and signal B_z . Signal of a thinner plate decreases faster than that of a plate with larger thickness. Fig. 3 shows the signal of 5, 8, 10, and 20 mm thick plate when the conductivity are respectively 0.5, 0.7, 0.9, 1.0, 1.1, and 1.5 MS/m. It is clear that, for plates with same thickness, the larger the conductivity, the slower the decrease of signal B_z .

The conductivity and plate thickness affects signal B_z simultaneously. In order to determine the thickness and conductivity respectively, an optimization approach, which ensures the lowest sensitivity to thickness and highest sensitivity to conductivity, when conductivity is required; and vice versa for thickness, is adapted and the result will be reported in full paper.

Multidirectional Remanent Flux Leakage Transducers for Evaluation of Stress and Fatigue Loaded Steel Samples.

T. Chady, G. Psuj

Department of Electrical and Computer Engineering, Szczecin University of Technology, Szczecin, Poland

Abstract. In this paper stress and fatigue loaded ferromagnetic samples made of SS400 and S355J2G3 steels were evaluated using three different remanent flux leakage transducers. GMR sensors were used as the pick-up elements. Each transducer has its own integrated local magnetizing section which allows to magnetize the tested material in different direction. The performance of the transducers was verified using steel plate (S355J2G3) with EDM notches.

1. Introduction

The magnetic flux leakage method finds widespread use in a number of industries. It is based on a detection of leakage fields, caused by a change in the reluctance of ferromagnetic materials, which are magnetized in a DC field. The leakage magnetic fields are then measured by scanning a surface of the specimen with a flux density sensitive transducer. Observations confirm that this method is useful in evaluation the stage of degradation of stress loaded samples [1], [2]. However, obtaining uniform magnetization of the material in many practical cases can be a complicated task. Therefore, utilization of a local magnetizing coil seems to be an interesting alternative. In this paper three transducers with integrated magnetizing sections, which allow to magnetize in different directions will be presented. The minimization of the defect detection dependency on angle was achieved by integration of the data from different transducers.

2. Transducers

Figure 1 shows the view of the proposed transducers. Each transducer consists of two elements: a pick-up section and an integrated magnetizing section. The configuration of sections was different in each transducer. The magnetizing section of the TMAG_X transducer consists of two excitation coils wound on the C-shaped ferrite core. The magnetization field was parallel to the scanning direction (x axis). The pick-up section was made of two absolute GMR elements differentially connected with the sensing axis parallel to the scanning direction. The first GMR was placed close to the specimen surface. The second one was placed above, so that it measured only unwanted interfering signals. In case of the TMAG_Y transducer, magnetizing section is rotated by 90° in order to magnetize the material in perpendicular direction to the scanning direction.

The magnetizing section of the TMAG_Z transducer consists of an excitation coil wound on the rod ferrite core. In this case the magnetization was perpendicular to the sample's surface. The pick-up section consists of two absolute GMR elements connected differentially and placed one over another. The sensitivity axis of the GMR elements was parallel to the magnetization axis.

3. Selected Results of Experiments

Each sensor presents different range of angles, for which it is possible to detect the defect. To verify the performance of the measuring system the preliminary experiment was carried out using steel plate (S355J2G3) with EDM notches (depth 80%, width 0.2 mm, length 5 mm) manufactured at different angles (0, 30, 60 and 90 degrees) to the scanning direction. The results obtained for TMAG_X and TMAG_Y were presented in Figure 2. In order to enhance the performance of the measuring system, the results obtained from all transducers were combined using signal level data fusion algorithm. The results of the data fusion achieved for TMAG_X and TMAG_Y were presented in the Figure 2c. It can be observed that the fused results enable to detect all defects. The final tests were carried out on planar specimens made of steel (SS400, S355J2G3) stress or fatigue

loaded in longitudinal direction. Figure 3 shows selected results of the measurements. Other results as well as the details of the fusion algorithm will be presented in the final version of the paper.

Understanding Adjacent Track Erasure in Discrete Track Media.

Y. Tang¹, X. Che², J. Zhu¹

1. Electrical and Computer Engineering, Carnegie Mellon University, Pittsburgh, PA; 2.

Samsung Information Systems America, San Jose, CA

Recently there are arising interests in the implementation of discrete track media (DTM) in perpendicular recording with drive level implementation demonstration by Toshiba and the recording areal density of 602 Gb/in², highest area density in HDD demo, achieved by TDK. It is believed that with grooves separating data tracks magnetically and physically, higher recording track density can be achieved in DTM mainly due to the improved adjacent track erasure (ATE) performance in recording^{1,2}, which is the key factor preventing today's continuous disk medium from achieving higher track density. This paper presents a micromagnetic modeling analysis that is performed on both continuous media (CM) and DTM with same magnetic properties for understanding the underlying physics of ATE.

In simulation, coupled-granular-continuous (CGC) media is modeled with a two layers structure. The bottom layer is exchange decoupled with 10 nm thickness, and $H_k = 10$ kOe. The top capping layer is 4 nm thick with varied inter-granular exchange coupling A_1 , and $H_k = 12$ kOe. The saturation magnetization for both layers is $M_s = 550$ emu/cc. The etching wall angle effect is considered in modeling by reducing the top layer track width.

A trailing shielded head with 120 nm pole width and 50 nm write gap is used to simulate ATE in recording. First periodic patterns with 200 KFCI linear density are recorded on the center track. Then the head write 800 KFCI patterns with an offset from the center track. The ATE is obtained by measuring the on-track signal profile in frequency domain. Figure 1 shows the ATE in continuous media and DTM with/without exchange coupling in the capping layer. The track/trench width is 100 nm. The offset, i.e. squeeze, is 135 nm. In frequency domain (second row in figure 2), it is obvious that the on-track signal are erased by the adjacent track recording except DTM with exchange coupling. By varying the offset of adjacent track recording, the roll-off curves of on-track signals for DTM and continuous media are plotted in figure 2. Without exchange coupling in the capping layer, there is no obvious ATE improvement in DTM. When exchange coupling in the capping layer is 5×10^{-7} erg/cm, believed to be a typical value for today's media, the track pitch can be reduced by 20 nm compared to continuous media with same amount of ATE. The fact there is ATE gain in DTM is because of the existence of inter-granular exchange coupling in today's PMR media. Our simulation results shows the improved ATE performance monotonic increases with increasing inter-granular exchange coupling in the capping layer of the media.

10 Tb/in² recording simulations on patterned domain wall assisted media.

A. Y. Dobin, H. J. Richter, J. Xue, D. Weller
Seagate Technology LLC, Fremont, CA

Magnetic recording on patterned media is predicted [1] to significantly increase the areal density owing to the ultimate reduction of the number of magnetic particles per bit of recorded information: from more than 20 grains per bit in current conventional perpendicular recording down to 1 dot per bit for patterned media. Domain wall assisted switching provides a means to reduce the size of magnetic particles without sacrificing their thermal stability and write-ability [2,3]. In this work we demonstrate theoretically that domain wall assisted patterned media can reach a record 10Tb/in² areal density.

We use a writer with a very small 10nm by 10nm pole tip at the ABS, and 45-degree flares and bevels in cross-track and down-track directions increase the write field. Side shields with 10nm gaps and trailing shield with 40nm gap are used to increase the down/cross-track field gradients to improve the bit-error rate and reduce adjacent track erasure. We chose aggressive values for the head-medium separation HMS=2nm and medium-SUL separation (interlayer)=1nm. The dot-to-dot spacing is 8nm, resulting in the areal density of 10Tb/in², and the dot diameter is 4.5nm. The composite hard/soft magnetic dots structure is shown in Fig. 1. The hard layer anisotropy and saturated magnetization are slightly below L10 FePt values, while the soft layer parameters are close to those of pure Co.

The contributions of different noise sources to the total write jitter are presented in Table 1. The standard deviations of the down-track dot position error (determined by lithography) and the timing synchronization (read/write electronics) were fixed at 5% of the bit length in our study. We calculated the jitter (see Fig. 2) owing to the hard layer anisotropy distributions (assuming $\sigma(H_k)/H_k=5\%$) using 1D micromagnetic model for the domain wall assisted media [3] and FEM write fields. The demagnetization fields from neighboring dots produce fluctuations of the perpendicular field with $\sigma(H_{\text{demag}})=210$ Oe, the corresponding jitter is presented in Fig. 3. The jitter from both sources is found to be significantly reduced owing to the switching field distribution reduction in domain wall assisted media with optimized soft and hard layers [4]. The total jitter, calculated as a sum of variances of uncorrelated Gaussian distribution of all noise sources, has $\sigma(\text{jitter})=11\%$ of the bit length, which corresponds to written-in BER of $\sim 10^{-5.3}$.

The energy barrier of the hard/soft structure (calculated using the recipe described in [3]) is $E_b/k_B T_{300} \sim 98$ which is more than enough to keep the information thermally stable for more than 10 years. The energy barrier for the adjacent track erasure was calculated using a similar scheme with the FEM off-track write fields, yielding $E_b(\text{ATE})/k_B T_{300} \sim 35$. With the attempt frequency of 3000GHz and 1ns exposure time for each erasure cycle, we find the additional error rate of $\sim 10^{-5.7}$ after 1 million erasure cycles.

Patterned media (PM) magnetic recording is envisioned for ultra-high recording densities. High density PM should utilize elements with high anisotropy to render a sufficient thermal stability, which can be reversed with sufficiently low head fields. Here, we introduce a new type of PM that utilize elements, referred to as “ledge” elements, and show that these PM can lead to recording densities of 10 Tbit/in² [1].

A ledge element is comprised of a magnetically hard and soft sections of dimensions w_x , w_y , t_h and a_x , a_y , t_s , respectively. The left corners of the sections are shifted with respect to each other by s_x and s_y in the x and y dimensions, respectively. Both sections have a damping constant α , saturation magnetization M_s , and exchange length l_{ex} (with A the exchange constant). The sections are coupled with energy per unit area J_s . A PM comprises an array of such elements with the pitch d_x and d_y . When $a_{x,y} < d_{x,y}$, both the soft and hard sections are physically separated. When $a_{x,y} = d_{x,y}$, the hard sections are separated whereas the soft sections form a continuous soft layer. An external magnetic field is $\mathbf{H}_{ext} = -H_a \text{erf}(2t/\tau)(\mathbf{z}_0 \cos\theta + \mathbf{x}_0 \sin\theta)$, where θ is the field angle, H_a is the field magnitude, and τ is the field rise time. Reversal occurs when H_a is above a certain reversal field H_r .

Figure 2(a) shows the normalized reversal field H_r/H_K (with $H_K = 2K_h/M_s$) versus a_x/w_x for small and large α in the cases of a “gamma” element with $s_x = 0$, “mushroom” element with $s_x = (a_x - w_x)/2$, and “capped” structure with $a_x = d_x$. For all structures, H_r/H_K decreases substantially with increasing a_x/w_x . For large damping ($\alpha = 1$), the reversal field saturates rapidly as a_x/w_x increases. The saturation is obtained due to a domain wall in the soft section. For smaller damping ($\alpha = 0.1$), the decrease of H_r/H_K with a_x/w_x is much more pronounced with smallest values ($H_r/H_K \sim 0.07$) obtained for the “gamma” and “mushroom” structures. These values are more than an order smaller than those for homogeneous elements, and ~ 5 times smaller than those for conventional composite elements (i.e. for $a_x/w_x = 1$) [2-4].

The reduction of $H_r/H_K \sim 0.07$ for small α is associated with precessional reversal [5-7], which occurs when α is small, θ is non-vanishing, and $\tau < \tau_{crit}$ with τ_{crit} being the critical rise time, i.e. the maximal τ allowing for precessional reversal. Figure 2(a) shows normalized τ_{crit} for the structures in Fig. 2(a). For the ledge elements, values of τ_{crit} are remarkably larger than those for homogeneous and conventional composite elements with largest values obtained for the “gamma” structure. For example, for $H_K = 72 \text{ kOe}$, $\tau_{crit} = 120 \text{ ps}$ for the ledge elements in Fig. 2, whereas it is $\tau_{crit} \sim 16 \text{ ps}$ and $\tau_{crit} \sim 2 \text{ ps}$ for the conventional composite and homogeneous elements, respectively. The τ_{crit} can be further increased significantly by optimizing the values of J_s . While $\tau_{crit} \sim 100 \text{ ps}$ for ledge elements can be obtained in realistic recording heads, $\tau_{crit} \sim 10 \text{ ps}$ for composite/homogeneous elements is hard or impossible to achieve.

Potential of the ledge structures for ultra-high density recording can be estimated based on the Neel-Arrhenius estimate. We require $(K_h V)/(k_B T) > 50$, where $V = w^3/2$ is the hard section volume, T is the temperature, k_B is the Boltzmann constant, and the factor 50 is chosen to lead to sufficiently a long relaxation time. For recording at a density slightly above 10 Tbit/in², a medium with $w = w_x = w_y = 4.2 \text{ nm}$, $d_x = 2w = 8.4 \text{ nm}$, $d_y = 1.6w = 6.72 \text{ nm}$, $M_s = 1500 \text{ emu/cc}$, $a_y = w_y$, $a_x = 1.9w = 7.98 \text{ nm}$, $t_s = t_h = w/2 = 2.1 \text{ nm}$ satisfies the thermal stability criterion for $T = 300 \text{ K}$. The reversal field and criti-

cal rise time are on the order of $H_r = 10 \text{ kOe}$ and 100 ps , respectively (τ_{crit} increases to $\sim 170 \text{ ps}$ for $J_s/(2K_h t_h) = 0.1$ with a slightly stronger H_r). Such H_r and τ_{crit} can be obtained in practical recording systems. Moreover, these structures use elements of a small height. Therefore, recording heads with a small head-underlayer gap can be used thus allowing for strong head fields. Higher densities for thermally stable recording can be achieved with larger H_r .

Additional study is being conducted to characterize effects of various structure parameters, including interactions between the PM elements, and initial magnetization states.

Characterization of timing jitter in synchronous writing of bit patterned media.

Y. Tang, X. Che
Samsung, San Jose, CA

One challenging problem in writing bit patterned media is synchronizing the write current reversal and the physical bit pattern location[1]. Since synchronizing signal is usually only available through averaging or interpolation, the relative jitter between bit pattern location and the write current reversal can have an important effect in synchronous writing. This paper characterizes two sources of jitter in a disk drive that can potentially affect write timing accuracy.

The first source is the jitter in disk speed. To correlate it to timing jitter, we wrote periodical isolated magnetic transitions on a PMR disk. One of the transition was used as the reference and other transitions were measured and the position jitter verses average transition distance is plotted in Fig. 1. Here jitter magnitudes of 5 heads in the same HDA are plotted in different symbols. It can be seen that the jitter increases with the transition distance. This is consistent with the effect of slow rotation speed variation. Also, the jitter for all heads increases at similar rate with distance, which suggests that the distance dependent jitter comes from the spindle speed variation. The jitter at near zero distance represents the jitter from electronics including the instrument itself.

While the spindle speed variation and electronics circuit are major sources of timing jitter during normal head flying, an additional timing jitter can occur when a head is in or near in contact with disk. In this case, the slider may vibrate in the down track direction, which will cause write timing jitter. To characterize this effect, we wrote periodic signals over many sectors on a disk and recorded the readback signal. The read signal is digitally processed to calculate the frequency and magnitude of its vibration mode[2]. Fig. 2 showed that with high power applied to head heater, a 78KHz vibration mode with about 37nm in amplitude was observed.

To demonstrate the effect of this head/media interface induced jitter on writing, we wrote consecutive tracks in a disk drive with patterns derived from a bit map image of Samsung logo. Each row of the bit map was written onto one sector of one track with blue and white area coded in opposite magnetization directions on the disk. The writing was done with two different heater powers. In both cases, the signal was read back under the normal flying condition and recorded using a digital oscilloscope. The image is reconstructed by representing read signal level from each track in image brightness and pasting them together. Fig. 3 showed the reconstructed image under normal write condition and under high heater power during writing. The effect of down track jitter is manifested by the poorer image quality the image on the right side. In particular, the vertical lines in letters "M", "U" and "N" showed clear difference in smoothness.

From these experiments, we have identified two sources of jitter in addition to electronics noise that can potentially cause difficulty in writing bit patterned media: disk speed variation and head-media contact. In addition, the effect of write timing jitter is demonstrated with reconstructed images.

Many attempts have been made to form ordered magnetic nanostructures for scientific interest and practical use in magnetic devices. In particular, fabrication of patterned magnetic media is the important area due to ultimate data density of 1 Tb/in² and retardation of superparamagnetic limitation. We will show that the multilayered Co/Pd nano-dot array with an areal density of 1 Tb/in² which can be obtained by combination of the double development technique of HSQ resist [1] and the two-step plasma etching process [2]. Critical process issues and our solution will be described in view of the proximity effect in e-beam lithography and the redeposition problem in plasma etching.

10 Å Pd (top) / (3 Å Co / 8 Å Pd) / 10/50 Å Pd / 40 Å Ta (bottom) multilayer was deposited on a 1000 Å SiO₂/Si(001) substrate, and a 300 Å thick amorphous Si layer was deposited as an etch mask and resist adhesion promotive layer. Afterwards, dot array patterns with pitches from 50 nm to 25 nm were defined by e-beam lithography using 100 keV accelerating voltage and 300 Å thick hydrogen silsesquioxane (HSQ). Resist development was carried out in tetramethylammonium hydroxide (TMAH) 25 % aqueous solution at 21 °C for 1 min. These resist patterns were transferred to the underlying metal layer by two-step etching. Amorphous Si and metal layers were etched successively using Cl₂ and Ar plasma.

Plan-view SEM images of the nano-dot array pattern with a 50 nm pitch are presented in Fig. 1 as following process steps. As presented in Fig. 1a, some material around nano-dot were appeared and built up during Ar plasma etching. These material might be a redeposit of Co or Pd. Non-volatile etch products are easily stuck on the sidewall or surface of pattern by back scattering from the Ar plasma [3,4]. The redeposit phenomenon could be solved by restriction of scattering event between sputtered material and Ar plasma. The morphology of nano-dot array was seriously altered by reducing of chamber pressure from 100 mTorr (Fig. 1a) to 10 mTorr (Fig. 1b). Inset of Fig. 1b clearly shows that redeposit around nano-dot array can be neglected. Using this plasma etching method, we successfully fabricate the Co/Pd nano-dot array with the pitch size of larger than 30 nm. However resist patterns below the 25 nm pitch, which corresponds to the areal density of 1 Tb/in², were not transferred to the underlying layer. The reason of process failure is that each dot in the resist patterns was not fully isolated after resist development due to the e-beam proximity effect. Interestingly, in addition, we found that development of HSQ stops at 1 min in a 25 % TMAH developer and the insoluble siloxane layer covers the resist surface. To continue the development, we introduced the siloxane layer removal step using a dilute HF solution between development steps [1]. Using the double development method (TMAH/dilute HF/TMAH), we could extend the development time and obtain fully isolated resist pattern with 25 nm pitch. These well defined resist pattern was transferred faithfully to the magnetic layer.

From the proposed method of resist development and plasma etching, we demonstrated of the patterned magnetic storage of the areal density from the 0.25 to 1 Tb/in² as shown in Fig. 2. More detail discussion on the fabrication process issues and magnetic properties of fabricated nano-dot array, will be given.

SUB 100 nm FePt NANODOT ARRAYS FOR ULTRAHIGH-DENSITY MAGNETIC RECORDING.

H. Ko¹, P. Alagarsamy¹, K. Lee¹, S. Shin¹, J. Jung², H. Jung²

1. Physics, KAIST, Daejeon, South Korea; 2. Chemical and Biomolecular Engineering, KAIST, Daejeon, South Korea

Introduction

Numerous studies have been carried out to search suitable materials for perpendicular magnetic recording (PMR). FePt thin film has been found to be one of the promising candidates of PMR media because of their excellent magnetic properties [1]. However, there are many limitations to obtain high areal density with continuous recording media [2]. The other type of magnetic recording to obtain extremely high density beyond Terabits / in² is patterned media. To achieve such ultra-high areal density, it is very much important to fabricate magnetic nanodot structure with dot size of few tens of nm. Recently, the use of scanning beam lithography method (conventional E-beam technique) helped to realize the regular pattern shape [3]. However, from the application point of view, one has to consider the simple and convenient method to fabricate the patterned nanostructure because high production cost and enormous preparation time are destructive features for the mass-production with large pattern area. So far, by bottom-up approach, there have been no detailed results to show regular dot shape and dot distance. Therefore, it is highly demanded both to develop new patterning technique and to get optimum magnetic properties from nanodot arrays with dot size of few tens of nm. In this work, we have successfully fabricated the patterned FePt nanodots with a regular dot size down to 80 nm using CFL (Capillary Force Lithography) imprint technique and studied the variation of magnetization state with changing the degree of ordering of the FePt nanodot arrays.

Experiment

FePt films were prepared on MgO(100) substrates using dc magnetron sputtering of FePt targets with a base pressure of better than 5×10^{-7} Torr. The film thickness was changed from 10 to 50 nm. Large area magnetic pattern was produced starting from the features of various dimensions made by CFL. The Si mold has a square shape with the size of 2.5 mm². Each dot has a cylindrical shape with diameter (100 nm) and inter-dot distance (150 or 300 nm). After patterning nanodot arrays, all the samples were post-annealed at substrate temperature up to 600 °C. The crystal structure of the nanodots was characterized using X-ray diffractometry (XRD). The position and shape of the nanodots were confirmed with Atomic Force Microscope (AFM). Room temperature magnetic measurement was carried out using Superconducting Quantum Interference Device (SQUID). The magnetic domain patterns were observed using a Digital Instrument 3000 Magnetic Force Microscope (MFM).

Results and Discussion

Fig.1 shows the surface image of the patterned structures observed by AFM. A small variation of dot size comes from the different etching time. With more etching time, the dot size reduces. With as-made dot arrays, post-annealing has been carried out to obtain L10 ordered structure with a large magnetocrystalline anisotropy. Fig. 2 shows (a) the XRD patterns and (b) M-H loop of FePt nanodots annealed at various temperatures and 600 °C, respectively. The obtained results confirm the highly ordered L10 phase and the proper magnetic hysteresis loop for magnetic recording. Fig.3 shows the domain structures of low and high anisotropy dots. We could obtain the completely single domain structure in the higher anisotropy dot, which is in good agreement with our simulation results. Such a single domain structure makes it possible to realize more accurate writing and read-

ing of recording bits. In addition, we have confirmed the presence of strong magnetic stray field around dots using electron holography method. However, it is found to be less than switching field of FePt nanodots. The coercivity change and switching field distribution of M-H hysteresis loops does not have any influence due to the magnetostatic interaction between neighboring dots, indicating that each dot works independently without any interference from the other dots.

This research work was supported by Korea Science and Engineering Foundation through the Basic Research Program.

Dot size dependence of magnetization reversal process in $L1_0$ FePt dot arrays.

D. Wang¹, T. Seki¹, K. Takanashi¹, T. Shima²

1. Institute for Materials Research, Tohoku University, Sendai, Japan; 2. Faculty of Engineering, Tohoku-gakuin University, Tagajyo, Japan

The demand for ultrahigh density magnetic storage devices drives the bit size into a nanometer scale. One of the crucial issues for nanostructured magnetic materials is the thermal instability of magnetization due to the reduction of the magnetic volume. $L1_0$ ordered FePt alloy is one of the most promising materials for future ultrahigh density magnetic storage devices because the huge uniaxial magnetocrystalline anisotropy ($K_u = 7 \times 10^7$ erg/cc)[1] leads to excellent thermal stability of magnetization. For the application of FePt to storage devices, it is very important to understand the magnetization reversal process of nanostructured FePt, including the effect of the dimensions.

In previous papers, it was reported that nucleation-type magnetization reversal processes were observed in self-assembled FePt particulate films[2] and lithographically patterned FePt dot arrays[3]. In addition, the coercivity (H_c) depended strongly on the film morphology and the dot size. In order to understand the magnetization reversal process of nanostructured FePt, however, it is necessary to consider the effect of structural inhomogeneity on the magnetization reversal process. A phenomenological analysis, proposed by Kronmüller and his collaborators[4,5], described the magnetization reversal process of sintered permanent magnets such as Nd-Fe-B and Sm-Co from the viewpoint of the inhomogeneity of microstructure, and has been applied to a wide range of magnets to date. Such phenomenological analysis makes it possible to evaluate the defect region for magnetization reversal in nanostructured FePt and to classify it as the nucleation-type or the pinning-type reversal mode.

In this paper, the phenomenological analysis has been applied to the FePt dot arrays with different dot sizes fabricated by lithography technique. Their magnetization reversal processes are discussed in terms of structural inhomogeneity, and compared with that for self-assembled FePt particulate films. Furthermore, the micromagnetic simulation has been performed, and compared with the phenomenological analysis.

FePt films were prepared on a MgO (001) single crystal substrate using a UHV compatible magnetron sputtering system. A 1 nm-thick Fe seed layer and a 40 nm-thick Au buffer layer were first deposited at room temperature. A 50 nm-thick FePt (001) layer was epitaxially grown at 300 °C, and subsequently annealed at 500 °C for 15 minutes. FePt dots with a circular shape were fabricated through the use of electron beam lithography and Ar ion etching. The dot size (i.e., dot diameter, abbreviated as d , hereafter) was varied in the range from 250 nm to 5000 nm. The distance between two adjacent dots was designed to be the same as d . Post-annealing was performed at 500 °C for 15 min. Structural characterization was performed using x-ray diffraction (XRD) with Cu-K α radiation. The magnetization curves of FePt dots were measured by a superconducting quantum interference device (SQUID) magnetometer.

The XRD measurement for a FePt continuous film indicates the formation of $L1_0$ ordered structure and the epitaxial growth with the (001) preferential crystallographic orientation normal to the film plane. The magnetization curves show that the easy axis of the film is perpendicular to the film plane. H_c is a small value of 0.8 kOe, in spite of a large K_u of 2.8×10^7 erg/cc. After patterning, however, H_c is enhanced up to 7.5 kOe for the dots with $d=250$ nm. Post-annealing after patterning leads to the further increase of H_c up to 10 kOe. The phenomenological analysis of magnetization curves gives the sizes of defect regions for $d=250$ nm to be 26 nm and 18 nm before and after annealing, respectively, suggesting that post-annealing promotes the recovery from the structural defects

caused by Ar ion etching. Furthermore, this indicates that the structural defects play a key role for the value of H_c and H_c increases with decreasing the defect region. Micromagnetic simulations also show the reduction of H_c is caused by structural defects with a low degree of chemical order in a dot, which is consistent with the phenomenological analysis.

The defect regions of dots with different d have also been evaluated. H_c gradually increases with decreasing d , and the defect region also tends to decrease with decreasing d . Furthermore, the phenomenological analysis indicates that for $d=250$ nm and 1000 nm the magnetization reversal occurs through the nucleation of reversed domains. The minor loops starting from the demagnetized state show that the magnetic field required for the saturation of H_c is much smaller than H_c , which is characteristic of nucleation-type magnetization reversal. With increasing d to 5000 nm, in contrast, no characteristic behavior of nucleation-type magnetization reversal is seen, suggesting that magnetostatic energy and/or domain wall pinning are dominant factors.

All the dot arrays prepared show small effective demagnetizing factors compared with those for sintered permanent magnets. These small effective demagnetizing factors may result from with the high crystallinity of epitaxial films and/or the small dipolar interaction between dots with the well-defined geometry prepared by lithography technique.

A critical requirement for future bit patterned media (BPM) applications is the control and reduction of the magnetic switching field distribution (SFD) for reliably addressing single magnetic islands (bits) in the write process. Here, we use the DH(M,DM) method [1-3] to separate dipolar interactions due to neighbor islands from the intrinsic SFD by measuring a series of partial reversal curves of perpendicular anisotropy Co/Pd based multilayer films deposited onto pre-patterned Si substrates. For a 100-nm-period island array the dipolar broadening contributes 22% to the observed SFD. For a 45-nm-period array (318 Gbit/in²) this value increases to 31%. Corresponding experimental data from BPM fabricated by deposition of magnetic ML on pre-patterned substrates are shown in Fig. 1. In Fig. 1a we show the full Micro-Kerr remanent reversal curve together with an MFM image after demagnetization. Figure 1c shows partial reversal curves obtained by setting initially 64%, 38%, and 22% of the islands into the positive magnetized state. In this magnetization plot we compare at any fixed horizontal level the reversal of different portions of islands in the same average dipolar environment i.e., the same average magnetization. The observed horizontal field displacements of the partial reversal curves with respect to the full reversal curve reflect the intrinsic SFD of the islands. If the intrinsic SFD were a delta function and the reversal were only broadened by dipolar interactions, then the partial reversal curves in Fig. 1c would show no horizontal displacement from the full reversal curve. In Fig. 1d we plot the same partial reversal curves after subtracting the initial magnetization values, such that the initial Kerr amplitudes match. Here we compare the reversal of the same islands in different dipolar environments. In the absence of dipolar interactions the partial reversal curves should follow the major reversal curve until saturation is reached. The observed horizontal displacements in reversal field for the different curves thus provide a direct measure of the dipolar interaction strength. While the plots in Fig. 1c and d provide a straightforward visualization of the intrinsic SFD and the dipolar interactions, a more quantitative determination is obtained by using the DH(M,DM) method [1-3]. Corresponding results are presented in Fig. 1b, where we compare the total SFD as obtained from Fig. 1a with the intrinsic SFD as extracted via the DH(M,DM) method from the partial reversal curves in Fig. 1c and d.

Our results highlight the importance of quantifying long-range dipolar interactions for determining the intrinsic SFD of patterned media [4,5]. In order to tighten the SFD in BPM it is necessary to address both the intrinsic SFD as well as the dipolar contribution. The intrinsic SFD can be tightened by optimizing pattern and media uniformity, but may also be influenced by tuning the reversal mechanism of the islands via more advanced media structures, such as for example exchange spring media. Dipolar broadening can be reduced by decreasing the magnetic moment of the media itself. However, there are limits to this approach, as it is the field from an island that generates the response in the read sensor and thus more sensitive read heads would be required as well.

Introduction

One method which has been proposed in an attempt to delay the onset of the superparamagnetic limit in magnetic recording is the patterning of thin films into discrete islands each storing one bit [1]. Several fabrication techniques have been explored including Ar⁺ ion milling with a hard mask, which typically results in good pattern transfer with near vertical sidewalls [2]. However, as the island size is reduced, the effects of edge damage and ion implantation become more significant leading to a reduction in magnetic anisotropy and coercivity [3].

In this paper we show the effect of Ar ion milling on the coercivity of Co/Pt multilayer islands at low temperature. Here we present remanence loops measured at two discrete temperatures (9.3K and 21.5K). Studies at room temperature will follow to give a more complete temperature analysis.

Sample Fabrication and Measurements

A Co/Pt multilayer thin film, 100ÅPt + 15x (4ÅCo/10ÅPt), was deposited on a Si substrate using e-beam evaporation at 200C. A 7nm C overcoat (to act as a hard mask for milling) was then deposited by e-beam evaporation on the surface of the multilayer. Direct electron beam lithography (LEO 1530 Gemini FEG SEM and Raith Elphy Plus Lithography System with Laser Interferometer Stage) was then used to expose nanostructures in the resist. 15nm of Ti with a 5nm Au cap layer (required for SEM imaging) was deposited by e-beam evaporation. After lift-off, O₂ plasma etch was used to transfer the Ti pattern into the underlying C layer. The combination of the Ti and C islands then acted as a hard mask for Ar ion milling (2keV, 18mA) which transferred the pattern into the magnetic layer.

Low temperature MFM experiments were then undertaken on several arrays of islands on square lattices with periods ranging from 200nm to 50nm using a custom built low temperature scanning force microscope at 9.3K [4]. The microscope is located within a superconducting magnet capable of producing fields of up to 7T perpendicular to the sample's surface. The sample was firstly saturated to -1.2T after which the field was reduced to zero. An MFM image was then taken at 0T using a Team Nanotec GmbH silicon cantilever with a 4nm Co coated oxidized tip. The field was then positively increased in small increments with MFM images taken at remanence after each field step. Remanence curves were later obtained by counting the number of dots which had reversed between successive scans. These experiments were then repeated on a subset of the arrays of islands (50nm to 100nm period) at 21.5K to observe the effect of temperature.

Results and Further Work

Figure 1a shows a typical MFM image for 60nm period islands. The islands are distinct with clearly discernable up and down states, which are readily countable, facilitating calculation of the SFD and remanence curves. The resulting remanence curves are shown in Figure 1b for the 50-100nm periods. Above 100nm coercivity is approximately constant with a slight peak around 150nm period. Below 100nm island period the coercivity falls steadily from ~5.5kOe to ~1.2kOe at 50nm island period. Although a more detailed study is required, this coercivity reduction indicates that milling does damage edges and that fabrication of smaller islands by this method will be challenging. However, the coercivity of the smaller islands is significantly higher than that achieved in our earlier work using Gold as a hard mask for ion-milling [3], showing that thin Carbon layers can

be used successfully as a hard mask for ion-milling and that significant improvements in performance may be achieved by process optimisation. The temperature effect upon coercivity is clearly seen with the coercivity reducing when the temperature rises from 9.6K to 21.9K, the reduction being larger at higher coercivities as would be expected. Further measurements will be taken at room temperature to determine remanent coercivity across a wider range of temperatures. Analysis of size distributions will be presented and correlations between island size and switching field will be sought.

Magnetic properties of exchange-coupled composite nanoparticles and nanopatterns.

D. Goll, A. Breitling, S. Macke

Max-Planck-Institute for Metals Research, Stuttgart, Germany

Perpendicular magnetic recording on the basis of exchange coupled composite (ECC) media is currently considered to be the most straightforward method to realize ultrahigh recording densities of 1 Tbit/in² and more. ECC media are nanopatterns of magnetically isolated grains each consisting of a hard magnetic and a soft magnetic layer which are coupled by exchange interaction. The phase boundary between the two materials can be sharp or gradual. The composite system combines both high thermal stability of the stored information even for reduced grain dimensions close to the superparamagnetic limit and moderate switching fields which can be afforded by conventional write heads. Here, the first aspect is guaranteed by the magnetically hard component and the second aspect by the magnetically soft component. We have investigated the switching behavior and thermal reversal of composite particles and prepared different FePt/Fe composites.

The switching behavior of a composite particle is shown to be determined by the nucleation field of the soft component and the depinning field of a Neel wall at the phase boundary. Depending on the thicknesses of the layers the reversal process either takes place in two steps by nucleation and a following depinning of a Neel wall (Fig. 1), or in one unique step by an inhomogeneous rotation process. On the basis of micromagnetism analytical and numerical results for critical fields are determined as a function of the thickness of the layers (Fig. 2). Using the nudged elastic band method the minimum energy paths between equilibrium magnetization configurations of the hysteresis loop are calculated. From the minimum energy paths the minimum thermal activation energies for thermal reversal are determined as a function of the applied magnetic field and of the film thickness which is illustrated in Fig. 3 for a FePt/Fe ECC particle.

Composite FePt/Fe bilayers have been prepared by ion beam sputter deposition on MgO(100) substrates. Using electron beam lithography the bilayers have been nanopatterned into arrays of squared nanodots covering 3 mm x 3 mm. Fig. 4 shows for composite FePt/Fe elements the systematic decrease of the coercivity with increasing thickness of the soft magnetic Fe layer. The thickness of the hard magnetic FePt layer has been kept constant. The magnetic properties of the nanostructures are discussed within the framework of analytical and computational micromagnetism. The dependencies of switching fields, switching times and thermal stability of the composite nanoparticles on material parameters, shape, film thicknesses and character of the phase boundary are systematically analyzed. The results allow explicit predictions for the development of optimum high-density recording devices based on ECC media.

Magnetic disk recording is considered to be the most useful storage system in recent days. Discrete track media and patterned bit media are excellent candidates for achieving high density recording such as 1 Tbyte/in² (1)-(5). Because the grooved surface of discrete track media makes head-slides flying instability, the media needs flat surface. To date, a flattening process that SiO₂ is fulfilled into the grooves and extra materials were etched by ion milling has been reported (1). Recently, a gas cluster ion beam (GCIB) process has been proposed and investigated as a novel smoothing technique (6)(7). Gas cluster ions are aggregations of a few or several thousand atoms or molecules. These cluster ions have extremely low energy and show a unique characteristic of lateral sputtering. Thus, GCIB is expected to perform the planarization of discrete tracks in a dry condition. We studied GCIB planarization effect on discrete track carbon surfaces using test samples with fine grooves fabricated by focused ion beam (FIB). Figure 1 shows a schematic diagram of the GCIB apparatus. Ar gas clusters are generated through a skimmer and a nozzle from high pressure Ar gas source, then, ionized and accelerated. In this study, the cluster was formed from about 3000 atoms at maximum in the distribution. Acceleration energy for a cluster is 20 keV. The dose was set 5×10¹¹ ion/mm². At first, we fabricated test samples with variant track pitch by FIB (Hitachi, FB-2000A). The discrete tracks were fabricated on magnetic record media disks with 30-nm-thick carbon overcoat. The track pitches were 100/150/200/300 nm, and the heights of peak-to-valley (P-V) were 15-20 nm. The surface roughness was measured by atomic force microscopy (AFM). At second, the test samples were irradiated by GCIB and the resultant surface roughness were measured by AFM. We compared the roughness before and after GCIB irradiation. Figure 2(a) shows the AFM comparison of the surface roughness of the test sample with the track pitch of 100 nm. The AFM measurements were carried out on the same areas. The discrete tracks with approximately 20 nm P-V were formed by FIB, and the tracks were clearly disappeared by GCIB. The surface after GCIB has peaks and valleys which are different from the initial surface. The decrease of Ra from 4.62 nm to 0.85 nm indicates that the tracks were smoothed by GCIB. The comparison of the power spectrum of the surface roughness (Fig. 2(b)) shows that the low harmonic cycles with 100 nm of the sample after FIB were high, but the sample after GCIB has no dependence on wavelength of 100 nm. We resulted that GCIB irradiation is effective for the planarization of discrete track disks.

The material at the edges of a patterned magnetic thin film is different from the material away from the edges not only owing to the broken symmetry at the edge surface, but also because the patterning process exposes the edges to different conditions that may include high energy ion bombardment, different growth geometry and exposure to air. It seems likely, therefore, that the magnetic properties of the material at the film edge will be different from the magnetic properties in the interior of the structure.

In this talk, we will present recently developed measurement methods for the magnetic properties of the edges of thin films, describing the modeling that underpins the measurement method as well as example measurement results.

The primary method we have chosen for edge property measurements relies on detecting a “trapped spin wave” edge mode [1,2] in the magnetic resonance spectrum of a transversely magnetized, long, straight stripe. Figure 1 shows the modeled precession mode profiles in a stripe of Permalloy. The edge mode forms in the low-field region near the stripe edge with a precession frequency that is lower than the “bulk” modes. Because the edge modes are localized at the film edges, they can be used to monitor the properties of the edge material.

Modeled and measured edge mode frequencies have been found to closely follow a Kittel form:

$$\omega = \gamma[(H_{\text{appl}} - H_{\text{sat}})(H_{\text{appl}} + H_2)]^{1/2}.$$

The importance of this expression is that the two measurable parameters, H_{sat} and H_2 , are properties of the film edge; H_{sat} is the field required to saturate the magnetization perpendicular to the stripe axis, and H_2 is an effective out-of-plane anisotropy for the edge mode.

The thickness dependence of H_{sat} for ideal edges is summarized by a simple approximate expression: $H_{\text{sat}} = 0.5M_s t/(t + d_e)$ where t is the film thickness and d_e is a characteristic distance that an edge mode extends into the interior of the film, approximately 27 nm for Permalloy. Surprisingly, the edge mode depth changes only by a factor of two as the film thickness spans three orders of magnitude [3]. Measurements of the thickness dependence of H_{sat} in real Permalloy stripes qualitatively follow the model predictions for ideal edges, except that the measured values are consistently lower, i.e. the real edges are easier to saturate than an ideal edge [4].

We have also modeled the effects of three types of edge defects on the magnetic edge properties [3]. Dilution of the magnetization near the edge, addition of a surface anisotropy term, and tilting of the edge each have the effect of reducing H_{sat} . At a microscopic level, each of these defects leads to a magnetostatic charge distribution that is less concentrated than the charges on an ideal edge.

The modeled effects of edge surface tilting have largely been confirmed by measurements on 20 nm-thick Permalloy stripes with edge surface angles that vary from 45° to 80° as the etch depth is varied [5]. Over this range, H_{sat} varies by nearly a factor of two. Here, as in the thickness dependence measurements, the measured values of H_{sat} are lower than the modeled values, suggesting that the edges have other non ideal characteristics beyond tilting of the edge surfaces alone.

Magnetic nanodevices of current interest often involve a multilayer stack, so we have recently begun modeling the behavior of interacting edge modes. For stripes of 10 nm Permalloy/ x spacer

/ 10 nm Co stacks, the dynamic modeling reveals two edge modes with two edge saturation fields that correspond to saturation of the Permalloy layer first, and the Co layer at higher fields. Both saturation fields are increased relative to their single-film values. While the saturation fields are clearly identifiable with one film or the other, above the saturation fields, the edge mode precession is not localized in one film or the other. The modes approximate an in-phase (acoustic) mode and an out-of-phase (optical) mode. At 20 nm spacer thickness the mode frequencies (and H_{sat} and H_2 values) are quite close to the single-film values, but the mode intensities show that there are still significant interactions.

Spin injection driven magnetization dynamics: physical insights gained from numerical micromagnetics.

D. V. Berkov¹, J. Miltat²

1. *Magnetic and Optical Systems, Innovent Technology Development, Jena, Germany;* 2. *Laboratoire de Physique des Solides, University Paris-Sud & CNRS, Orsay, France*

If solely referring to magnetization distributions at equilibrium, it seems fair to state that the predictive power of numerical micromagnetics is now well established. In the dynamical regime, magnetization precession around the local and time dependent effective field provides a simple framework for picturing phase-coherent ballistic switching, both under the action of a pulsed field [1], or a pulsed spin-polarized current [2]. In some instances, mode analysis especially, a remarkable agreement has been obtained between cutting-edge experiments and micromagnetic simulations (see, e.g., [3-5]).

In this talk we present an overview of qualitatively important physical insights obtained from micromagnetic simulations of the spin-transfer induced magnetization dynamics. At present it is well established that spin transfer may lead to switching or sustained magnetization precession to be characterized by the power spectral density of one observable, usually the GMR or TMR response. First we focus on a specific nanopillar geometry that experimentally leads to remarkably narrow line widths and unique dispersion characteristics in GMR-type nanopillars [6-7], attempting to evaluate the relevance of numerical micromagnetics in forecasting the dynamic properties of these nano-magnetic Hopf oscillators. More precisely, the following issues will be addressed:

- Phase noise and line width,
- Dispersion in the micromagnetic regime and relevance to experimental data,
- Line width and power spectral density analysis.

In pillars, the main parameters entering the magnetization dynamics master equation may now be extracted from suitable experiments. It will nevertheless be shown that different working hypotheses do lead to markedly different micromagnetic predictions, none of them yet really fitting experimental data and thus potentially raising fundamental physics issues [8].

In the second part of this talk we present a detailed discussion of the point contact experiments [9,10]. We show that in the point-contact geometry highly regular and strongly non-linear oscillation modes can be found immediately after the current exceeds the oscillation onset threshold and persist up to the highest current values for which microwave oscillations in a nanocontact persist [9,10]. Such a behaviour is in strong contrast to the nanopillar devices, where slightly above the threshold regular small-angle oscillations have been detected, and by increasing current quasi-chaotic magnetization dynamics can emerge.

Discussing the non-linear modes in point-contact devices [11], we show that only one of them - the so called 'bullet' - has a relatively homogeneous magnetization configuration of its core, thus enabling its analytical description [12]. For higher currents numerical simulations predict more complicated modes, where the core consists of one or more vortex-antivortex pairs which creation and annihilation governs the mode behaviour. We also show that the formation and mutual rotation of vortex and antivortex could be responsible for the low-frequency oscillations (frequencies ~ 200 MHz) observed in [10] for small external fields and point contacts with relatively large diameters (~ 80 nm).

We conclude this talk by emphasizing first, the importance of an exact knowledge of the Oersted field generated in each specific experimental setup and second, the absolute need for an accurate sample characterization.

Hierarchical multi-scale model: application to FePt.

U. Nowak

Physics, University of York, York, United Kingdom

Well-established methods for the evaluation of magnetic material properties include spin density functional theory, spin models, and micromagnetics. Each of these methods covers only a certain range of time and length scales. In the present paper we introduce a multi-scale modelling approach, bridging the gaps between the three approaches above. The goal is to describe thermodynamic equilibrium and non-equilibrium properties of magnetic materials on length scales from the single atom reaching to micrometres, starting from first principles.

In the first step we model, as an example, bulk FePt in the ordered phase using an effective, classical spin Hamiltonian. This atomistic model [1] was constructed earlier on the basis of first-principles methods. The next step is to simulate this spin model using the stochastic Landau-Lifshitz-Gilbert (LLG) equation. Due to the atomic resolution, this approach covers only length-scales up to some nanometres. However, the thermodynamic equilibrium properties for the magnetisation, the parallel and perpendicular susceptibilities and the exchange stiffness [2] are then used to develop a micromagnetic approach [3,4], based on the Landau-Lifshitz-Bloch (LLB) equation [5]. With the latter approach, thermodynamic equilibrium and non-equilibrium properties of magnetic materials can be calculated for a temperature range from zero up to above the Curie temperature, enabling computer simulations of heat-assisted writing procedures.

As an example, the figure below shows the response of a 48nm x 48nm x 72nm FePt particle to a rapid heat pulse with varying peak temperature. The cell size for the simulation was 3nm. These curves successfully reproduce experimental results, including the times scales for the break down of the magnetisation and the recovery. Especially, even the slow recovery after complete demagnetisation [6] is reproduced.

Magnetisation versus time following a 1ps heat pulse with different peak temperatures. The microscopic damping constant is assumed to be 0.1.

Micromagnetics of Patterned Media Recording.

*T. Schrefl, A. Goncharov, J. Dean, G. Hrkac, S. Bance
University of Sheffield, Sheffield, United Kingdom*

Multiscale micromagnetic simulations are performed for bit patterned magnetic recording. We solve the equation of motion for the magnetization in the head, the media, and the soft underlayer simultaneously. The input for the simulations are the detailed microstructure of the recording media, the geometry of the write head, the intrinsic magnetic properties and the current wave form of the write current. Macropscopic properties like current wave form or read back voltage are input/output of a multiscale simulation that treats the functional behavior of a recording system while taking into account the microscopic magnetization processes during recording and read back. A matrix compression technique is used for fast multiplication of matrices arising from the boundary element method, which is used to calculate the interaction fields between the write head and the storage media.

Recording on bit patterned media requires the synchronization of the write field with the predefined bit pattern. The write field rise time and the phase shift between the write field and the write current depend on fast magnetization reversal and fast changes of the domain configuration within the write head. Whereas the overall behavior is similar from write cycle to write cycle, the local magnetization configuration is not periodic. The domain configuration may change from one period to the next which causes rise time induced jitter. For a head velocity of 20 m/s the rise time jitter will translate into a position jitter of up to 1.5 nm.

Recording simulations on bit patterned media were performed using a standard single pole head with a trailing shield. The islands were of ellipsoidal shape with a length of 30 nm and a width of 7.5 nm. The center to center spacing was 8.98 nm. The island thickness was 3 nm, the air bearing surface (ABS) to media spacing was 3 nm and the ABS to soft underlayer (SUL) spacing was 8 nm. These dimensions lead to a recording density of 2 Tbit/in². For this head media combination we calculated the maximum write margins assuming a distribution of the magnetocrystalline anisotropy between the islands that is effectively zero. The simulations show that it is essential to including magnetostatic effects (interactions between the dots and head-media-head interactions). Using pre-computed write fields for recording simulations reduces the write margins by 42 percent with respect to full micromagnetic simulations that take into account the mutual interactions between head and media.

To compute the write margins we were running the simulations several times with different initial positions of the head. The maximum possible write margin was found to depend on the write frequency. For writing at 1 bit per nanosecond the write margin was 3.5 nm and for writing at 2 bits per nanosecond the write margin was 1.75 nm. Moving the head out of phase a distance greater than the write margin leads to bit errors. Bit errors especially are found for bits where the stray field from the neighboring track is high. The non-uniform magnetization reversal of the dots and the magnetostatic interactions between the dots narrow the write margin. Most of the dots are multi-domain for an extended time period before they reach their final magnetic state (up or down). A snap shot of the magnetization configuration during writing is shown in Figure 2. The switching field of an island can be reduced by about 20 percent applying a microwave assist field with an amplitude of 20 mT and a frequency of 14 GHz.

In order to estimate adjacent track erasure we calculated the energy barrier of bits in the neighboring track under the influence of the cross track head field and compare it with the energy barrier of an isolated single island. The calculated barriers are as follows in units of $k_B T$ ($T=300K$): 52 for the

isolated island, 37 for an island under the interaction field of neighboring islands, and 7.4 for an island under the interaction field of neighboring islands and the cross track head field. Without side shields adjacent track erasure might be a problem if the magnetostatic interaction field and the cross track head field add up.

Figure 1: Multiscale simulation of bit patterned recording. The characteristic length scale ranges from 10 micrometer (writer) to about 2 nanometer feature size in the data layer.

Figure 2: Magnetization reversal of the islands occurs by the nucleation of an reversed domain and successive domain wall motion. The shaded area denotes the position of the pole tip of head.

MODELING THE MAGNETIC PROPERTIES OF NANOPARTICLES: FINITE-SIZE, SURFACE AND EXCHANGE BIAS EFFECTS.

O. Iglesias^{1,2}, X. Batlle^{1,2}, A. Labarta^{1,2}

1. Dpt. Física Fonamental, Universitat de Barcelona, Barcelona, Spain; 2. Institut de Nanociència i Nanotecnologia de la UB (IN2UB), Barcelona, Spain

Magnetic nanomaterials present new magnetic and transport properties that arise due to a complex interplay between the intrinsic properties of the constituents (such as specifically tailored microstructure and finite size or surface effects) and the interactions among the entities forming them [1]. In particular, magnetic systems formed by nanosized particles have attracted increasing interest during the last decade because of their technological applications, ranging from magnetic recording to biomedicine. From the fundamental point of view, the computational approach to the modeling of the peculiar phenomenology of nanoparticle systems is an attractive challenge because, usually, it involves a wide range of time and length scales.

When reducing the size of magnetic particles to the nanoscale, surface and finite-size effects become fundamental in order to explain their unusual magnetic properties. As the size decreases, the magnetic properties of the particles depart from bulk behavior, resulting in reduced magnetization and different thermal dependence. In addition, the reduction in lattice symmetry caused by broken bonds at the particle surface, results in distinct local magnetic anisotropy and exchange interactions at the outer shells with respect to the core spins. Moreover, particle surfaces are exposed to environment and are, therefore, easily oxidized, resulting in compound structures with a ferromagnetic core surrounded by an antiferromagnetic. When cooling in the presence of a magnetic field the magnetic order established at the shell may result in a pinning of magnetic moments at the interface between the two phases giving rise to the so-called exchange bias (EB) effect.

In this contribution, we will review our recent work on the modeling of magnetic nanoparticles. We will focus on Monte Carlo (MC) simulation methods to study the phenomenology associated to finite-size and surface effects in models for a single nanoparticle [1], and to study the microscopic origin of EB effects in nanoparticles with core/shell structure [2,3].

Concerning the first point, we will present phase diagrams of the low temperature equilibrium configurations as a function of the surface anisotropy k_s for different particle diameters that have allowed us to identify a change in the magnetic ordering at high enough (but realistic) values of k_s . Through the simulated low temperature hysteresis loops, we have also identified a change in the magnetization reversal mechanism from quasi-uniform (induced by the core) rotation at low k_s values to a process in which the formation of surface hedgehog-like structures, like the ones displayed in Fig. 1, induce the non-uniform switching of the whole particle.

We will also report on results of MC simulations based on a model of individual core/shell nanoparticle with the aim to clarify the microscopic origin of the experimental phenomenology related to EB. The increase of the exchange coupling across the core/shell interface leads to an enhancement of exchange bias and to an increasing asymmetry between the two branches of the loops (as can be seen in the example shown in Fig. 2), which are due to different reversal mechanisms. A detailed study of the magnetic order of the interfacial spins shows compelling evidence that the existence of a net magnetization due to uncompensated spins at the shell interface is responsible for both phenomena and allows to quantify the loop shifts directly in terms of microscopic parameters with striking agreement with the macroscopic observed values.

Over the past decade, magnetic nano-phased materials have been intensively investigated due to their great potential in many spintronics applications ranging from magnetic data storage to magnetic random access memory and other magnetoelectronic devices. These systems present unique challenges that often cannot be met with conventional simulation techniques. Due to the complex nature of atomic-scale interactions between both localized and induced moments that change drastically over short distances, the mechanisms governing nanostructure stability routinely differ between surface and interior, and are often dominated by entropic effects even at ambient temperatures. The magnetization dynamics close to the Curie point is governed both by transverse and longitudinal fluctuations, which requires accurate representation of the free energy as function of the magnetization. In this milieu, the physics can only be unraveled at the first principles level when combined with statistical methods to include entropy. Specifically, in nanomagnets such as FePt nanoparticles that are only a few nanometers in diameter and where the fraction of atoms within a lattice constant of the surface is large, complex non-collinear magnetic states and entropic effects will contribute significantly to the system's magnetic properties. Modeling the changes in the electronic structure and local magnetic properties requires ab initio electronic structure simulations. Such calculations can be done reliably within the zero temperature framework of the Local Spin Density Approximation (LSDA) to Density Functional Theory (DFT). However, due to the enhanced role of magnetic fluctuations in nanoparticles at finite temperature, the energy of an individual magnetic state is not as useful as in the study of bulk magnetic systems. Rather, it will be necessary to configurationally average over all states accessible at a given temperature using a stochastic sampling technique.

In this talk I will review a generalization [1] of the Wang-Landau method [2] with which we can efficiently compute the density of states and from it the temperature dependent free energy in nanoscale systems with a few thousand microscopic degrees of freedom. I will discuss its application to a first principles based model [3] of FePt nanoparticles to compute the temperature dependent free energy barrier for magnetization reversal in the particles. Results obtained from this new method compare well with simulations using traditional Metropolis method and extrapolate to the correct zero-temperature limit that can be calculated exactly from the model. Interestingly, even in these simple model calculations, where we simply truncate the exchange interactions at the surface, we see deviations from the expected Stoner-Wohlfarth behavior in small particles, as incoherent reversal modes that originate from "looser" spins in the surface regions become important. Furthermore, I will present results of DFT based ab initio calculations for FePt nanoparticles with up to ~1000 atoms. These calculations indicate that there are significant deviations in the local atomic moments compared to bulk values that are not captured in the simple model of the nanoparticles. Finally, I will discuss preliminary results of full-blown hybrid simulations in which the DFT calculations are encapsulated in the stochastic sampling to compute the first principles based free energy of the nanoparticles.

Effective resistance mismatch and magnetoresistance of a CPP-GMR system with current-confined-paths.

J. Sato, K. Matsushita, H. Imamura

Advanced Industrial Science and Technology, Tsukuba, Japan

Current-perpendicular-to-plane giant magnetoresistance (CPP-GMR) has attracted much attention for its potential application as a read sensor for high-density magnetic recording [1, 2]. In order to realize a high-density magnetic recording, we need MR devices with high MR ratio and low resistance area product (RA). Although the RA value of a CPP-GMR system is much smaller than that of a tunneling magnetoresistance (TMR) system, the MR ratio of a conventional CPP-GMR system still remains a small value of a few %. Much effort has been devoted to increasing the MR ratio of the CPP-GMR system.

Recently, Fukuzawa et al. reported that they achieved the MR ratio of 10.2 % by CPP-GMR spin-valve with a current-confined-path (CCP) structure made of a nano-oxide-layer (NOL) with a lot of small metallic channels [3]. They showed that the MR ratio increases with increasing the RA value, which means that the MR ratio is enhanced for the system with narrow metallic channels. The similar enhancement of the MR ratio due to the CCP structure containing a domain wall was also reported by Fukue et al. [4]. The enhancement of the MR ratio due to the CCP structure is theoretically explained by one of the author [5]. However, the analysis of Ref. [5] is based on the assumption that the thickness of the non-magnetic layer is zero.

In 2000, Schmidt et al. pointed out that the conductivity mismatch is a basic obstacle for spin injection from a ferromagnetic metal into a semiconductor. Spin polarization of the injected current is strongly suppressed by the conductivity mismatch between these materials. Since the CPP-GMR system is made of thin films of different materials, we also have the conductivity mismatch in this system. However all the materials of the usual CPP-GMR systems are metals, the effect of the conductivity mismatch is not important. In Fig. 1 (a) we plot the MR ratio of the ferromagnet (F) / non-magnet (N) / ferromagnet (F) trilayer system as a function of the ratio of the effective resistance. One can see that the MR ratio takes the maximum value when the effective resistances of ferromagnetic layer and non-magnetic layer are the same, i.e., the effective resistance are matched to each other.

However, for the CPP-GMR system with current confined paths, the effective resistance of the contact region increases with decreasing the width of the contact. Therefore, it is intriguing to ask how the mismatch of the effective resistance affects the MR ratio of the CPP-GMR system with current confined paths.

We numerically solve the spin diffusion equation [7] by use of finite element method in the contact geometry shown in Fig. 1(b) and calculate the MR ratio due to spin accumulation. A narrow non-magnetic metallic contact is sandwiched in between two ferromagnetic electrodes. CoFe and Cu are adopted as the ferromagnetic layers and non-magnetic metallic contact, respectively.

In Fig. 1(c), we plot the MR ratio of the CPP-GMR system with current-confined-paths against the radius of the narrowest cross section of the contact region. We use five values for resistivity of non-magnetic metallic contact, which corresponds to the variety of the purity of Cu in the NOL. Decreased resistivity of non-magnetic metallic contact means increased purity of Cu in the NOL. As is seen in Fig. 1(c), MR ratio increases with increasing the purity of Cu, which is consistent with the experimental results [3].

Moreover, one can see that the contact radius at which the MR ratio takes the maximum value decreases with decreasing the resistivity of non-magnetic metallic contact. This behavior can be

understood as the concept of conductivity matching between ferromagnetic layer and non-magnetic metallic contact. In order to maximize the MR ratio of the system with the contact of low (high) resistivity, the contact should be narrow (wide) since the effective resistance is proportional to the resistivity over cross section.

As pointed out by Schmidt et al. [6] and Rashba [8], the large interfacial resistance can resolve the conductivity mismatch problem. Therefore, we are now studying the effect of the interfacial resistance on the MR ratio of the CPP-GMR system with a current confined path. We will present details of our analysis, effect of the interfacial resistance on the MR ratio and comparison with recent experimental results.

The magnetization direction of the magnetic layers can be reversed by spin-polarized currents [1,2], and this current-induced magnetization switching (CIMS) at reduced critical current density (J_c) has been studied in various magnetic tunnel junction (MTJ) structures. In particular, giant tunnel magnetoresistance (TMR) ratios together with CIMS have been expected theoretically and observed experimentally as well in the CoFeB/MgO/CoFeB MTJs. In a recent study, CIMS with synthetic ferrimagnetic (SyF) free layers of $\text{Co}_{40}\text{Fe}_{40}\text{B}_{20}$ /Ru/ $\text{Co}_{40}\text{Fe}_{40}\text{B}_{20}$ has been investigated, and J_c has been found to be reduced without losing thermal stability [3]. In order to elucidate the underlying physical mechanism for the use of antiferromagnetically coupled CoFeB/Ru/CoFeB trilayer systems as a free layer, knowledge of magneto-transport properties of both CoFeB and CoFeB/Ru interfaces is required. In this work, CoFeB-based exchange-biased spin valves (EBSVs) and CoFeB/Ru multilayers were fabricated to examine the spin diffusion length l_{sf} and the bulk spin-scattering asymmetry β of CoFeB and extract the interfacial specific resistance $2AR^*$ and spin-scattering asymmetry γ of CoFeB/Ru interfaces, respectively. The $[\text{FeMn}(8)/\text{CoFeB}(t_F)/\text{Cu}(20)/\text{CoFeB}(t_F)]$ EBSVs (the numbers in the parentheses indicate the thickness of the layers in nanometers) were made by DC magnetron sputtering, and the MR measurement (at 4.2 K) has been done in the current-perpendicular-to-plane (CPP) geometry using a bridge circuit with a superconducting quantum interference device (SQUID) null detector. The hysteresis curve for the CPP specific resistance AR (area times resistance) of a $\text{Co}_{40}\text{Fe}_{40}\text{B}_{20}$ -based EBSV with $t_{\text{Co}_{40}\text{Fe}_{40}\text{B}_{20}} = 7$ nm is shown in Fig. 1 (see the inset). We found almost ideal CPP-MR behavior for the EBSV samples with $t_{\text{Co}_{40}\text{Fe}_{40}\text{B}_{20}} \geq 5$ nm which show the well-separated pinned (solid arrows) and unpinned (dashed arrows) loops, giving well-defined parallel (P) and antiparallel (AP) states. For the samples with $t_{\text{Co}_{40}\text{Fe}_{40}\text{B}_{20}} < 5$ nm, the strong exchange-biasing effect exists and only the pinned loop is observed. We also tried the experiment with a $\text{Co}_{56}\text{Fe}_{24}\text{B}_{20}$, and the overall trend of ΔAR (the difference in the specific resistance between the P and AP state) with various CoFeB thicknesses remains unchanged except that ΔAR in $\text{Co}_{56}\text{Fe}_{24}\text{B}_{20}$ is smaller than one in $\text{Co}_{40}\text{Fe}_{40}\text{B}_{20}$ for the same CoFeB thickness partly due to the smaller saturation magnetization (M_s) of $\text{Co}_{56}\text{Fe}_{24}\text{B}_{20}$. ΔAR versus t_{CoFeB} for a series of EBSVs is summarized in Fig. 1 (solid circles for $\text{Co}_{40}\text{Fe}_{40}\text{B}_{20}$ and open circles for $\text{Co}_{56}\text{Fe}_{24}\text{B}_{20}$, respectively). The data in Fig. 1 saturate in value beyond $t_{\text{CoFeB}} \sim 15$ nm and the saturation value of ΔAR , $\Delta AR(\text{sat})$, is given by a Valet-Fert (VF) [4] extension to finite spin diffusion length as, $\Delta AR(\text{sat}) = 4(\beta_F \rho_F^* l_{sf}^F + \gamma_{F/N} AR_{F/N}^*)^2 / (2\rho_F^* l_{sf}^F + \rho_N t_N + 2AR_{F/N}^*)$, where β_F and l_{sf}^F are the spin-scattering anisotropy and the spin diffusion length of the ferromagnetic layer F, respectively, and the resistivity $\rho_F = \rho_F^* (1 - \beta_F^2)$ can be measured independently by Van der Pauw (VdP) measurement. The saturation of ΔAR requires a short spin diffusion length of the ferromagnetic layer, and makes the numerical VF fit indispensable. In this experiment with EBSVs, the important parameters to be extracted are the spin diffusion length l_{sf}^F and β . For both CoFeB concentrations, we thus ignored the interfacial resistance $2AR^*$ and spin-scattering asymmetry γ of CoFeB/Cu interfaces, and we have found that those parameters have negligibly small effect on the fitting results. It should be noted that VF theory with $\beta = 0.26 \sim 0.3$ and $l_{sf}^F = 4.5 \sim 4.8$ fits well to our experimental data. By comparing the obtained l_{sf}^F with that of $\text{Co}_{91}\text{Fe}_9$ [5], it is easily seen that the mean distance electrons diffuse between spin-flipping collisions is much

shorter in CoFeB, which may be an evidence of increased spin accumulations at CoFeB/Ru interfaces in the SyF free layer which would lead to the efficient spin-transfer-torque exerting on the magnetization of the free layer. In summary, the magneto-transport properties of CoFeB have been carefully studied to give a useful clue for J_c reduction in MgO-based MTJs with CIMS. The spin diffusion length for $\text{Co}_{40}\text{Fe}_{40}\text{B}_{20}$ and $\text{Co}_{56}\text{Fe}_{24}\text{B}_{20}$ is found to be $4.5 \sim 4.8$ nm while the spin-scattering anisotropy β is about 0.3.

Magnetoresistance and switching properties of $\text{Co}_x\text{Fe}_{100-x}/\text{Pd}$ -based perpendicular anisotropy single and dual spin valves without exchange bias.

R. Law^{1,2}, R. Sbiaa¹, T. Liew¹, T. Chong¹

1. Data Storage Institute, A*STAR (Agency for Science, Technology and Research), Singapore, Singapore; 2. NUS Graduate School for Integrative Sciences & Engineering, National University of Singapore, Singapore, Singapore

Magnetoresistive devices based on layers with perpendicular magnetic anisotropy (PMA) have been receiving increasing interest as they do not suffer from magnetization curling at the edges of patterned elements, which causes switching field fluctuations and cell instability. Recently, exchange-biased spin valves [1] and spin transfer switching in all-metal current-perpendicular-to-plane pseudo-spin valves with PMA have been demonstrated [2]. We report high current-in-plane giant magnetoresistance (CIP-GMR) of 9.7% and 13.0% in single-spin valves (SSV) and dual-spin valves (DSV) with PMA based on $\text{Co}_x\text{Fe}_{100-x}/\text{Pd}$ bilayers, respectively, a significant improvement over previous work [3]. Good separation and large coercivity difference in the magnetic layers was achieved without exchange biasing.

Perpendicular anisotropy spin valves were deposited using UHV dc magnetron sputtering onto thermally oxidized (100) Si wafers. The film structures of Ta/Pd/Soft layer/Cu/Hard layer/Pd/Ta and Ta/Pd/Hard layer1/Cu/Soft layer/Cu/Hard layer2/Pd/Ta were realized for SSVs and DSVs, respectively. The soft and hard magnetic layers were based on $(\text{Co}_x\text{Fe}_{100-x}/\text{Pd})_n$ bilayers, with layer thicknesses optimized for PMA and MR performance. In our spin valves, we have studied the effect of seed layer, crystalline orientation, annealing and various $\text{Co}_x\text{Fe}_{100-x}$ alloy compositions on PMA and GMR. Ta seed layers and the fcc (111) orientation were shown to be necessary to obtain good perpendicular anisotropy and sharp switching in the MR curves. As shown in Fig. 1, annealing improved the PMA of the magnetic layers but at the same time significantly depressed the MR ratio. This irreversible reduction of MR with annealing temperature was attributed to interdiffusion and alloying of CoFe and Pd within the magnetic layers, resulting in increased film resistance and reduced spin polarization.

Fig. 2 shows the maximum MR achieved for Co/Pd-, $\text{Co}_{90}\text{Fe}_{10}/\text{Pd}$ - and $\text{Co}_{65}\text{Fe}_{35}/\text{Pd}$ -based SSVs by optimizing Pd layer thicknesses while keeping $\text{Co}_x\text{Fe}_{100-x}$ and Cu spacer thicknesses constant. The highest MR of 9.7% was achieved for both Co and $\text{Co}_{90}\text{Fe}_{10}$ due to their similar compositions and identical critical Pd thicknesses required to maintain PMA. However, we note that the Co/Pd layers exhibited significantly larger coercivities than the $\text{Co}_{90}\text{Fe}_{10}/\text{Pd}$ layers due to the lower saturation magnetization and better fcc (111) orientation of Co compared to $\text{Co}_{90}\text{Fe}_{10}$. On the other hand, the weaker PMA in $\text{Co}_{65}\text{Fe}_{35}/\text{Pd}$ bilayers required thicker Pd within the bilayers to maintain perpendicular anisotropy, resulting in a lower MR of 7.0% due to increased current shunting and spin depolarization of conduction electrons.

We also describe the switching behavior of a Co/Pd-based perpendicular DSV with four distinct resistance states, as shown in Fig. 3, confirming that a DSV structure behaves as a simple additive/subtractive combination of two single spin valves. Such a DSV structure has potential for reducing spin transfer switching current densities as well as for multi-state storage devices.

Magnetic structure of domain walls confined in a nano-oxide layer.

K. Matsushita, J. Sato, H. Imamura
 Nanotechnology Research Institute, AIST, Tsukuba, Japan

Geometrically confined domain walls of nano-meter size contacts have drawn enormous attention because of its potential applications to future spintronic devices [1]. In the last decade much effort has been devoted to study the magnetoresistance of atomic wires. One of main obstacles to applications of the atomic wires is mechanical stability. For example, Chopra et al. [2] reported that a Co atomic wire that shows 300% magnetoresistance (MR) ratio is stable for periods of up to as short as 2-3 min.

Recently, Fuke et al. fabricated the spin-valve with a current-confined-path structure made of a nano-oxide-layer (NOL) with a lot of fine holes filled with ferromagnetic metal [3]. Structures of domain walls confined in an NOL are very stable and typical size of the holes is as small as a few nano meters. They showed that the MR ratio increases with increasing a value of the resistance area product, which means that the MR ratio is enhanced for the system with narrow metallic channels. Doi et al. reported that a microwave oscillation of the domain wall in the NOL is induced by applying current perpendicular to the plane [4]. In order to understand these experiments, it is important to study magnetic structures of the domain walls and its effect on the MR ratio and on the current induced microwave oscillation. Since the domain walls are confined in an NOL, it is very difficult to observe the magnetic structure directly. The micromagnetics simulation technique provides a powerful tool for studying the magnetic properties of such domain walls in an NOL.

We study size dependence of magnetic structures in three-dimensional contacts as shown in Figs. 1 (a)-(c). The systems are divided into 2365 elements and dynamics of local magnetization of these elements are calculated numerically by solving the Landau-Lifshitz-Gilbert equation. Magnetic field due to the dipole-dipole interaction is evaluated by a finite-element-method and boundary-element-method (FEM-BEM) hybrid method [5]. For simplicity, we consider permalloy contacts, the crystalline anisotropy of which can be ignored. The material parameters are taken as $A = 1.3 \times 10^{-11}$ J/m and $M_s = 8.0 \times 10^5$ J/m³. The characteristic length of magnetic structures in the contacts is Bloch line width defined as $(2A/\mu_0 M_s^2)^{1/2} \sim 2.2$ nm.

Figures 1(a) and 1(b) shows typical magnetic structures of the nano contacts. When the contact is much larger than the Bloch line width the vortex-like magnetic structure shown in Fig. 1(a) is favored. As we decrease the size of the contact the Neel-wall-like structure shown in Fig. 1(b) becomes more stable than the vortex-like structure. For the contact with 20nm height, the vortex-like structure shown is a meta-stable magnetic structure and the other meta-stable magnetic structure is the Neel-wall-like one. For the contact with 2nm height, which is comparable small to the Bloch line width, the Neel-wall like structure shown in Fig. 1(b) is the only stable magnetic structure.

The typical thickness of the nano-oxide-layer studied by Fuke et al. and by Doi et al. [3,4] is about 2 nm. In the case, the magnetic structure of the domain wall should be Neel-wall like as shown in Fig. 1(b). Figure 1(c) shows the stiffness energy distribution on a cross section of the contact. One can see that the domain wall is well confined in the contact region and the stiffness energy. Absolute values of a gradient of local magnetization rotation angles are almost uniform in the contact region. Since magnitude of spin transfer torque is proportional to the absolute values of the gradient of the local magnetization rotation angle, the spin transfer torque is uniformly distributed in the whole of the contact. We will report details of our study and comparison of the calculated inter-layer coupling field with the recent experimental results.

MICROMAGNETIC STUDY ON DOMAIN WALL SIZE FOR NANOCONTACT MAGNETORESISTANCE IN SPIN VALVE STRUCTURE.

M. Takagishi, H. N. Fuke, S. Hashimoto, H. Iwasaki
Corporate R&D Center, TOSHIBA Corporation, Kawasaki, Japan

Introduction

New MR technologies are expected with both a high dR/R of more than 100% like TMR and a low RA of less than $0.5\Omega\mu\text{m}^2$ like CPP-GMR. Recently it has been reported that FeCo nanocontacts (NCs) in CPP spin valve shows an MR ratio of about 10% [1], which MR origin is considered to be domain wall MR with a theoretical dR/R of more than 100% because of NCs of 1-3nm in diameter observed by a conductive AFM technique and large interlayer coupling, compared to CCP-CPP-GMR using Cu metal paths. It is expected that the smaller nanocontact size with the smaller domain wall increases MR ratio. Fig 1 shows the MR ratio dependency on domain wall size by using the theory of reference [2], with a spin asymmetry as a parameter. The theory indicates that FeCo NC with 2nm domain wall length shows an MR ratio of 160%. If nanocontact size is roughly equivalent to domain wall size, the experiment MR ratio can not be explained by the theory. In this paper, we report the relation between nanocontact size and domain wall size by using micromagnetic simulation and discuss about the discrepancy between experiment and theory

Simulation model

Fig 2 shows the model geometry of the nanocontact. Periodic boundary conditions are set on the four surfaces of this model. We have investigated domain wall size when changing NC size and Nano-Oxide-Layer (NOL) thickness in this figure, which are corresponding to NC width and NC length respectively. The contour of Fig 2 shows magnetization component in the direction of y-axis when $H_y(\text{external field})=500\text{Oe}$.

Result and Discussion

Fig. 3 shows domain wall size dependency on NOL thickness and NC size. The domain wall size is defined as the span from +90% to -90% magnetization changing points. Domain wall size decreases with reducing NC size and NOL thickness. The domain wall size of our experimental film is estimated to be about 3nm from figure 3 because the experimental NC size is around 2nm and the NOL thickness is 1.2nm. Note that figure 1 shows an MR ratio of around 72% for 3nm NC size. This theoretical MR ratio is still larger than that of experiment.

There could be two reasons of the MR ratio discrepancy. One is impurity in NCs area. dR does not change clearly for zero field cooling, while it clearly changed at 150~200 degree C for 10kOe field cooling to the PtMn exchange-biased direction, as shown in Fig.4. Furthermore, interlayer coupling between pinned and free layers also change as dR changes for field cooling. Not that some Fe(Co) oxides have a magnetic transition at low temperature. This implies that magnetic oxides exist around NCs and cause a change of MR characteristic.. Another possible reason is that the NCs size might be too small to apply the Levy and Zhang theory for diffusive bulk scattering[3]. We will try to apply the more ballistic theory for our NCs.

Introduction

The magnetic and transport properties in magnetic nanowires have become an interesting topic in recent years, partly due to the need for a nanometer-scale magnetoresistance (MR) device in spintronic and high density magnetic recording applications. The advance in nano technology has made fabrication of magnetic multilayer structure in nanowires possible. As the dimensions of the device shrink to hundreds of atoms, many unexpected phenomena related to quantum size effect appear [1]. Previously, we have shown that in metallic nanowires, surface roughness plays an important role that can substantially increase the resistivity beyond the bulk value. In this work, we explore the effect of surface scattering on the magnetoresistance in a multilayered nanowire. It is found that even without any spin-flip scattering, the MR is significantly reduced by surface roughness.

Model

We consider two segments of 3-dimensional ferromagnetic (FM) nanowire joined by a spacer with negligible thickness and attached to two clean semi-infinite leads on both sides, as shown in Fig. 1. The FM leads are modeled by a single band tight binding Hamiltonian with a hopping integral 1eV and exchange splitting is also chosen to be 1eV. The nanowire is embedded into an insulating surrounding environment serving as the template in which the wire is deposited. The commonly used template material is alumina with a scattering potential of 3eV [2]. The rough interface between the nanowire and template is assumed to follow a Gaussian distribution with a standard deviation of one atomic spacing. The Landauer formalism along with a recursive Green's function technique is employed to calculate the transport properties. The resistance of parallel (PA) and anti-parallel (APA) alignment of magnetization, as well as the MR, are numerically calculated as a function of wire length and diameter.

Results

Resistance of both PA and APA channels is first calculated as a function of wire length as shown in Fig. 2 (a) for a wire of 10 atoms by 10 atoms. The variation of the MR ratio is plotted in Fig. 2 (b). When length is zero, electron transport is ballistic and MR ratio is maximal. As L increases beyond the mean free path, the transport crosses over to the diffusive regime. In this regime the resistance scales linearly with wire length obeying a quantum version of Ohm's law. A key observation in Fig. 2 (a) is the resistance for PA and APA channels increases at similar rates. Therefore, the numerator in the usual MR definition ($MR = (R_{APA} - R_{PA}) / R_{PA}$) remains a constant, but the denominator keeps increasing with L . Therefore the MR ratio drops with increasing length as expected (Fig. 2 (b)).

More interestingly, the resistance is calculated as a function of width for wires of equal length in Fig. 3 (a). As the wire becomes wider, the resistance of PA and APA channels decreases at approximately the same rate. As a result the MR increases as shown in Fig. 3 (b). Surface roughness beyond the minimal value (approximately 0.25nm) assumed here will greatly accentuate the effect. Therefore, surface scattering, which is inevitable in many fabrication processes, can significantly reduce the MR ratio. The MR can be recovered by increasing the sample width. As the size of MR devices shrink to a scale comparable to the mean free path, we expect this surface effect to seriously impact performance.

CPP-GMR characteristics of full epitaxial spin valves film with alternate monatomic [Fe/Co]_n superlattice.

I. Chu, T. Mano, M. Doi, M. Sahashi

Department of Electronic Engineering, Tohoku University, Sendai, Japan

[Introduction]

In order to realize higher areal density magnetic recording, it is necessary to improve the sensitivity of read heads and to find a new Magneto-Resistance (MR) mechanism for sensing the weak signal from media with higher efficiency. MgO-TMR (Tunnel Magneto-Resistance), which is low resistance area product (RA) of around $0.5 \Omega\mu\text{m}^2$, is most powerful to realize 1 Tbps magnetic recording in considering the areal density with lower RA. The read head with a lower RA than $0.5 \Omega\mu\text{m}^2$ are preferable from the standpoint of a frequency response because RA of MgO-TMR is still high due to its oxide barrier. So, a full metal CPP (Current Perpendicular to Plane)-GMR is considered to be the candidate for over 1 Tbps. So far the body-centered-cubic (bcc) Fe₅₀Co₅₀ spin valve GMR is reported to show the large spin scattering asymmetry coefficients (β and γ) in CPP geometry¹⁾, which suggests that Fe₅₀Co₅₀ alloy has the advantage of a high spin polarization. When the ordered state with B2 structure is realized, how high is MR performance in comparison with the disordered Fe₅₀Co₅₀ alloy. So, the study of the alternate monatomic layer (AML) [Fe/Co]_n epitaxial film system with artificially ordered B2 structure is very interesting from the view point of a spin conductance mechanism in CPP geometry. And moreover this B2 structure Fe₅₀Co₅₀ (001) has the property of a symmetry Δ_1 Bloch state at $k_{\parallel}=0$ for only majority, where the symmetry based spin-filtering effect is most effective for $k_{\parallel}=0$ ²⁾. The ordered Fe₅₀Co₅₀ alloy is likely to be a suitable material for application to CPP-GMR and TMR devices in CPP system.

[Experimental]

The Epitaxial film stacks were prepared on MgO (001) substrates by Electron Beam (EB) evaporation technique. To examine the structure of the deposited epitaxial films, we used in-situ Reflection High-Energy Electron Diffraction (RHEED) technique for investigating the epitaxial property and in-situ STM for topography of the epitaxial film surface³⁻⁵⁾. Normally, the deposition using the Fe₅₀Co₅₀ alloy target was also performed as the reference. The growth of an epitaxial film with 21 MLs (1 Monolayer : 0.14nm) of [Fe/Co] on MgO (001) was performed at a substrate temperature of 75 °C and a typical base pressure of less than 10^{-7} Pa. The mismatch of lattice between the samples and MgO substrate is estimated as 4.1 %. The disordered Fe₅₀Co₅₀ alloy film with thickness of 2.94 nm was fabricated at a substrate temperature of 75 °C, corresponding to that of AML [Fe/Co] 21 MLs in alternate monolayer deposition. The Au electrode and spacer layer were selected for the full epitaxial system because of the small lattice mismatch around 1.0 % to the AML [Fe/Co]_n layer. The seed Fe layer and Au epitaxial film for bottom electrode were performed at a substrate temperature of 300 °C. The full epitaxial trilayer on Au electrode was prepared with the design of Au 300 (nm)/ AML [Fe/Co]_n/ Au 5 (nm)/ AML [Fe/Co]_n. Finally, IrMn layer for pinning was deposited on the top of full epitaxial trilayer. The CPP-SVs elements were fabricated with the size from 1.5 to 4 μm by the conventional photo lithographic method.

[Results and discussion]

We confirmed the structural properties of trilayered epitaxial films with AML [Fe/Co]_n (R_a : 0.18 nm) and Fe₅₀Co₅₀ alloy epitaxial film on Au electrode by RHEED before confirming the characteristic of CPP-GMR³⁾.

The performance of CPP-GMR sensors that use spin-valves made of conventional materials with Cu spacer is limited by their less than $1.6 \text{ m}\Omega\mu\text{m}^2$ specific magnetoresistance change (ΔRA : resist-

ance-change x area). This value is small because of the small change in film resistance that occurs when the relative angle between magnetizations of two magnetic layer materials is changed. The resistivity change ΔR originates from only functional parts in CPP-GMR. The specific resistivity change, ΔRA , were estimated to be 1.02, $1.59 \text{ m}\Omega\mu\text{m}^2$ for SVs with Fe₅₀Co₅₀ alloy and AML [Fe/Co]_n respectively. If we assume the short distance of spin diffusion length of Au spacer compare to Cu, the observed ΔRA is fairly large value. The ΔRA of SVs with AML [Fe/Co]_n is 1.5 times higher than that of SVs with Fe₅₀Co₅₀ alloy. We assume that high ΔRA results from high spin polarization of AML [Fe/Co]_n due to increasing the degree of ordering by artificial AML [Fe/Co] deposition method.

Generating a microwave signal by the pure electronic way using the spin transfer effect has become an important axis of the present evolution of spintronics. The physics of the interaction between a spin current and a magnetization is new and many questions remains. Especially it will be very important to get a deeper insight on the excited modes induced by spin transfer depending on the dc current or the applied field as well as the relaxation process that govern the linewidth of the emission. This new type of microwave oscillators also called STOs (Spin Transfer Oscillators) are non-linear oscillators very promising for applications in next generation telecommunication devices[1,2]. However the increase of the output power is a major challenge since the emitted power by a single STO is far too weak (< 1 nW). Some solutions have to be found to increase the amplitude of the spin torque and also to find some mechanisms to achieve the synchronization in frequency and phase of an array of STOs [3-6].

In the present work, we have focussed our study on spin valve nanocontacts. In fact, up to now, these are the device geometry that have yield the best microwave characteristics (agility, linewidth etc.). We have elaborated ultra small nanocontacts (less than 20 nm of diameter) using the original nanolithography process we have recently developped using a real time controlled nanoindentation technique [7]. On Fig 1, we present a scheme of the two types of structures we have studied : standard nanocontacts (a) and hybrid nanocontacts (b).

For standard nanocontacts, we have studied two configuration i.e. applied field in the plane and out of the plane. In the first case, we have detected some power emission only at high field and very low frequency (50-100 MHz). Moreover, the power amplitude remains always very weak. De plus, les niveaux de puissance sont relativement faibles. In Fig.2, we show the results obtained for an out of plane field of -2740 Oe. Like for the in plane field, we have detected only some low frequency oscillations (around 50 MHz) that can however achieve 2GHz. As it can be seen, several orders of harmonics can be observed. The power emission is much higher in this configuration and can be as high as $50 \text{ pW/mA}^2/\text{GHz}$. The frequency of the emission are much lower than the ones expected for FMR resonances of the uniform mode. Thus, we believe that these microwave emissions are probably associated to non uniform dynamics created by both the spin transfer torque and the Oersted field. These recent results we want to extend are in very good agreement with the latest results of Puffall et al from NIST, Boulder [8].

For the hybrid structures, some very interesting and promising results have been obtained in this geometry. It is important to note that we have identified that we detect indeed some excitations inside the Co nanocontacts (50nm thick) and not in the extended NiFe layer. On Fig. 3a, we present one of the most intense peak that has been ever measured in STOs about $1 \text{ nW/mA}^2/\text{GHz}$. Moreover, These sub-GHz oscillations present an hysteretic character as a function of the injected current. As shown in Fig.3b, the onset of the oscillations is around 420 MHz and -4.2 mA for increasing current whereas they exists down to -4 mA with frequencies down to 300 MHz. These results are compatibles with some translationnal motion of a vortex or any other type of non homogenous magnetic configuration. In fact, several groups express a big interest for these types of oscillations since they present very thin linewidth [9].

Layered annular magnetic bridges for storage and logic applications.

F. J. Castano, B. G. Ng, C. H. Nam, C. A. Ross

Depart. of Material Science and Engineering, MIT, Cambridge, MA

The magnetotransport response of magnetic elements patterned from hard layer/ non-magnetic spacer/ soft layer structures is dominated by giant magnetoresistance (GMR) and results in distinct resistance levels depending on the relative alignment of the magnetization in the hard and soft layers. The ability to electrically discriminate these non-volatile magnetic states in elliptical structures has already been exploited commercially in magnetic random access memories and has recently been proposed to create logic devices [1]. On the other hand, ring-shaped layered elements have been recently shown [2] to display multiple resistance levels due to the existence of vortex-like configurations in both the hard and soft layers, which may be utilized to store more than one bit-per-element in storage applications. The present work explores the magnetotransport response of annular NiFe/Cu/Co structures using Wheatstone bridge (WB) contact configurations. Such bridges became unbalanced as each layer transitions into a vortex-like state, giving large changes in voltage. This behaviour is observed even for annular structures with deep-sub-micron dimensions and offers the possibility of operating these devices as non-volatile logic gates that do not require reprogramming after each operation.

Prototype devices (Fig.1) consisting of elliptical, circular and rhombic NiFe/Cu/Co ring-shaped elements with up to six Ta/Cu electrical contacts were fabricated using lift-off processing and a combination of optical and electron-beam lithographies.

(Fig 1)

The magneto-transport response was investigated using a 4-point technique with a 0.01mA current at 1kHz. The results from two different measurement configurations will be presented. In the first one the current is injected using two diametrically opposed leads and the voltage measured using two leads located on one side of the ring (Fig1.(a)-(d)). The highest resistance using this method (V13 in Fig.2 (a)) corresponds to both layers being antiparallel each in onion states, in agreement with previous work [2]. In the second configuration both current and voltage leads are located at diametrically opposed sites in the rings forming WB configurations, Fig.1(a)-(f). These measurements allow for the difference between both branches of the bridge to be measured. Interestingly, the greatest unbalance of the bridges corresponds to field ranges over which each ring is in a vortex configuration.

(Fig 2)

These results can be understood using micromagnetic modeling combined with an electrical model. Fig. 2(c) shows the calculated MR major half-loop for WB configurations. As the field is decreased from positive saturation, two 180deg domain walls form in the hard layer and their stray fields promote a reversal of the soft layer unlike that observed in single-magnetic layer rings. The soft layer reverses from both ends by the propagation of four 180deg domain walls. As these walls traverse the structure, they form intermediate configurations stable at remanence, such as state [1] shown in the inset in Fig.2c, which corresponds to the soft layer peak resistance in the WB model. As the reversal of the soft layer proceeds the four 180deg domain walls form metastable 360deg walls (state [2]), which collapse at higher fields. The hard layer transitions into a vortex-like state with multiple 360deg walls, which results in parallel and antiparallel orientation between the soft and hard layers in each half of the ring (state [3]), creating an unbalanced bridged particularly for smaller and narrower rings. Further increase of the reverse field nucleates a bi-domain state in the hard ring (state [4]) and the soft and hard ring become parallel (except for small areas corresponding to

residual 360deg walls). These magnetic configurations are shown in Fig. 2. We will compare this field-induced reversal with current-induced reversal in identical structures.

Investigation of strong biquadratic coupling in Co₂MnSi based trilayer structures.

Y. Sakuraba, S. Bosu, K. Saito, H. Wang, S. Mitani, K. Takanashi
Institute for materials research, Tohoku univ., Sendai, Miyagi, Japan

Half-metallic ferromagnets, which have perfectly spin-polarized conduction electrons, have attracted much interest in the spintronics field. One of full-Heusler alloys, Co₂MnSi(CMS), is expected as a promising half-metal because of its high Curie temperature well above RT ($T_C = 985$ K). Recent studies on magnetic tunnel junctions with CMS have showed extremely large TMR ratio of 570%, which clearly indicates half-metallic nature of CMS.[1] Although interlayer exchange coupling (IEC) behavior in FM/NM/FM nanostructures has extensively been studied in a wide variety of materials for a few decades, the knowledge of IEC in half-metal-based structure has been limited so far. Recently we have reported strong biquadratic coupling ($H_s \sim 8$ KOe) with large oscillation period (3.3-3.5 nm) in epitaxial CMS/Cr/CMS trilayers. [2] The origin of this novel IEC behavior is still unclear. The electronic basis for the coupling between ferromagnetic layers through an intervening metal depends on the relative energy alignment of the spin-split bands. [3,4] Therefore it is interesting to investigate whether there is any relation between half-metallicity i.e. spin polarization and IEC or not.

The electronic structure of CMS was predicted to be sensitive to its chemical ordering [5]. Picozzi *et al.* reported that, Co-antisite creates in-gap state and causes a large depolarization effect. Therefore it is possible to examine the relation between IEC behavior and half-metallicity by fabricating CMS having different degrees of chemical ordering which can be controlled by annealing temperature. The purpose of this study is to clarify the relation between observed novel IEC behavior and half-metallicity of CMS by investigating the IEC behavior for CMS/Cr/CMS trilayers with different annealing temperatures for the bottom CMS. CMS(20 nm)/Cr(1.2 nm)/CMS(7 nm) trilayer samples were prepared by a UHV-compatible dc-sputtering method on MgO substrates. We annealed bottom CMS at different annealing temperatures (T_{ann}) to change the degree of the chemical ordering, i.e. to modulate the electronic structure. Top CMS was not annealed for all the samples to prevent inter-diffusion between Cr and CMS. The values of surface roughness (R_a) for top and bottom CMS measured by AFM are very small and almost the same upto $T_{ann} = 400^\circ\text{C}$, as shown in Fig. 1(a), which means the IEC behavior is not affected by the interfacial roughness of trilayers. Long-range order parameter (S) of CMS single layer estimated from superlattice peak intensity in XRD is plotted against T_{ann} in Fig.1(b). Almost perfect B2 ordered structure was observed even at as-deposited state, whereas $L2_1$ -ordering appears from 300°C and takes maximum at 400°C . Magnetization curves in Fig. 2 show strong 90 degree coupling in CMS/Cr/CMS at different T_{ann} (100°C - 400°C). There is no significant change of strength and type of the coupling with T_{ann} . Explicitly, the IEC behavior does not depend on whether it is B2 or intermixing of $L2_1$ and B2 ordered structure in this case. Previous theoretical studies have showed that B2 structure is enough for CMS to have half-metallicity.[2] Therefore, if there is any relation between half-metallicity and strong biquadratic coupling, this result does not contradict with theoretical predictions. Further study about Co-Mn-Si composition dependence of IEC behavior in CMS/Cr/CMS structure will also be shown in the presentation.

CPP magnetoresistance effect through Graphene sheets.

E. W. Hill, T. G. Mohiuddin, D. Elias, A. K. Geim, F. Schedin, K. Novoselov, P. Blake, A. Zhukov
Centre for Mesoscience and Nanotechnology, The University of Manchester, Manchester, United Kingdom

Introduction

Single layer Graphene is a most remarkable material, consisting of a single layer of carbon atoms and was shown to be stable as a 2D crystal by Novoselov et al.[1] only a few years ago. Prior to that discovery Graphene had been something of a theoretical novelty, but in the last few years the material has been of great experimental interest particularly as its charge carriers can behave as a 2D gas of massless Dirac fermions [2] and it can support spin polarized conduction in the sheet plane [3], [4]. In this work we have looked at the conduction of spin polarized currents perpendicular to the plane of the sheet using the so-called CPP geometry.

Device Fabrication

Graphene flakes were prepared using the technique described by Novoselov et al. [1] on substrates which were covered with an array of patterned rectangular bars of 30 nm thick NiFe or NiFe30nm/Au10nm. Suitable single layer flakes which overlaid a NiFe bar were then identified using an optical microscope and their coordinates recorded. A PMMA resist layer was applied and the upper electrode and contacts were patterned over the previously selected flakes. Some devices were also patterned in regions without flakes for comparison. An over-layer of 30 nm thick NiFe was then deposited by evaporation onto the patterned resist layer. Lift off was then employed to define the top electrode together with the contacts to the top and bottom electrodes. A schematic view of the final device is shown in figure 1a together with an optical micrograph of a device with a Graphene flake in place (figure 1b).

Results and discussion

Four probe measurements of the resistance of the crosses with and without the flake present were taken. Using NiFe without an overcoat of Au means that a thin oxide layer will form during the flake preparation stage. The measurements showed that this increased the contact resistance to the flake, but was not sufficiently continuous to magnetically uncouple the two NiFe layers when the flake was absent as shown in figure 2a. Thus, we observed only an AMR response without the flake, but there was a stable high resistance state at zero field indicating an anti-parallel magnetization state between upper and lower layers. We were concerned about the presence of the oxide layer which gave a high contact resistance and so we repeated the experiment with a thin Au capping layer on the lower NiFe electrodes. In this case we saw a spin valve response for both NiFe/Au/NiFe and NiFe/Au/Graphene/NiFe devices, but the response with the graphene present was larger by a factor of two. This is shown in figure 2b. We believe that the current is being channeled through the Graphene layer at what are effectively pin holes and the increase in the MR response is thus due to the CPP conduction as opposed to the CIP conduction in the devices without the graphene sheet. Thus a single sheet of Graphene is sufficient to break the exchange coupling between two ferromagnetic layers and the presence of a Graphene sheet can give rise to current channeling and produce a good CPP response using simple cross electrode geometry.

Spin transport in organic semiconductors has been receiving widespread attention since the first experimental demonstration of magnetoresistive effects (change in resistance under an applied magnetic field) in hybrid ferromagnetic/organic/ferromagnetic structures [1]. Continuous effort in the field has led to the realization, for example, of vertical organic spintronic devices with different organic semiconductor layers [2,3] or organic tunnel barriers [4]. However, there is still a lack of understanding on the mechanism that governs spin injection and transport in organics, leading to general disagreement even on the expected sign of the devices output magnetoresistance.

With the aim to clarify the spin transport behaviour in organic semiconductors, we present new results on hybrid inorganic/organic spin valves with the most successful up-to-date combination of materials [2-6]. The highly spin polarized manganite $\text{La}_{2/3}\text{Sr}_{1/3}\text{MnO}_3$ and Cobalt have been used as ferromagnetic electrodes for spin injection into thick layers (up to 200 nm) of tris(8-hydroxyquinoline)aluminum(III) (Alq3). In a critical design improvement, we have for the first time introduced an artificial tunnel barrier (Al_2O_3 or LiF) between the organic and the Co top electrode to study its influence on spin injection into organic semiconductors and to improve the chemical stability and reproducibility of the devices.

In our manuscript we: explore the importance of artificial tunnel barriers for spin injection in organics, record room temperature magnetoresistance, demonstrate that only ferromagnetic electrodes and not organic semiconductor limit device output and, finally, sketch an energy diagram able to explain negative magnetoresistance in LSMO/Alq3/Co spin valves.

Our work is a new step forward in organic spintronics, as we prove that organic semiconductors do not have a clear limit for room temperature performance with the adequate ferromagnets, and we present a reliable model that could be easily extrapolated to predict the output of different materials combinations in hybrid spin valves.

A novel 'pseudo' direct-drive brushless permanent magnet machine.

K. Atallah, J. Rens, S. Mezani, D. Howe

Electronic & Electrical Engineering, The University of Sheffield, Sheffield, United Kingdom

For low speed electrical machine applications, it is usually weight/size and cost effective to employ a high speed machine together with a mechanical gearbox. However, in many instances, the disadvantages associated with mechanical gearboxes, such as acoustic noise, mechanical vibration, the need for lubrication, concerns regarding reliability and maintenance requirements, make direct-drive solutions more functionally and/or economically attractive. Permanent magnet (PM) brushless machines exhibit relatively high torque densities, typically being $\sim 30 \text{ kNm/m}^3$ for radial-field and $\sim 50 \text{ kNm/m}^3$ for transverse-field liquid-cooled topologies [1-3]. However, although transverse-field machines exhibit the highest torque density, since their power factor is very low [4], typically between 0.3 to 0.5, the required inverter/converter VA rating is a factor of 2-3 times higher than that for an equivalent conventional brushless machine. This results in a significant cost penalty, which is limiting the take-up of transverse-field machine technology.

The paper describes a novel 'pseudo' direct-drive electrical machine, Fig. 1, in which a magnetic gear [5] and a radial-field PM brushless machine are mechanically and magnetically coupled. The machine combines the high power factor of a conventional brushless machine with the high torque density capability of a transverse-field machine. As can be seen in Fig. 2, which shows the harmonic spectrum of the radial flux density distribution due to the 2 pole-pair (ph) high-speed rotor permanent magnets, in the airgap adjacent to the outer 21 pole-pair (pl) permanent magnets (fixed to the stator bore), the 23 ferromagnetic pole-pieces (ns) on the low-speed rotor result in a large 21 pole-pair asynchronous space harmonic field, which interacts with the 21 pole-pair outer permanent magnets to achieve gearing, the gear ratio ($Gr = ns/ph$) being 11.5:1. However, a large 2 pole-pair fundamental field component still exists, which is employed to transfer power from/to the stator winding.

Fig. 3 compares the variation of the predicted geared electromagnetic torque and the measured output torque with the rms current density. It can be seen that, although the current density is less than 2 Arms/mm^2 , a torque density in excess of 60 kNm/m^3 is achieved with natural cooling, at a power factor in excess of 0.9. In other words, whilst the stator winding is responsible for torque being developed by the high-speed rotor, since this is amplified by the magnetic gear action, the magnetic limit of the machine is reached before the thermal limit.

Design optimization of a single-phase permanent magnet synchronous generator.

J. El Hayek¹, J. Brünisholz², P. Pittet³

1. Industrial Technologies, University of Applied Sciences Western Switzerland, Fribourg, Switzerland; 2. ATPS, ABB, Turgi, Switzerland; 3. Power Service, ALSTOM Ltd, Baden, Switzerland

This paper aims to present a study dealing with the design improvement of a single-phase permanent magnet synchronous machine used for distributed generation. It is a result of collaboration with a start up that is in phase of industrializing a Pico-hydroelectric power station, which answers a large request from developing countries where electrical supply networks do not reach the outskirts of large cities.

The investigation includes the permanent magnet reaction in short-circuit case, and the optimization of the maximum power that can be delivered by the generator. The heating and lifespan of the magnets, as well as the reduction in the harmonic distortions are also considered in this study.

1. Finite element (FE) magneto-dynamic model of the generator:

A model has been developed using the software Flux of Cedrat. Fig. 1 and Fig. 2 show respectively a part of the model with its meshing, and the associated electric circuit linked to the this model as well as the eventual load.

Simulation results are illustrated in Fig. 3. Voltage and load current present a certain harmonics rate, which can be minimized through a right choice of permanent magnets shape. Fig. 4 gives an optimized shape of the voltage, and Fig. 5 the temperature distribution in the machine.

2. Measurements and comparisons:

When Fig. 4 and 7 are compared, one can easily note the matching between simulation and reality.

3. Conclusion:

We could achieve an accurate model of the single-phase generator. Thank to this model the volume efficiency has been improved by a factor two; actually with same volume, the generator can deliver twice more power than before. In addition, the total harmonics distortion rate (THD) has decreased by a factor 5, from 15 % down to 3 %. And it is important to mention that these optimizations did not call any increase in terms of financial cost.

An Ultra-High Speed PM Motor for Small Milling Machine Applications.

J. Asama, K. Maruyama, Y. Yanagihara, A. Chiba

Electrical Engineering, Tokyo University of Science, Noda, Japan

I. Introduction

Small palm-sized milling machines, such as high precision machining grinders and dental milling tools, require an ultra-high rotational speed in its spindle. In these machines, an air turbine is often employed. However, the rotational speed decreases when a torque load is applied to the spindle. In addition, the air turbine produces high-frequency noises. An ultra-high speed electrical drive using a PM motor is expected for alternative drive sources. Many research groups have developed ultra-high speed PM motors [1]-[3]. However, these PM motors are relatively larger in size for palm-sized small milling tools. The objective of this paper is to design, fabricate, and test a small ultra-high speed PM motor. To achieve an ultra-high speed motor drive, a coreless stator with a magnetic yoke is fabricated. Basic motor characteristics are experimentally investigated with a comparison of calculated results by a computer simulation. The authors set a target of a few tens of watts in a shaft output at a rotational speed of 300,000r/min.

II. Design and Fabrication of Coreless PM Motor

Fig. 1 shows a configuration of a proposed coreless PM motor. Two motor units with a same design are built in tandem. One is used for a motor test, and the other is used for a torque load as a generator. An axial length and an outer diameter of a stator yoke is designed to be 5mm and 12mm, respectively. A rotor diameter including a sleeve is 6.1mm. Three-slot concentrated windings with non-magnetic teeth, *i.e.*, a coreless structure, are adopted. A low iron loss material, Super Core, is applied to the stator yoke. A fiber sensor is attached for a detection of a rotational angular position. The rated voltage and current are 24V and 2.3A, respectively. A forced air cooling is provided to remove heat generation. A fast controller with a FPGA device is fabricated for this ultra-high speed PM motor drive.

III. Basic Motor Characteristics

The fabricated motor was found to rotate up to 310,000r/min. By driving a motor, induced line-to-line emf is measured at a generator unit, as shown in Fig. 2. The measured induced emf is 20% smaller than the calculated values, which may be mainly caused by a flux leakage. Fig. 3 indicates measured copper loss of the motor, W_{cm} , and a sum of both mechanical and iron losses, W_m and W_i , at no load condition. W_i includes both the motor and generator losses. A rapid increase in losses may be caused by mechanical bearings because of both a coreless structure and a low iron loss yoke. By using these losses at no load condition and adjusting generator loads, a motor torque, T , is estimated from Eq. 1, where P_i is input power and W_{cg} is a generator copper loss at a load condition. Fig. 4 shows measured and calculated torques. At a speed higher than 250,000r/min, torque could not be measured because motor currents exceeded a rated value of 2.3A. The actual torque is below the calculation because the measured emf is smaller than the calculated one. The shaft output at 250,000r/min was 13W. In conference presentation and paper, more details in bearing and machine structures, measuring equipments, and test results of modified test motors will be included.

Design and analysis of a novel hybrid excitation synchronous machine with asymmetrically stagger permanent magnet.

Y. Chengfeng¹, L. Heyun¹, G. Jian¹, Z. Ziqiang²

1. School of Electrical Engineering, Southeast University, Nanjing, China; 2. Department of Electronic and Electrical Engineering, University of Sheffield, Sheffield, United Kingdom

There is an increasing tendency to study hybrid excitation machines for flux weakening operation recently. This kind of electrical machines combines the advantages of permanent magnet (PM) machines with the possibility of controllable flux by field windings [1-2]. Thus, it is easier to control the air-gap magnetic flux. A novel hybrid excitation synchronous machine with asymmetrically stagger PM (ASHESM) is developed in this paper. This machine combines the fixed excitation of PM with the variable flux produced by a toroidal field winding located on the inner stator. Besides, the PM pole and the solid iron pole are asymmetrically designed so that the flux of the prototype can be adjusted in a wide range with a relatively low field current. A set of design equations for ASHESM is derived. Three-dimensional (3D) finite element analysis (FEA) is employed to calculate the magnetic field distributions and to predict the flux adjusting performance of 1-kW ASHESM prototype. The predicted results are validated by experiments.

Fig. 1 shows the structure of the ASHESM, which consists of a rotor, an outer stator and an inner stator. The surface of claw-pole on rotor is divided into two sections, one is PM pole, and the other is a solid iron pole. PMs create a nearly constant flux, while the field winding currents generate a variable flux, both form the resultant flux in the air-gap. The flux generated by field windings may enhance (magnetize) or weaken (demagnetize) the PM flux according to the direction of field current, as shown in Fig. 2. If the flux generated by the field current flows in such direction that it is subtracted to the flux of the PM, the flux per pole closes its path in the same magnetic pole. Fig. 2(b) depicts this operating condition. In fact, in the air-gap, flux emanating from the PM and the iron pole cross the air-gap in opposite directions. As a result, the total flux per pole decreases as the field current increases. Flux essentially crosses the stator yoke axially. If the field current is reversed, the field flux uses the magnetic circuit as before, but flows in the opposite direction. Therefore, both components of the air-gap flux cross the air-gap in the same direction. Flux closes its path crossing the stator yoke essentially tangentially as is shown in Fig. 2(c).

The stator design for ASHESM is similar to that of the common PM synchronous machine. Due to the special design and control requirements of ASHESM, electric load, magnetic loading, machine sizing, field winding, rotor magnetic circuit structure and so on, all need to be specially designed. The electromagnetic design details will be given in the full paper. Based on the electromagnetic design method proposed for the ASHESM, a 1-kW 8-poles prototype is designed and manufactured as shown in Fig. 3. 3D Finite element method is used to analyze the static magnetic field of the ASHESM and to evaluate the field adjusting performance of the prototype machine. Fig. 4 shows the air-gap flux density with three different field currents. The resultant flux linkage and back EMF versus rotor position have also been obtained under different field currents and confirmed by experiments, as shown in Fig. 5. It shows that nearly 60% field control range can be achieved at no load and 55% at full load with a relatively low field current.

Novel axial flux permanent magnet synchronous machines with segmented and laminated stator configuration.

W. Fei, P. Luk

Department of Aerospace Power and Sensors, DCMT Cranfield University, Shrivenham, United Kingdom

Axial flux permanent magnet (AFPM) machines have unique characteristics such as high aspect ratio, high torque density, and excellent efficiency that make them cogent candidates for electric propulsion. However, stator lamination fabrication is more difficult for AFPM machines when compared with their conventional radial flux counterparts. Recently, a new AFPM machine using soft magnetic composite (SMC) instead of laminated steel has been introduced [1,2], where a new yokeless and segmented armature (YASA) topology is also proposed to improve torque density. However, SMC machines are normally suitable for medium and high speed applications due to the poor core loss behaviour of the material under low frequencies (below 1 kHz) [3]. SMC is also much more expensive than laminated steel. This paper presents a novel AFPM for low speed applications utilizing steel laminated stator. In order to manufacture the steel laminated stator poles, an innovative stator pole structure is employed as shown in Fig.1 The machine stator poles with concentrated windings are segmented individually, and stacked together as an integrated stator by two high strength aluminium alloy ring holders. This structure thus possesses a number of advantages similar to the YASA configuration: (a) shortened end windings leading to higher power density, (b) ease of winding process and high winding fill factor, (c) reduced mutual inductance between the machine phases resulting in improved phase independency and fault tolerance, and (d) reduced stator core weight due to the absence of the stator yoke.

Generally, distributed integral-slot-windings are used for AFPM synchronous machines to produce sinusoidal or near sinusoidal back EMF waveforms. A high number of stator poles are essential for integral-slot-winding machines, which might make the proposed structure more difficult, or even impossible. In this paper, concentrated fractional-slot-windings are employed in order to achieve the proposed structure. To overcome the complexity in the modelling and analysis, an efficient yet accurate analytical model for AFPM machine is synthesized. Two typical fractional slot structures (12/10 and 12/8) with same stator pole number (twelve) and different magnet pole numbers (ten and eight) are studied first using the analytical model. It is found that, both non-triplen back EMF harmonics and cogging torque are much lower in the 12/10 structure. Consequently, a 5-kW 1000rpm AFPM synchronous machine with a 12/10 structure is designed, and the prototype machine is shown in Fig.1. To validate the analytical model, a comprehensive three-dimensional (3-D) finite element analysis (FEA) model of the prototype is developed. The cogging torque values from the analytical, 3-D FEA models and experimental measurements are compared in Fig.2. The results show close agreements, and the relatively low cogging torque of the proposed machine. The line back EMF values are compared in Fig.3, which also shows very close agreements. Noticeably, the line back EMF waveform is nearly sinusoidal, which can bring about excellent machine performance. From the results, it can be concluded that the proposed analytical model is efficient to be used for optimization and performance prediction of AFPM machines and the proposed 12/10 structure machine using the novel laminated steel stator is an eximious contender for electric propulsion.

Actuators with complex movements are of greatest interest [1]. In this paper, we study an open slot PM synchronous actuator which is aimed at implementing linear and/or rotary (l&r) movements simultaneously or independently. First, the actuator is described. Then, using a 3D-FEM code, calculations were carried out. The results are given as well as first measurements on a constructed prototype.

The actuator is constituted of two stators and a cylindrical rotor. Open slot PM synchronous machines were used for either the linear or the rotary movements where the PM are placed inside a non magnetic cylindrical support. Concentrated coils were chosen for the phase windings to simplify the construction. To ensure a dynamical behaviour, the numbers of the pole pairs have been chosen the lowest possible. Features of the designed actuator are given in table 1.

A prototype has been designed. The windings on the inner stator were omitted. Therefore, we used the inner part to put on the guidance system (Fig. 1).

To perform the study, we used a 3D-FEM code with a scalar potential formulation [2]. A special procedure was used to take into account both movements in different directions.

The actuator studied was meshed using hexahedron elements. To limit their number, the air parts on both sides of the actuator have been reduced. Periodical conditions have been imposed assuming an infinite rotor. The mesh is constituted of approximately 261,000 elements and 272,000 nodes. Each air-gap has two layers of elements. The linear displacement is 1 mm and the rotation angle is 1.5 degrees.

In Fig.3, we present the linkage fluxes, at no load, for a diagonal movement. As expected, the fluxes constitute a product of cosines.

Other calculations have been carried out to obtain the forces and thrust either at no load or at rated operating. In table 2, we give the maximal value obtained from the numerical calculations at rated operating points.

A prototype has been constructed further to the results obtained from numerical calculations. In figure 4, we give pictures of the rotor and the whole constructed l&r actuator.

First measurements have been carried out. In figure 5, we compare a linkage flux obtained by the simulation and measurement when the rotor is moved in rotation. The results are in good agreement.

Analysis and experimental verification of a single phase, quasi-Halbach magnetised tubular permanent magnet motor with non-ferromagnetic supporting tube.

J. Wang, T. Ibrahim, D. Howe

Electronic and Electrical Engineering, University of Sheffield, Sheffield, United Kingdom

Direct-drive linear reciprocating compressors offer numerous advantages over conventional counterparts which are usually driven by a rotary induction motor via crank shaft [1]. A novel design of single-phase, short-stroke, linear permanent magnet (PM) motor has recently been developed [2], and used in the linear compressor application. The moving-magnet armature of the motor employs quasi-Halbach magnetised magnets mounted on a mild steel supporting tube. While this design results in a great force capability it also leads to a heavy moving mass and hence greater spring stiffness, which will compromise the dynamic capability of the compressor system [3]-[4]. Further it has been shown [5] that eddy current loss incurred in the supporting tube will affect the efficiency of the compressor system.

The paper describes an alternative design in which the quasi-Halbach magnetised magnets are mounted on a non-ferromagnetic support tube, as shown in Figure 1, and analyses its performance. The open-circuit magnetic field distribution is established analytically in terms of a magnetic vector potential formulated in the cylindrical coordinate system. The analytical field solution allows the prediction of flux linkage, back-emf and thrust force of the actuator in closed forms and facilitates design optimisation. The analytically predicted results are validated by finite elements analyses.

Figure 2 compares analytically predicted and finite element calculated variation of open-circuit radial flux density in the middle of airgap with axial position z . As will be observed, the analytical solution agrees broadly with the finite element prediction, the rms percentage difference is relatively small, being 5.09%.

A prototype has been constructed and its static performance evaluated. Figure 3 shows the test rig which was used to measure the static performance such as variation of flux linkage and thrust force with the armature position. The micrometer barrel was used to adjust the armature position, and the load cell, LVDT and flux meter (no shown) were employed to measure thrust force, axial position and flux linkage of the coil, respectively.

Figure 4 compares the variations of measured and finite element predicted thrust force with axial position of the armature. As will be seen, the experimental results agree reasonably well with finite element calculation.

Detailed analysis and design together with more experimental results such as flux linkage and cogging force will be included in the full paper. Comparative study in terms of efficiency and the cost of materials for two alternative tubular PM motor designs (with non-ferromagnetic or ferromagnetic supporting tube) will also be reported.

Optimization of a sea wave energy harvesting electromagnetic device.

M. Trapanese

Dipartimento di Ingegneria Elettrica, Elettronica e delle Telecomunicazioni, University of Palermo, Palermo, Italy

Current energy crisis and general concerns on environmental issues have triggered an ever increasing effort on harvesting renewable energies.

Amongst renewable energy sources, sea wave energy is definitely the one that has been less utilised. This is probably caused by three reasons: i) the low energy concentration in the sea waves, at least in the sites where it is technically possible to install conversion stations; ii) the strong technical novelties that are required to extract the energy that is contained in a highly and stochastically variable motion; iii) the difficulty to find a suitable electrical system able to convert the energy contained in the motion of the sea into electrical energy.

Several approaches to harvest sea wave energy have been proposed; almost all of them introduce a mechanical conversion device between the waves and the electromagnetic generator. This stage converts the mechanical energy contained in the waves into a more usable mechanical energy; it can be a hydraulic coupling device or a mechanical gear and, in any case, introduces additional losses and additional maintenance requirements. In order to reduce these losses a generator directly coupled to the sea waves should be used.

This paper presents the optimization of a permanent magnet linear generator directly coupled to sea waves.

Linear electrical generator has been recently studied for the exploitation of sea wave energy [1-2]. In order to maximize energy extraction, the stochastic features of the energy source must be included in the mathematical model of the system in order to satisfactorily tackle the problem. Moreover, they strongly influence the magnetic design. In order to study how to overcome the above said difficulties a PM linear electrical generator has been designed and built.

The principle of operation of the generator is shown in fig.1. The moving part of the generator is driven from the sea waves and induces an emf on the winding mounted on the armature.

The mathematical model includes the dynamic equations of the moving part of the generator and the electric equations of the winding. The coupling parameters (inductances, fluxes etc.) have been determined by a FEM analysis (which includes a careful analysis of the boundary conditions, because of the fact that the machine is working in a conductive medium).

The design has been optimized by including in the mathematical model used for the optimization the following aspects:

1. the dynamic and stochastic features of the waves;
2. a dynamic model of the hydraulic conversion system;
3. a parametric circuit model of the magnetic circuit as well as of the electric windings;
4. A circuit model of the power electronics converter used to connect the generator to the utility.

The main innovation of the optimisation approach proposed is that the speed of the machine is neither supposed known nor supposed fixed, but the stochastic features of the imposed movement are the factors that mostly influence the optimisation process.

The optimization has been performed by finding the maximum of an objective function that has been built on the basis of the mathematical model developed. The variables of the function were related to the magnetic circuit of the converter, the parameters to the stochastic features of the

waves as well as to the characteristics of the hydraulic system and of the power electronics converter.

The results show several maxima that indicate several possible alternative designs. In order to verify the results, a reconfigurable machine has been built and tested in laboratory.

The tests have verified the value of the emf, of the magnetic induction as well as of the power production in several configuration of the machine.

In a scaled down version of the machine, it has been possible to generate almost 100 watt and to reach an output voltage of 200 V peak to peak. These values were in agreement with the design values within an error of 15%.

Design and characteristic analysis on the short-stator linear synchronous motor for high-speed Maglev propulsion.

H. Cho¹, H. Sung¹, S. Sung¹, D. You², S. Jang²

1. Maglev Research Team, Korea Institute of Machinery and Materials, Daejeon, South Korea; 2. Electrical Engineering, Chungnam National University, Daejeon, South Korea

Recently, the linear motors has been used in linear motion load without gears, screws or crank shafts. They are used widely in automation systems, manufacture, transportation, transfer system and military area, etc [1]. In particular, the linear synchronous motor (LSM) has many advantages, such as high efficiency, high power factor, high positional precision and so on. By reason of these remarkable advantages, German 'Transrapid' and Japanese 'MLX' chose the LSM as a propulsion device for their high-speed Maglev. This paper deals with the design and characteristic analysis on the LSM for high-speed propulsion system. Important design criteria are established based on the two-dimensional (2-D) analytical method under several assumptions and the results are compared with the numerical solutions by the finite element analysis (FEA). An experimental system for SLSM propulsion was also constructed and tested to confirm the analytical design and high-speed operation.

In this study, in order to construct the experimental system for LSM, the short-stator linear synchronous motor (SLSM) has been employed. Fig. 1(a) shows the basic structure of SLSM. The primary member contains ployphase winding and is similar to its linear induction motor (LIM) counterpart. The secondary member requires a DC excitation winding. Interaction between the magnetic field and armature currents produces the thrust force. The speed of traveling magnetic wave depends on power supply's frequency. Fig. 1(b) shows the analytical model of SLSM. In order to establish analytical solutions for the magnetic field distribution in the machine, this study assumes that both the relative permeability of the core material and z-axis length is infinite. Letter (a)-(d) represent the surfaces at the indicated boundaries and y_0 denotes the airgap length.

Figs. 2(a) and (b) show the flux density distribution in the airgap region and core material, respectively. The analytical solutions agree well with the finite element analysis (FEA) results. Fig. 3 shows the three-dimensional (3-D) drawing of SLSM experimental system. Figs. 4(a) and (b) show the manufactured 3-phase primary and 1.5 meter diameter secondary of SLSM, respectively. Acceleration tests were performed from 0 rpm to 1000 rpm which corresponds to 0 km/h and 283 km/h, respectively. Fig. 5 shows the acceleration characteristics of the SLSM when the machine works with vector control. The airgap length is fixed on constant uniform length of about 10 mm.

The LSM with short-stator running at rated speed of 400 km/h (max. 550 km/h) has been designed, manufactured, and tested. The experimental results from a SLSM test set confirmed the validity of the proposed design scheme.

Eddy-current stator solid steel back-iron losses in small rotary brushless permanent magnet machines.

J. J. Paulides, K. J. Meessen, E. A. Lomonova
Technical university Eindhoven, Eindhoven, Netherlands

There is a growing interest in employing small slotless permanent magnet machines in direct-drive low-cost servo systems, i.e. demanding precision dynamic characteristics, due to their simple geometry, torque ripple reduction and possible self-bearing [1]. Albeit that the ever increasing necessity to miniaturize has placed severe constraints on the current slotless technology, since it inherently has a relatively large effective magnetic airgap which limits the magnetic loading that can be realised. However, even this reduced magnetic loading still results in considerable eddy-current losses, when a solid back-iron is implemented for costs purposes, which need to be reduced by selecting the most appropriate soft magnetic material for each application.

Considerable efforts have been devoted to analyze and improve the loss characteristics of laminated and solid soft magnetic materials [2]. These iron losses are a major roadblock in the efforts to miniaturize low cost slotless electrical machines, i.e. (0.1-1 watts). The classical approach to model iron losses are explained by the three well-known loss phenomena, namely, hysteresis loss, classical eddy-current loss, and the excess eddy-current loss [3]. In order to simplify the modelling of the eddy-current loss within the 2D finite element (FE) analysis (Fig. 1), the machine is assumed to be infinitely long. This means that instead of eddy-current loops, the induced currents are assumed to flow in the axial direction. It needs noting that 2D, compared to 3D, FE modelling provides a total eddy-current loss prediction that is overestimated, hence it is a useful approximation due to its ease of implementation. All the initial simulations, used to investigate the influence of different materials on the eddy-current loss, are performed at a fixed speed of 1200 rpm (470mW) and the hysteresis losses and excess losses in the back-iron are calculated to be 20 mW. To calculate the total eddy-current losses, the back-iron is split into 20 rings. In each ring, the current density is assumed to be constant in the radial direction. Fig. 2 shows the current density versus angle in the rings of the back-iron. The inner ring has the highest current density and the outer ring the lowest current density. The losses are calculated using the rms value of the current density in one ring, integrated over the surface of that ring. The current through the ring squared times the resistance of the ring gives the eddy current loss in each ring, which is summed to provide the total eddy current loss in the back-iron.

In most publications the iron loss analysis efforts are limited to making iron plates into thinner laminates or adding more silicon elements to steel boards to reduce iron loss. Although the benefits of employing higher electrical resistivity materials are indeed evident, viz. $1.4 \times 10^{-7} \Omega\text{m}$ and $6.0 \times 10^{-7} \Omega\text{m}$ give respectively 360mW and 80mW eddy-current loss this comes at a considerable premium in material costs. To validate the findings of the finite element study, iron losses under various speed conditions are measured on a prototype, as shown in Fig. 3. The measured iron losses include the hysteresis losses and excess losses, hence, it can be concluded that the prediction and the measurements provide a good clear perception of the eddy-current loss in the back-iron. Using the analysis and measurements it will be shown that the eddy-current loss, e.g. using the solid core material, causes a damping torque, which can be as high as the propulsion torque, and will initiate severe servo characteristic degradation.

Experimental Method and Verification to Characterize the Unbalanced Magnetic Force in Electric Motors.

C. Lee, G. Jang

Dept. of Mechanical Engineering, PREM Lab., Hanyang University, Seoul, South Korea

Magnetically induced vibration is becoming common and serious in many electric motors since the advent of high grade permanent magnet (PM). Motor or supporting structures are excited by the traveling magnetic force or the torque between the rotating PM and the stator in case of a brushless DC (BLDC) motor. Many researchers investigated the characteristics of unbalanced magnetic force (UMF) in a BLDC motor theoretically or numerically [1, 2, 3]. UMF exists even in the rotationally symmetric design due to various manufacturing errors such as uneven magnetization of PM, rotor or stator eccentricity. However, an effective experimental device or even a publication to measure the UMF of an electric motor has not been reported. This research develops the experimental device to measure the UMF in electric motors directly. It also characterizes the UMF due to uneven magnetization of PM in a BLDC motor with the finite element analysis and the spectral analysis.

Fig.1 shows the developed experimental device to measure the UMF of electric motors. UMF of electric motors can not be measured in the assembled state of a rotor and a stator with bearings, because the UMF is exerted to the rotor and the stator to move the rotor to another equilibrium state by deforming the bearing. So this device measures the UMF once the rotor is taken apart from the motor assembly. The stator is fixed on the rotating stage, and the rotating stage is connected to a stepping motor through a belt. A load cell is attached to the separated rotor which is fixed to the xyz-table. The center of the rotor assembly is located at the rotational center of the stator assembly by moving the xyz-table. Then, the stator assembly on the rotating stage is rotated constantly by the stepping motor, and the variation of UMF exerted to the rotor is directly measured by the load cell of the rotor assembly.

The developed device is applied to a BLDC motor with 12 poles and 9 slots used in a computer hard disk drive. Once the rotor is taken apart, the magnetic flux density of PM's surface is measured with a Gauss-meter. It was found that PM is unevenly magnetized in such a way that maximum and minimum values of surface magnetic flux density are 142.7 mT and 130.9 mT, respectively. The peaks of magnetization of PM are uneven with 9 % difference. Then separated rotor and stator are fixed to the developed device to measure the UMF due to uneven magnetization of PM. Fig. 2 shows the measured and simulated UMF in the x directions, and their frequency spectra. Simulated magnetic force is calculated by using the finite element method and the Maxwell stress tensor once the B-H curves of PM are determined from the measured surface magnetic flux density of PM. It shows that the measured UMF matches well with the simulated one. Fig.2 (b) shows that the UMF has the dominant first harmonic, and the 9th harmonics, i.e. 8th and 10th, and 17th and 19th, etc. The second, third, and fourth harmonics existed only in the measured UMF are presumed to be experimental error. This phenomenon is effectively explained with the principle of the experimental device. Because the stator assembly rotates and the UMF is measured in the stationary rotor assembly in this experiment, the measured value is the UMF in the rotating coordinate and it repeats whenever a slot passes the load cell. It generates the slot effect so that the UMF in the rotating coordinate, i.e. F_r can be decomposed with Fourier series as follows:

$$F_r = \sum F_i \sin(ik\omega t + \phi_i) \quad (1)$$

where k and ω are the slot number and the rotational speed, respectively. It can be transformed to the fixed stationary coordinate, and the UMF in the x direction can be expressed as follows:

$$F_x = \cos\omega t \sum F_i \sin(ik\omega t + \phi_i) = 1/2 \sum F_i [\sin\{(ik-1)\omega t + \phi_i\} + \sin\{(ik+1)\omega t + \phi_i\}] \quad (2)$$

The above equation shows that the slot effect in the rotating coordinate, i.e. ik is transformed to the slot harmonics ± 1 , i.e. $ik \pm 1$ in the stationary coordinate [2]. The developed method is also performed to investigate the characteristics of UMF of electric motors due to rotor or stator eccentricity. This research will contribute to the reduction of the magnetically induced vibration and noise of electric motors by identifying the characteristics of UMF in electric motors.

Study of an electromagnetic gearbox involving two PM synchronous machines using 3D-FEM.

M. Aubertin, A. Tounzi, Y. Le Ménach
L2EP - USTL, Villeneuve d'Ascq, France

An electromagnetic gearbox [1] has been designed for a combined automotive clutch and gearbox application. It is constituted of two PM synchronous machines with different rotation speeds. The system designed is presented and studied using 3D-FEM with the help of a procedure aimed to take account of two different speeds. Results are presented.

The designed system is a bell shaped device constituted of two open slot PM synchronous machines (Fig. 1). The rotor of the inner structure is linked to the source (i.e. the combustion engine) and rotates at high speed. The stator of the inner machine, which is also the rotor of the outer structure, is linked to the load (i.e. the wheel transmission). It rotates at a reduced speed. The stator of the outer machine is static. Both stators contain three phase windings but with different pole pair numbers. The stator of the inner part must be supplied through rotating rings.

The purpose of the system is to yield the combustion engine operating on constant power levels with a better efficiency. It only transfers power from the source to the load, thus its rated power is relatively low. Both windings are linked to a DC supply through converters. The supply of the inner stator windings allows varying the mechanical ratio of the gearbox through the frequency. The windings of the outer stator allow compensating the power between the one of the combustion engine and that of the load.

Using the locked step approach [2], slip surfaces, with regular meshes, are defined in each air gap. Thus, each of both displacements is modeled by a circular permutation of the unknowns by a mesh step or an integer multiple of this last according to the corresponding speed.

A prototype has been designed for a rated power of 5kW and the speeds related to the internal combustion engine and the wheels of a car, at 50km/h. A flux separator has been put to isolate magnetically both structures. Different features of the system are given in table 1.

In Fig. 2, a 3D view of the designed prototype is given with the different windings, magnets and magnetic separator.

The mesh of the whole modeled part is constituted of 610,200 elements and 177 000 nodes. Using a 3D-FEM code with the scalar potential formulation, calculations have been carried out at no load and rated operating taken into account the two speeds of both moving parts.

Fig. 3 shows the linkage fluxes at no load and rated speeds for both structures.

In Fig. 4, we present the electromagnetic torque, for both structures calculated at the rated supplying currents and speeds.

Domain wall propagation in thin magnetic wires.

R. Varga¹, K. Richter¹, A. Zhukov², V. Larin³

1. Institute of Physics, Faculty of Sciences, UPJS, Kosice, Slovakia; 2. Dept. Fisica de Materiales, Fac. Quimica, UPV/EHU, San Sebastian, Spain; 3. MFTI, Kishinev, Moldova

Domain wall propagation in thin magnetic wire is used to transport the information in modern magnetic devices [1,2]. Decreasing the dimensions of the wires leads us to the new phenomena, which could be successfully employed in such devices.

Amorphous glass-coated magnetic microwires are ideal material to study the single domain wall propagation [3-5]. Since the beginning of such study, the new effects appears like a negative critical propagation field [3], very fast domain wall propagation [4] that can even leads to the super-sonic domain wall [5]. In the given contribution, we show the effect of the Ni content in amorphous glass-coated $\text{Fe}_{77.5-x}\text{Ni}_x\text{Si}_{7.5}\text{B}_{15}$ ($0 \leq x \leq 50$ at.%) magnetic microwire.

Typical fast domain wall dynamics in microwires consists of two regions [5]. Firstly, it is low field region with low domain wall mobility (fig.1). it is characterized by the transversal domain wall structure. At higher fields (above 850 A/m), the domain wall configuration changes to the vortex one and the domain wall mobility increases reaching the domain wall velocity up to 10 km/s. Such a change has been formerly confirmed theoretically [6] and experimentally [5]. In this range, the domain wall interaction with the phonons is recognized at 4200 and 5600 m/s as it was formerly found in ferrites [7].

The parameters that determine the high domain wall velocity will be treated and their effect will be shown by the measurements of the domain wall dynamics in magnetic microwires of different compositions.

Domain wall propagation in nearly zero magnetostrictive amorphous microwires.

H. Chiriac, T. Óvári, M. Tibu

National Institute of Research and Development for Technical Physics, Iasi, Romania

Amorphous glass-coated microwires with positive magnetostriction ($\lambda > 0$), e.g. $\text{Fe}_{77.5}\text{Si}_{7.5}\text{B}_{15}$, exhibit a peculiar domain structure with an inner core (IC) that occupies most of the metallic core and an outer shell (OS) [1]. Such microwires display a bistable magnetic behavior, which is the result of this specific domain structure that originates in the minimization of the preponderant magnetoelastic term. A preexistent 180° domain wall is propagating within the IC when the applied field reaches to a certain value called the switching field, resulting in magnetization reversal. Studies of the domain wall velocity in such microwires have been recently performed [2, 3].

It has been recently shown that not only microwires with $\lambda > 0$ display bistable behavior, but also nearly zero magnetostrictive ones ($\lambda \approx 0$) [4], such as $\text{Co}_{68.15}\text{Fe}_{4.35}\text{Si}_{12.5}\text{B}_{15}$ ones with $\lambda = -1 \times 10^{-7}$, if their metallic nucleus diameter Φ is larger than $20 \mu\text{m}$. In case of $\lambda \approx 0$, the axially magnetized IC appears as a result of the minimization of the preponderant magnetostatic energy term in their total free energy. In spite of the differences between the preponderant energy term in microwires with $\lambda > 0$ and those with $\lambda \approx 0$, they both display a similar mechanism of axial magnetization, i.e. the propagation of the 180° wall.

In this paper, the propagation of this wall within the IC of microwires with $\lambda \approx 0$ is investigated in order to study its mobility and damping mechanisms in correlation with the low anisotropy of these microwires.

Domain wall velocity has been measured in $\text{Co}_{68.15}\text{Fe}_{4.35}\text{Si}_{12.5}\text{B}_{15}$ microwires using a Sixtus-Tonks-like experimental set-up. Fig. 1 shows the dependence of wall velocity on applied field for a glass-coated microwire with $\Phi = 22 \mu\text{m}$ and the glass thickness $\delta = 1.5 \mu\text{m}$. Bistable $\text{Co}_{68.15}\text{Fe}_{4.35}\text{Si}_{12.5}\text{B}_{15}$ microwires with $\Phi > 20 \mu\text{m}$ display a wall mobility of the order of $10^2 \text{ m}^2/\text{A s}$, two orders of magnitude larger than the values reported in $\text{Fe}_{77.5}\text{Si}_{7.5}\text{B}_{15}$ amorphous glass-coated microwires.

This result opens up the way for employing microwires with $\lambda \approx 0$ as fast switching pulse generator elements, as well as in spintronic devices, subject to the significant reduction in the value of Φ . Therefore, the next step was to reduce the influence of the magnetoelastic energy term in microwires with $\Phi < 20 \mu\text{m}$, in order to enhance the importance of the magnetostatic term, and to induce bistability in the thinner samples. This has been performed by removing the glass coating through chemical etching. All investigated samples became bistable after glass removal, even those with very small values of Φ , e.g. $\Phi = 1.5 \mu\text{m}$. Fig. 2 illustrates the dependence of wall velocity on applied field for a microwire with $\Phi = 12 \mu\text{m}$, which became bistable after glass removal.

Wall mobility decreases after glass removal, whilst maximum velocity reaches over 2000 m/s . Annealing at 400°C for 30 min results in mobility values comparable to those observed in the thicker microwires which are bistable in the as-cast state.

The obtained results have been explained mainly considering the spin relaxation damping mechanism: the damping coefficient associated with spin relaxation is proportional to the anisotropy constant of the IC, and, as a result, it is very small in $\text{Co}_{68.15}\text{Fe}_{4.35}\text{Si}_{12.5}\text{B}_{15}$ microwires.

Summarizing, we demonstrated that domain wall velocities in microwires with $\lambda \approx 0$ are much larger than in microwires with $\lambda > 0$, that thinner microwires with $\lambda \approx 0$ become bistable after complete glass removal, and that wall mobility can be enhanced by annealing.

1. Instituto de Magnetismo Aplicado, Universidad Complutense de Madrid, Las Rozas, Spain; 2. Física de Materiales, Universidad Complutense de Madrid, Madrid, Spain; 3. Micromag 2000, S.L., Las Rozas, Spain

We present an experimental investigation related to an electromagnetic radiation absorbent sheet made up of a dielectric material containing amorphous magnetic microwires located such that, in the absorber use position, said electromagnetic radiation falls.

Fe₈₉Si₃B₁C₃Mn₄ microwires with positive magnetostriction constant of $2 \cdot 10^{-5}$ and ρ between 0.2 and 0.6, where ρ is the ratio of the metallic core radius to the total radius of the microwire $\rho = R_m/R$ were cut in pieces of 1 mm length and imbibed in a sheet of dielectric permittivity, ϵ_r , between 5 and 6 located on a conductive base of the same dimensions. Two kinds of absorbent sheets were used. A first type (TI) consists in a sheet of $50 \times 50 \times 0.2$ cm³ where microwires are distributed in all volume. Silicon resin has been mixed with 10 g. of 1 mm length Fe-rich microwires to prepare $50 \times 50 \times 0.5$ cm³ sheets. A second type (TII), divided in three regions of thicknesses e_1 , e_2 and e_3 respectively where the microwires have been mixed in a paint with dielectric constant $\epsilon_r = 5$. The intermediate region of thickness e_2 of 100 μm contains 1mm length magnetic microwires. The characteristic curves have been obtained in normal radiation incidence in anechoic chamber and hysteresis loops by a conventional induction method.

Hysteresis loop shape depends on the composition geometrical characteristic of the wires[1]. The high-frequency magnetic behaviour is connected with hysteresis loop. Fig 1a shows hysteresis loops, corresponding to the Fe-rich microwire, as a function of ρ . A higher longitudinal anisotropy due to thinner inner core is associated with a higher anisotropy field, H_k and lower remanence. Ferromagnetic resonance (FMR) is connected with spin precession about magnetization vector at the effect of high frequency electromagnetic field applied such that magnetic component is perpendicular to magnetization vector and in a magnetic metal is characterized by a maximum in the absorbed power and a minimum in the penetration depth of the electromagnetic field. The precession of the microwave magnetization M is in phase with the microwave drive field h at FMR. Longitudinal anisotropy is strongly connected with ferromagnetic resonance. An increase in the anisotropy field should enhance the ferromagnetic resonance frequency [1].

Figure 1b shows the characteristic curves obtained for four TI silicon sheets prepared, each one with a different type of magnetic microwire from those shown in Figure 1a. It confirms the increase of the frequency associated to the maximum in the spectrum with microwire magnetic anisotropy field raise.

Although the maximum peak position can be understood by means of the microwires magnetic anisotropy field the bandwidth associated to the spectrums should be further analysed. Malliavin et al [2] have shown that the shape of the ferromagnetic resonance peak associated to a unique microwire should be the result of relaxation mechanisms. The dissipative effects include attenuation and relaxation terms in the magnetization movement equation. The high bandwidth of Figure 1b should be understood as a result of microwires volume dispersion.

In order to clarify these aspects, several TII absorbent sheets with thickness e_1 varying from 400 to 1050 μm have been prepared using in all cases 1mm FeSiBCMn magnetic microwires with anisotropy field $H_k = 5$ Oe associated to hysteresis loop (c) on Figure 1a. These results are shown on Figure 2. An increase in e_1 is associated to a decrease of the frequency associated to the maximum absorption, fr.

The interpretation of the results, shown in Figure 2, related with the influence of e_1 in the reflectivity requires a careful analysis of the interaction between the sample and both electric and magnetic fields of the wave.

The intensive studies of the magnetic properties of nearly zero magnetostriction Co-rich glass covered microwires attract considerable science interest in relation with the giant magnetoimpedance (GMI) effect observed in these microwires. The role of the helical anisotropy in GMI effect is well known. Up to now the value of the torsion angle, but not the value of the helical anisotropy, was brought in correspondence to the value of GMI effect. In the present work, we establish, for the first time, the correspondence between the value of the angle of the helical anisotropy and the value of the torsion stress.

Glass covered amorphous microwires exhibiting nearly zero negative magnetostriction, of nominal composition $\text{Co}_{69.5}\text{Fe}_{3.9}\text{Ni}_{11.8}\text{B}_{10.8}\text{Si}_{10.8}\text{Mo}_2$ (metallic nucleus diameter $19\mu\text{m}$, glass coating thickness $2.6\mu\text{m}$) were supplied by TAMAG Iberica S.L. The experiments have been performed using the transverse magneto-optical Kerr effect (TMOKE) in axial magnetic field. The intensity of the reflected light is proportional to the magnetization oriented perpendicularly to the plane of the light polarization, i.e. to the circular projection of the magnetization in the surface area of the microwire. The torsion stress have been applied to the microwire during the experiments.

The process of surface magnetization reversal in the presence of the torsion stress of different amplitude and directions has been studied. Figure 1 presents examples of the TMOKE dependencies on the axial magnetic field with the amplitude of the torsion stress as a parameter. Fig. 1 (c) shows the magnetization reversal in absence of applied torsion stress ($\tau=0$). The surface magnetization reversal consists of two steps: the rotation of the magnetization from axial to circular direction in the outer shell of the wire and the jump between two states with opposite directions of surface circular magnetization.

The applied torsion stress induces strong transformation of the surface hysteresis loops. The most essential feature of this transformation is the stress induced change of the value and direction (sign) of the jump of the Kerr intensity ΔI (the circular magnetization ΔM_{CIRC}). For the torsion stress of $-2.2 \pi \text{ rad m}^{-1}$ value (Fig. 1(b)) the surface magnetization reversal consists only of the rotation of the magnetization from one axial direction to another and there is no jump of circular magnetization. The following increase of the applied stress of negative value causes the appearance and increase of the ΔM_{CIRC} of the opposite sign.

The obtained results are related to the torsion induced change of the helical anisotropy, therefore, the analysis of the experimental results has been performed taking into account the existence of a helical magnetic anisotropy in the wire [1]. The comparative analysis of the experimental results and the results of the calculations permits us to determine and construct the dependence of the angle of the helical anisotropy on the applied torsion stress (Fig. 2). The obtained results are in agreement with the model [2] which considers the torsion stress as an interference of two tensile stresses of opposite signs (pressing and straining) directed at 45° and 135° relative to the longitudinal axis of the wire. Now we have the method which permits us to present the results of the experiments with torsion stress as a dependence on the angle of helical anisotropy.

Circular magnetoelastic anisotropy induced in the nucleus of FeSiB/CoNi soft-hard biphasic microwire.

J. Torrejón, M. García-Hernández, G. Infante, K. J. Merazzo, G. Badini
Magnetism, ICMM (CSIC), Madrid, Spain

Bi-phase magnetic microwires have been recently introduced [1], whose main interests lay in the observed magnetostatic bias in the soft magnetic phase [2] and in their use as multifunctional sensing elements in magnetoelastic-based sensor devices [3]. Different families of biphasic microwires have been introduced by adding an outer magnetic shell (hard CoNi or soft FeNi alloys) onto glass-coated microwires (soft FeCoSiB or hard FePtSi alloys) through combined sputtering and electroplating techniques. Depending on the relative magnetic character of nucleus/shell, bi-phase magnetic microwires can be tailored with different characteristics. The magnetic behaviour of each phase is determined by its intrinsic magnetic softness and by their magnetic interaction including magnetoelastic and magnetostatic contributions. The bias effect in soft/hard and hard/soft biphasic microwires has been particularly investigated.

In this work, an analysis of the magnetoelastic interactions has been performed in a particular biphasic system: a magnetically soft and bistable amorphous Fe-based nucleus plus a magnetically harder crystalline CoNi outer shell. The bistable character and the remagnetization process by a single domain wall displacement of the Fe-based nucleus is shown to be strongly modified by the presence of the CoNi shell.

The studied biphasic system consists of a $\text{Fe}_{77.5}\text{Si}_{7.5}\text{B}_{15}$ nucleus (12 μm diameter), intermediate non-magnetic layers (Pyrex glass layer, 9 μm thick, and Au, 30 nm thick), and an external $\text{Co}_{90}\text{Ni}_{10}$ external layer which thickness is ranged up to 5 μm by control of the time and current density during electroplating. Magnetic measurements as a function of CoNi thickness and temperature have been performed in VSM and SQUID magnetometer, respectively.

Previously, the low-field behaviour of the soft nucleus was investigated under the remanent stray field of the hard shell to determine the magnetostatic bias effect. Here, the study is performed after demagnetizing the biphasic system to identify the sole influence of the magnetoelastic interaction of the outer shell on the soft nucleus.

Figure 1a shows the low-field loops of the FeSiB nucleus for a range of CoNi thicknesses. As thickness, t_{CoNi} , increases the switching field and the remanence decreases. For t_{CoNi} of around 4-5 μm , bistability fully disappears and the remagnetization proceeds only by magnetization rotation denoting the presence of a strong circular magnetoelastic anisotropy. A similar effect is observed when reducing sufficiently the measuring temperature (see Figure 1b) for a biphasic microwire with $t_{\text{CoNi}}=1.5 \mu\text{m}$. Magnetic bistability is no more observed below around 150 K measuring temperature because of the induced circular anisotropy, 1 kOe circular anisotropy field at 100K (no shown here), whose main origin is related to the different thermal expansion coefficients of different layers.

A detailed study has been performed on the magnetoelastic anisotropy with circumferential easy axis induced in the nucleus of the biphasic system by increasing the thickness of the outer shell and by reducing the measuring temperature.

Temperature behaviour of magnetic anisotropy of nanocrystallized Finemet-based glass-coated microwires.

V. Dubuguet^{1,2}, A. Adenot-Engelvin¹, F. Bertin¹

1. CEA, Monts, France; 2. LEMA, UMR CNRS 6157, TOURS, France

Introduction

Glass-coated nanocrystallized microwires have already been studied by many groups owing to their excellent soft magnetic properties and good thermal stability [1]. These one are ascribed to the structural state, which consists of α -Fe(Si) crystallites with a grain size of about 15 nm, embedded in an amorphous residual matrix. The magnetic softness of these alloys is theoretically explained by the random anisotropy model [2,3]. As a feature of the glass coating, the magnetic properties seem to be strongly dependent on magneto elastic effects and engineering of the anisotropy has been achieved through the magnetostriction coefficient. However, in the case of nanocrystallized alloys, both composition and annealing procedure play on the magnetostriction value. The aim of this work is to determine which one is the best way from the study of the thermal behaviour of the effective anisotropy.

Experimental details

The microwires, with composition $\text{Fe}_{73.5}\text{B}_7\text{Si}_{15.5}\text{Cu}_1\text{Nb}_3$, were elaborated using a Taylor-Ulitovsky process. The diameter of the amorphous ferromagnetic core is 8.5 μm and the thickness of the Pyrex glass coating is 6.5 μm . The nanocrystalline state was obtained by conventional annealing at different temperatures from 830 K to 870 K during 1 hour to vary the magnetostriction coefficient. The temperature dependence of static magnetic properties was measured by means of a Lakeshore VSM from room temperature up to 970 K. The saturation magnetostriction (λ_s) was determined at room temperature from the experimental value of the anisotropy fields from various applied tensile stresses.

Results – Discussion

In figure 1, hysteresis loops are sketched from room temperature to 970 K for the microwires annealing at 870 K. The decrease of the saturation magnetization with temperature is observed up to the Curie temperature, $T_c = 870$ K, corresponding to the T_c of the α -Fe(Si) phase. From the magnetization curves, the magnetic anisotropy energy (K_{eff}) was calculated by $K_{\text{eff}} = 4\pi J_{\text{HdM}}$. A decrease in K_{eff} is also observed as shown on figure 2.

The dependence of the λ_s on the annealing temperature is presented in table 1. When the T_{an} increases, a decrease in λ_s is observed from -5.2×10^{-7} for $T_{\text{an}} = 830$ K to -1.6×10^{-6} for $T_{\text{an}} = 870$ K. The nanocrystalline fraction v_{cr} induced by the various thermal treatments can be therefore deduced from the value of λ_s [2]. According to Herzer [2], the magneto-crystalline anisotropy can be estimated by $K_{\text{m-c}} = v^2 D^6 K^4 / A^3$. For a given geometry of microwire (8.5-15 μm), the magneto-elastic anisotropy was calculated using a thermo-elastic model [4]: $K_{\text{m-el}} = 3/2 \lambda_s (\sigma_{zz} - \sigma_{\theta\theta})$. As shown in table 1, $K_{\text{m-el}}$ is larger than to $K_{\text{m-c}}$.

A non-zero “residual anisotropy” is found, corresponding to the difference between the effective anisotropy and the sum of magneto-elastic and magneto-crystalline anisotropy. The residual anisotropy decreases with the annealing temperature and constitutes a non – negligible contribution of effective anisotropy.

Conclusion

The effective magnetic anisotropy of the nanocrystallized ferromagnetic glass-coated microwires determined from the magnetization curves at different temperatures is reported. This one is compared to the sum of the magneto-elastic anisotropy and the magneto-crystalline anisotropy. The

thermal behaviour of these samples has to be compared with a microwire with the same magnetostriction coefficient but with a different composition, in order to determine which is the best way to engineer the effective anisotropy in nanocrystalline glass-coated microwires.

The temperature dependence of the magnetization reversal process for a Fe_{77.5}-xNiSi_{7.5}B₁₅ (x = 0-0.4) glass-coated microwires, with internal diameter 15 µm and total diameter 33 µm, has been systematically studied in the temperature range 4–373 K. The magnetization reversal consists on the nucleation and propagation of a single-domain wall along the wire when certain value of the static magnetic field is applied (switching field)[1-3]. The hysteresis loops were measured by the VSM at room temperature in order to confirm the magnetic domain structure (see fig. 1), which has also been observed by means of Bitter technique, revealing a magnetic structure according to the core-shell model, with a surface radial domains having about 3 µm width, as it can be seen in fig. 2. The switching field dependence on temperature has been studied in amorphous glass-coated FeNiSiB by means of an induction method as a function of the nickel content and in the temperature range of 80–400 K, exhibiting a monotonous decreasing with temperature increasing for the microwire with 15% of Ni (inset of fig.1). The temperature dependence of both saturation and remanent magnetization was also measured for the different microwire Ni contents by using a Squid Magnetometer (Quantum Design), also shown in the inset of fig.1 for the above mentioned sample. The domain structure and therefore the magnetic behaviour of these microwires strongly depend on their composition, which is directly responsible of the sign and magnitude of their magnetostriction constant. It also depends on the value and distribution of internal stresses induced during the fabrication of the microwire, and the stresses produced by the difference in thermal expansion coefficient between the inner nucleus and the outer glass-coating. The observed switching field dependence on temperature is explained in terms of a simple model by considering two energy contributions of magnetoelastic pinning and structural relaxation [4]. The substitution of Ni for Fe creates new magnetostrictive interactions and this new short range order affects the effective anisotropy and magnetostriction. Different magnetization processes and magnetic structures can be obtained modifying the magnetostriction and the effective anisotropy in this way [5], and therefore different temperature dependence. The obtained results allow us to tailor the microwire magnetic properties for its application in magnetic sensors in different temperature ranges through the selection of their composition.

Introduction

The one-dimensional nanostructure such as nanowire is an emerging nanomaterial both from fundamental and engineering standpoints. For example, magnetic nanowires are useful candidates for data storage and biomedical application [1]. In particular, Fe holds an important position because it possesses high saturation magnetization, and it can be easily converted to oxides where Fe-oxides are biocompatible. Fe can also be combined with Au to form a multifunctional nanowire in a barcode arrangement [2]. Compared to Fe/FeOx core/shell nanoparticles [3, 4], limited study has been carried out for core-shell nanowires. In the present study, we aim to achieve biocompatible surface (FeOx shell) while retaining high magnetization (Fe core).

Experimental

First, pure Fe nanowires were synthesized by dc pulse electrodeposition in nanopores of an anodized aluminum oxide (AAO) membrane using a FeSO₄ aqueous solution. To obtain FeOx shell structure, the Fe nanowires embedded AAO membrane was annealed in air at elevated temperatures up to 700°C. Samples were characterized by SEM, TEM, XRD, nano-Raman spectroscopy, and vibrating sample magnetometry (VSM).

Results and Discussion

As shown in Fig. 1(a), the formation of the core-shell nanostructure (elemental Fe core and Fe oxide shell) was demonstrated by TEM. The oxidation was controlled by the annealing conditions. Fig. 1(b) shows a series of Raman spectra of the Fe nanowires thermally treated under different elevated temperatures in air, spatially resolved from a single nanowire using nano-Raman spectroscopy [5]. In the case of 400°C, the spectrum shows dominant α -Fe₂O₃, while Fe₃O₄ was formed at 500°C. The finding is further substantiated by XRD and magnetic measurements. Magnetization curves of the core-shell nanowires embedded in AAO were obtained by VSM (Fig. 2 and Table 1). At the as-deposited state, they showed soft magnetic property such as low coercivity. After annealing in air (Fig. 2(b) for the case of 500°C), the saturation magnetization was reduced as expected, but the coercivity increased from 55 Oe to 203 Oe (field parallel to the wire axis), and from 115 Oe to 239 Oe (perpendicular). This phenomenon appeared equally in all other annealing samples at different temperatures (Table 1). The enhancement in the magnetic properties of the nanowires is probably due to the grain growth, the formation of new species, and the core iron part of the nanowires prevented from further reaction with oxygen owing to spatial arrangements.

Introduction:

In recent years nanoporous templates have been attracted by many researchers due to their potential use for fabrication of metallic nanowires. A promising method to obtain nanowires with large shape anisotropy is based on membrane technology [1]. It can be considered an alternative to conventional lithography methods. Arrays of nanowires are obtained by filling a porous template that contains a large number of straight cylindrical holes with narrow size distribution [2]. The use of nanoporous membrane increases the coercivity and squareness compared to that of a thin film or bulk material. Electrodeposition is of interest because it works under atmospheric pressure, does not require expensive equipment.

Experimental procedure :

Cobalt nanowires were grown into the resulting template by electrodeposition using three electrode cell configuration. The gold layer of 200 nm was sputtered on one side of the polycarbonate membrane which serves as a working electrode. The half cell potential, which was kept at -0.95 V throughout the experiment, for reduction of the metallic ions from the electrolyte, was monitored with respect to a standard calomel reference electrode. An 8-cm² thin platinum sheet was used as a counter electrode. The room temperature electrolyte bath consists 80% by volume of 80 g/l of CoSO₄·7H₂O, 40 g/l of H₃BO₃, and 20% by volume of methanol to wet the nanopores prior to deposition in distilled water. The pH of the electrolyte was adjusted to 3.4. In order to understand the growth rate of nanowires during deposition, the current-time profiles were recorded and are shown in fig.6 along with their corresponding magnetic hysteresis profile. The deposition processes were accomplished under mild stirring of the electrolyte while monitoring the current-time profiles to derive information related to the deposition rate. The magnetic properties of the generated nanowires were investigated by vibrating sample magnetometry and their morphologies were observed by scanning electron microscope. The polycarbonate membrane was taken with 50 nm diameter and length ≤ 6 μm. The morphology of the nanowire arrays were investigated. Arrays of cobalt nanowires have been obtained by filling a porous polycarbonate membrane.

Results and Discussion:

Fig.1 shows the SEM images of the cobalt nanowires which were electrodeposited at -0.95 V relative to the Ag/AgCl reference electrode. Deposition was carried out for different times in order to grow 6- 11 μm long nanowires during the deposition. The samples were prepared by electrodeposition into the pores of commercially available track etched polycarbonate membranes with nominal pore diameter 50 nm and thickness 6 μm. A layer of gold with thickness 200 nm was sputtered on one side of the polycarbonate membrane to serve as a conducting electrode. The morphology of the nanowire arrays was investigated by SEM. Deposited membranes were fractured after immersion in liquid nitrogen, thus exposing the cross section for SEM studies. The SEM cross-sectional images of the nanowires (Fig. 1) show a dispersion of the wire axes with slight deviation with respect to the normal. In very few cases the wires are parallel. Fig. 2 shows the angular dependence of Coercivity (H_c) and remanent-saturation magnetization ratio. Here theta is the angle between the surface of the membrane and the applied magnetic field. It can be observed that the maximum M_r obtained for an applied field parallel to the nanowires while H_c of the array reaches the maximum

when the field is applied perpendicular to the nanowires. The saturation magnetization and remanent magnetization were considered in order to calculate the squareness ratio.

Conclusion:

Cobalt nanowires were successfully deposited into polycarbonate membrane. The track-etched polycarbonate membranes are commercially available. The deposition was done for few hours before structural and magnetic characterizations. The SEM images confirm growth of nanowires, but their alignment is disturbed due to fracture. The magnetic hysteresis loops of the samples are in support of the observations made structurally.

Introduction

Electrodeposition of nanowires has been widely studied due to its advantage of controlling the deposition parameters to tailor the properties of the material. Thus, this method offers advantage for the fabrication of poles for write heads and for use in integrated microsystems. Previous work carried out has been on X-ray diffraction and magnetic study of FeCoNiB films and nanowires¹. In this paper the study is on FeCoNiB nanowires with 10% boron in the electrolyte but the focus is on studying the effect of changing the deposition current, on the elemental percentage deposition in the nanowire and hence on the magnetic characteristics. **Experimental**
FeCoNiB nanowires of thickness 50 nm were deposited in the alumina template of different diameters ($D = 20, 100$ and 200 nm) using the electrochemical deposition method. The galvanostatic conditions used for the sample preparation were, time $t_{\text{on}}/t_{\text{off}} = 12/380$ (ms/ms) with the current density varying from 8 to 12 mA.

Results and Discussion

Effect of Diameter

Both H_c and squareness (SQ) decreased with the increase in the wire diameter. The coercivity values for FeCoNiB nanowires deposited in nanopore template of diameter 20 nm is comparable to the values obtained for CoFeB nanowires. The coercive values (H_c) for out-of-plane (o-o-p) measurements varied from 41 to 277 Oe for nanowire arrays of different diameters. It seemed to vary in the same manner for nanowires deposited at 8 and 9 mA pulsed current as can be seen from Figure 1. For nanowires of 20 and 200 nm the easy axis is in the o-o-p direction whereas it is the in plane (i-p) direction for nanowires of 100 nm. For most of the samples, the o-o-p plane coercivity was higher than the i-p coercivity suggesting lower magnetostatic interactions amongst the nanowires. It was observed that the o-o-p axis switched from easy to hard when the wire length increased beyond a critical value as observed for crystalline Co, but this was clearly not the case with the samples investigated here². The variation in the ΔH_s ($H_s^{\text{oop}} - H_s^{\text{ip}}$) values were not large for the 100 nm pore diameter and for one of the samples with 200 nm pore diameter. This indicated an intermediate switching of the easy axis from out-of-plane to in-plane. EDX study showed that the atomic concentration of Fe and Co for the template diameter 20 and 100 nm did not vary as much as the change observed for 200 nm template diameter. This was attributed to the diffusion rate being higher in 200 nm diameter template leading to larger segregates compared to 20 and 100 nm diameter templates. From Figure 2a, the atomic concentration of Fe, Co and Ni deposits in nanopores diameter of 100 nm was higher than that of the deposits in the 20 nm nanopores diameter. Simultaneously, it was also observed in Figure 2b that the increase in the pulsed current from 8 to 9 mA for the 200 nm nanowires allowed the deposition concentration to increase which indicated that pores of larger diameter did allow the formation of larger agglomerates with more ions concentration at higher currents.

Effect of temperature

The thermal stability of the FeCoNiB nanowires deposited at 9 mA pulsed current was studied over the temperature range 10-300 K. Figure 3 shows that the o-o-p coercive values increased from 45 Oe at 300 K to 76 Oe at 10 K. Similarly, the squareness increased from 0.01 at 300 K to 0.023 at 10 K. There was not a significant improvement in the coercive or squareness values. The results

reported here for FeCoNiB sample are consistent with the values for CoNi nanowires obtained in the sense that the increase in coercivity and squareness occurs with the decrease in temperature³.

Centro de Ciências Exatas e Tecnológicas, Universidade de Caxias do Sul, Caxias do Sul, Brazil

The aim of this work is to develop a process to produce silicon steel wire with the lowest possible magnetic losses, allowing its use as magnetic core material in a new type of transformer [1]. The technical feasibility of this patent strongly depends on the production of steel wires with magnetic losses similar to the grain oriented silicon steel sheets used in conventional transformers. The starting material was a wire with a diameter of 7.2 mm that was drawn down to 0.4 mm, in several steps. Heat treatments were performed in order to promote the stress relief and the recrystallization of the deformed material. Magnetic losses can be reduced by increasing the grain size and by improving the crystallographic texture [2]. Our aim is to obtain a wire with a strong $\langle 100 \rangle$ texture component parallel to its length [3]. X-ray diffraction (XRD) and electron backscatter diffraction (EBSD) were performed for monitoring the evolution of texture.

The crystallographic texture of steel wires has received little attention in the international literature. The feature mentioned in all articles is the effect of plastic cold deformation which induces a strong $\langle 110 \rangle$ texture parallel to the length of the wire. Recrystallization does not seem to modify this texture. The absence of literature about recrystallization texture and/or grain size increase in low carbon steel wire encourages us to believe that processes may be developed, analogous to those used to control the texture of electrical steel sheets, which would achieve the desired $\langle 100 \rangle$ texture parallel to the wire length. In this work three wire drawing and annealing processes were investigated, which resulted in three lots of wire, each with a final diameter of 0.4 mm. Samples 7387, 7388 and 7402 correspond to the final stage of each process of wire drawing and annealing.

From EBSD analysis (Figure 1), it was possible to determine the orientation of each grain and thus to determine which directions are parallel to the wire length. Grains for which the easy magnetization direction $\langle 100 \rangle$ will be parallel to the wire length are red in Figure 1 (see Figure 2). From a comparison of the EBSD images of these samples, it was possible to confirm that sample 7402 had the greatest grain size, and that the grain size of sample 7388 was larger than that of sample 7387. Moreover, from the EBSD and DRX results it is possible to verify the decrease in the number of grains with $\{110\}$ planes parallel to the transverse direction (green grains).

This result shows that one can modify the final texture to one completely different from that commonly seen in the literature. Magnetic loss measurements are the most important yardsticks for electrical steels used with ac current, for motors, generators, transformers, energy meters, etc. The loss value is related to the inner area of the hysteresis curve. In a preliminary test, whose objective was to obtain the wire smallest diameter (final diameter of 0.2 mm from the same starting material with diameter of 7.2mm) the magnetic losses were 12.4 W/kg. With greater control during wire drawing and heat treatment, as described in this paper, it was possible to reduce the magnetic losses to 4.81 W/kg, approximately 2.6 times lower, showing ours to be a promising technique. Magnetic field application during the heat treatment [4] is also being studied.

A proposed “747” test to establish the areal-density capability of a magnetic recording system based only on data-block failure rate.

Z. Jin, M. Salo, R. Wood
HDD AdTech, Hitachi GST, San Jose, CA

The so-called ‘747’ curve provides a well-accepted and convenient method of establishing the areal-density capability of a magnetic recording system [1]. The test and the imaginative naming can be attributed to two engineers, Earl Cunningham and Dean Palmer, working at IBM Rochester, Minnesota in 1978. The test is based on thresholds established for ‘raw error-rate’ measured prior to any error-correction. However the boundary between data detection (which transforms waveforms into bits) and error-correction (which operates at the level of bytes or symbols) is becoming increasingly blurred. In particular, the introduction of LDPC codes with powerful iterative detectors may obviate the use of conventional error-correction codes (ECC) altogether. To circumvent this problem, a ‘747’ test is proposed that looks only at the rate of decoding failures of complete data-blocks after full ECC is applied.

The classical test traced out a curve resembling the profile of a ‘747’ airliner. On the horizontal axis was plotted the distance between the ‘home’ track and the single encroaching or ‘squeezing’ track. On the vertical axis were plotted the distances that the head could be moved off-track, both towards and away-from the interfering track, before a certain threshold error-rate was exceeded. It has become more common to make the measurement by squeezing the ‘home’ track simultaneously from both sides (figure 1) and to report the average off-track capability (OTC). This yields similarly valuable information while avoiding problems associated with track-drift during the test.

The 747 test is traditionally based on raw error-rates, typically quoted as bit-errors per customer bit or sometimes symbol-errors per customer bit. A certain amount of ECC overhead is assumed. This ultimately has to be factored in as part of the format-efficiency calculation. The new proposal is to base the test on block failure rates after ECC and to quote areal-densities including the ECC overhead. This approach will enable the direct comparison of, for example, a system employing a conventional channel code with perhaps 10% ECC overhead vs. a system with only an LDPC code and no explicit error-correction overhead.

After error-correction or the application of a powerful iterative detector, the system will not have any measurable error-rate on-track or for significant amounts of off-track or squeeze. However at some critical displacement the failure-rate will rise rapidly from 0% to 100% over a short distance. To get the best discrimination and statistics, we set the threshold block failure rate to be 50%. A conventional test for areal-density capability usually also defines a certain on-track raw error-rate, for example, 1-symbol per 10^5 customer bits. The new proposal replaces the on-track error-rate criterion with a requirement for a certain margin before a linear-density ‘push’ would cause 50% data-block failures.

Figure 2 shows one example of a 747 curve with the new and the old criteria for one particular read/write channel with 17 symbols (10-bit) of error-correction power (34 symbols of overhead). The new criterion offers much more margin, correctly reflecting the strength of modern ECC systems, and will allow considerably higher track-density and/or linear density to be quoted for given components. However, the net areal-density quoted will change little because the ECC overhead is now included into the areal density calculation.

It is hoped that this new criterion will in future allow more realistic and fairer comparisons of signal-processing systems that may have very different architectures.

[1] E.A.Cunningham and D.C. Palmer, “A Model for the Prediction of Disk File Performance from Basic Component Capabilities,” Paper JE-3, 1988 joint MMM-Intermag Conference, Vancouver, BC, Canada, July 12-15 1988

Figure 1. ‘747’ with double-sided squeeze illustrating margins against failures caused by mistracking. The contour plotted corresponds to the distance that the reader can be moved off-track before a certain threshold raw error-rate is exceeded. The intercept between the 747 curve and dashed line at say 15% SQTP is a typical way of defining track-pitch in an areal density demonstration

Figure 2. Example of 747 curves measured with the proposed 50% block failure criterion vs. a conventional raw error-rate threshold of 1-symbol (10-bit) per 1000 customer bits. The new criterion allows considerably more off-track and squeeze margin at a given linear density. This is consistent with the increased strength of modern error-correction systems. However, such error-correction systems add significant overhead. With the new criterion, this overhead is included into the calculation of areal-density. Thus the net areal-density quoted will not change greatly.

Probabilistic Analysis of Off-track Capability for Higher Track Density Disk Drives.

K. Aruga, H. Ueno, T. Iwase, Y. Ogawa

HDD division (E3-333), Fujitsu Limited, Kawasaki, Japan

Introduction

The trend of track density(TPI) increase is larger than bit density(BPI) increase due to the difficulty of BPI improvement. However, the investigation of TPI increase is inadequate comparing to the BPI increase. This is because the track misregistration (TMR) budget is too complicated, and includes many area of technology, recording process, mechanical positioning, servomechanisms, read write channel etc.

In this paper, we will study TMR budget using probabilistic approach. The process from track misregistration to read write error will be simulated.

Basic formulation

The read MR head has a narrower core width (Cr) than write core width (Cw), shown in Fig.1. In the figure, mechanical track misregistration is displayed as a probability density pw, pr. Figure 2 indicates a typical 747 curve which shows the track density capability. To describe 747 characteristics, we introduce offset-margin and TPI-margin shown in Fig.2. According to the geometry model, we assume the signal output level is proportional to the width of overlapped section between write and read core. We define track offset as $\Delta x = x_w - x_r$, and the basic relation is described as,

$$Sout = \begin{cases} 1 & \text{if } (\Delta x < 0, (Cr + \Delta x)/Cr \cdot pw(x_w)pr(x_r), \text{ else } 1) \end{cases} \quad (1)$$

$$Nctk = \begin{cases} 1 & \text{if } (\Delta x < 0, -\Delta x/Cr \cdot pw(x_w)pr(x_r), \text{ else } 0) \end{cases} \quad (2)$$

$$pw(x) = pr(x) = 1/(\sqrt{2\pi}\sigma) \exp(-x^2/(2\sigma^2)) \quad (3)$$

$$ErrorRate(xoffset) = \int \int f(SN0) pw(x_w) pr(x_r) dx_w dx_r \quad (4)$$

The precise formulation will be presented in the full paper.

Comparing to experimental results

We measured the offtrack capability using 15krpm, 140kTPI, 3.5inch drives. Figure 3 shows the offset value vs Viterbi Margin. The NRRO (Non Repeatable Run Out) 6sigma values in the calculation are 6nm, 30nm, 54nm, respectively. In the case of NRRO6s 54nm, calculated result agrees experimental one very much. This indicates the probabilistic calculation is verified, and smaller NRRO can expand offtrack capability, of course.

Figure 4 shows the offset-margin correlation between calculated and measured value. The offset margin calculation was executed using by the measured data of Cr, Cw, and SN ratio at on-tracking, in every 500 heads. The both results correlate very well.

Conclusion

We tried probabilistic models of the track misregistration, and calculate from the offset probability to the error rate. The simulated results basically agree experimental value well. These results show the validity of these statistic modelling. We will be able to forecast the offset capability in future higher TPI recording by using this model.

Analysis of cross track response using a three dimensional model for Perpendicular Read Heads.

Z. Liu, B. Chen, S. Zhang

Data Storage Institute, Singapore, Singapore

The cross track response to perpendicular magnetization transitions are studied analytically and numerically. An analytical model for three dimensional reciprocity potential of perpendicular read heads has been developed for such studies. The model is able to predict efficiently the magnetic field and spectral response of the perpendicular read heads accounting to effect of the finite width of the read sensor element, the shields, and the soft underlayer magnetic properties. In contrast to previous analytical solutions [1-3], this model allows the effects of the skew angle and off track asymmetry to be considered. The 3d reciprocity potential and the spectral response function are verified using finite element simulations. Fig. 1 shows the field distribution of a read head. The spectral response function is represented in the form of 2d Fourier transform of the field intensity at the read sensor ABS, as shown in Fig. 2. The comparison of the analytical and finite element simulations is given in Fig.3. The response of the recorded transitions and pulses are obtained using the reciprocity principle. The influences of various head-media parameters on the read back signal and its distortions are investigated and discussed. It is noted that the property of the 2d Fourier transform is helpful when analyzing skew angle effects.

The reliability evaluation of piezoelectric micro actuators with application in hard disk drives.

Z. He¹, H. Loh², E. Ong¹

1. A*Star, Data Storage Institute, Singapore, Singapore; 2. Mechanical Engineering Department, National University of Singapore, Singapore, Singapore

In most cases, piezoelectric micro actuators/sensors will experience repeated load during their operations. The fatigue failure and the life cycles issues become important factors to be considered for researchers and engineers. So far a lot of research has investigated the fatigue behavior and mechanism of the piezoelectric actuators and the improvement methods [1~3]. However, the probability and statistics based reliability theory has not been well practiced in their applications. In this paper, a probabilistic design approach is presented to evaluate the reliability of piezoelectric micro actuators. The reliability evaluation of a disk drive dual stage positioning system using piezoelectric micro actuators are performed using the proposed approach.

Based on the relationship between the lifetime (number of cycles to failure) and degradation mechanism of piezoelectric actuators and the electric field strength, the concept of “electric strength” is proposed to indicate the electric field strength of the piezoelectric actuators at a specified lifetime. The lifetime of piezoelectric actuators, electric strength, and electric load are considered as the random variables and their probability distributions are discussed. A P-E-N curve, which described the relationship among the probability, electric strength, and lifetime are introduced for lifetime estimation for piezoelectric actuators. Based on the probability distributions of electric strength, E, and electric load, e, an interference model of electric load and electric strength is introduced to the reliability design of piezoelectric micro actuators. By this interference model, the relationship between the reliability and the usage lifecycles of the piezoelectric actuators can be obtained [4].

Furthermore the reliability model is expanded into two dimensional cases to take into account the effects of both driving voltage and temperature. Based on the relationships between the lifetime and degradation mechanism of piezoelectric actuators and the electric field strength, as well as the actuator working temperature, a two-dimensional probability model for evaluating reliability of piezoelectric micro-actuators is described. The concept of two-dimensional strength is proposed to incorporate the electric driving voltage, E, and the working temperature, T, of the piezoelectric actuators at a specified lifetime. The lifetime (number of cycles to failure) of piezoelectric actuator, electric load and temperature are considered as the random variables and their probability distributions are discussed. The P-N-E-T surface, which describes the relationship among the reliability, lifetime, electric driving voltage, and temperature, is presented. It is mathematically proven that there exists equivalence between the failure probability of electric driving voltage, temperature at a specified lifetime and that of the lifetime at a given electric driving voltage or temperature. Based on this equivalence, a two-dimensional strength probability distribution function is derived. A two-dimensional interference model between the two-dimensional strength and load is proposed to obtain the relationship among the reliability, lifetime, driving voltage and temperature [5].

A case study of a piezoelectric micro-actuator used for head positioning in a disk drive head positioning system demonstrates the application of the approach. The fatigue data of a piggyback piezoelectric micro actuator developed by Hitachi, Ltd. [1, 3] is collected. Firstly the electric load-strength interference model is applied to evaluate the reliability of the piezoelectric actuators and demonstrate the application of the reliability model. The quantified reliability versus usage lifecycles is obtained. With an assumption of 3 kHz drive of the piezoelectric actuators, the evaluated reliability is 96.70% with a 5 years operation in hard disk drives. By the two-dimensional model

with taking into account both the electric driving voltage and temperature variation, the reliability of 96.32% is projected for the assumed 5 years operation. This verifies the validity of the electric load-strength interference model. Therefore, the proposed reliability evaluation method can be used to evaluate the reliability and estimate the lifetime of piezoelectric micro actuators or, in general, of mechatronics devices.

1. Institute for Microtechnology, Leibniz Universitaet Hannover, Garbsen, Germany; 2. INESC-MN, Lisboa, Portugal; 3. Microsensor & Actuator Technology, Berlin University of Technology, Berlin, Germany; 4. Department of Engineering, University of Cambridge, Cambridge, United Kingdom

Introduction

Preconditions for achieving an optimal recording density in Hard Disk Drives (HDD) are a minimal flying height and a perfect track registration. For accomplishing the first one, a dynamic flying height adjustment during writing and reading may optimize the head-to-disc spacing and was implemented into the latest generation of recording heads [1]. To achieve a perfect track registration, a second stage actuation is desirable for compensating to compensate the frequency limitations of the main actuator. Both flexure and Micro Electro-mechanical Systems (MEMS) based designs for second stage actuators were suggested [2, 3]. However, due to the price competitiveness of the industry, the extra costs required for such a device so far hindered its wide scale use. Nevertheless, the requirements are obvious: an optimal solution will provide both capabilities for flying height and track following adjustment and will be cost competitive.

SLIM Concept

To address the actuator requirements, the following approach was taken: an electromagnetic micro actuator was integrated into a pico form factor slider, resulting in a slider with an integrated micro actuator (SLIM) [4]. The integrated micro actuator activates a mounting block to which a chiplet containing the read-write element is attached. The actuator is capable of moving the read-write element on the chiplet both in vertical direction (adjusting the flying height) and in lateral direction (allowing second stage actuation). The cost competitiveness results from the fact that the slim components can be fabricated at lower costs than a present day HDD slider. The micro actuator is substantially less complex than a classic slider while the chiplet containing the read-write element takes up only one third of a pico slider's real estate on a wafer.

SLIM Design and Fabrication

SLIM pursues a two-wafer approach. The actuator magnetics reside in the bottom wafer and the actuator mechanics in the top wafer. Sandwiched between the two wafers is a spacer compensating for the magnetic actuator's building height. The actuator magnetics consist of a pair of variable reluctance (VR) micro actuators [5], the actuator mechanics of a mounting platform suspended by a pair of leaf springs. The mounting platform carries the chiplet containing the read-write element. Simultaneously exciting both actuators adjusts the chiplet's flying height, while alternatively exciting them causes a minute rotation of the chiplet, creating a lateral displacement of the read-write element. Therefore, this design allows both flying height adjustment and track following. A desired lateral displacement of ± 625 nm results in a rotation of 0.18° . Due to the small rotational angle, the resulting change in flying height is only about one nanometer.

The SLIM fabrication is executed on a pair of Si wafers, creating both the actuator magnetics and mechanics in a thin-film batch fabrication process. Since the energy a microactuator is capable of transducing is proportional to its volume, high aspect ratio micro system technologies (HARMST) are applied for fabricating the actuator magnetics [5]. The microactuator mechanics are fabricated by applying silicon micromachining processes. At the wafer's back side, ultimately an ABS will be created by ion milling and will be covered by a DLC layer for sufficiently making the DLC slider

wear resistant. However, for the first prototypes, this ABS will not be included, since the initial testing is performed on a static tester.

Experimental Investigations

To evaluate the actuation capabilities of SLIM, a static test stand was created. It allows for mounting a SLIM device in a position similar to its future application when flying on a data disc. A set of drive electronics is exciting the SLIM micro magnets, allowing for both a lowering of the chiplet and a rotation of the chiplet. For these experimental investigations, a special test chiplet is used featuring a permanent magnet. A GMR detection system is monitoring the chiplet motion.

Introduction

For advanced hard disc drive recording heads, both a flying height adjustment and a second stage track following capability for fine tracking is desirable. To fulfil these requirements in a cost competitive way, a Slider with an Integrated Micro Actuator (SLIM) has been proposed [1]. The dimensions of SLIM correspond to a pico-slider ($1.240\text{ }\mu\text{m} \times 990\text{ }\mu\text{m} \times 300\text{ }\mu\text{m}$). SLIM allows for both vertical (for head-to-disk spacing adjustment) and lateral (for fine tracking) motion of the read-write element. To do so, the integrated micro actuator contains a pair variable reluctance (VR) micro actuators. They activate a mounting block to which a chiplet containing the read-write element is attached. The actuator is capable of moving the read-write element on the chiplet both in vertical direction (adjusting the flying height) and in lateral direction (allowing second stage actuation). This paper describes the design and fabrication of the electromagnetic micro actuator.

Magnetic Core Properties

For accurately simulating a magnetic micro device, the magnetic material properties of the micro components have to be known. The most essential parameter is the relative permeability μ_r , which influences the system's reluctance. For thin film components, it is strongly influenced by the structure's shape. Vibrating Sample Magnetometer (VSM) measurements with arrays of the desired magnetic structures allow to estimate the respective permeability μ_r [2].

Micro Actuator Design

For establishing the SLIM electromagnets, a Finite Element Method (FEM) analysis was performed using the software tool ANSYSTM Multiphysics. 2-D and 3-D simulations were executed to determine the optimal dimensions of the magnetic core. For the chosen actuator design, a 2-D simulation predicted a magnetic force of about $355\text{ }\mu\text{N}$ at an air gap of $2.5\text{ }\mu\text{m}$ while exciting the coils with a current of 175 mA . A 3-D simulation resulted in very similar values: a magnetic force of about $340\text{ }\mu\text{N}$ for the same air gap. Figure 1 shows a 3-D FEM simulation result for the magnetic flux density for an excitation of 175 mA and an air gap of $5\text{ }\mu\text{m}$. Based on the FEM results, the features and dimensions for the micro actuator were finalized. Each magnetic micro actuator (a complete system contains a pair) consists of a U-shaped soft magnetic core and of two double layered spiral coils for the excitation. The total size of one magnetic actuator is $460\text{ }\mu\text{m} \times 300\text{ }\mu\text{m} \times 62\text{ }\mu\text{m}$. Two micro actuators are integrated in the slider. Therefore, a vertical motion of the chiplet with the read/write element as well as a rotational motion (resulting in a lateral displacement of the read-write element) are possible.

Micro Actuator Fabrication

The micro actuator was fabricated in thin-film technology. The wafer process to fabricate the actuator mainly uses High Aspect Ratio Micro Structure Technology (HARMST), combining UV depth lithography and electroplating. The materials employed are NiFe_{45/55} for the magnetic flux guides and magnetic poles, Cu for the coils, a photosensitive epoxy (SU-8TM) for lateral insulation, and Si₃N₄ for insulating the two coil layers from each other. To achieve a constant magnetic layer thickness as well as flat surfaces, Chemical-mechanical Polishing (CMP) was applied. Figure 2 shows an SEM micrograph of a prototype.

Evaluation

For a functional evaluation, a first prototype was subjected to force and field measurements. Qualitative force measurements were conducted by allowing the micro actuator to exert forces on a

NiFe_{45/55} stripe. Executing quantitative force measurements and field measurements includes involving the Physikalisch Technische Bundesanstalt in Braunschweig, Germany and the University of Göttingen, respectively.

Characterization of timing based servo signals.

G. Cherubini¹, R. D. Cideciyan¹, E. Eleftheriou¹, P. V. Koeppel²

1. IBM Research, Zurich Research Laboratory, Rueschlikon, Switzerland; 2. IBM Systems and Technology Group, San Jose, CA

The timing based servo (TBS) format [1] was first used in IBM tape drives with 8-mm cartridge that utilized bidirectional multi-channel serpentine linear recording. In TBS systems, recorded servo patterns consist of magnetic transitions with two different slopes corresponding to two different azimuth angles. The head position is derived from the relative timing of pulses generated by a narrow servo head reading the pattern. Furthermore, encoding of additional longitudinal position information can be provided by shifting specific transitions from their nominal pattern position without affecting the generation of the transversal position error signal. The TBS format including longitudinal position encoding was adopted by the linear tape open (LTO*) standard, where four data bands are straddled by five servo bands that are preformatted during tape manufacturing with a special TBS pattern at $\pm 6^\circ$ azimuth [2]. Four generations of LTO tape drives have been supported by a single TBS format that enabled the doubling of cartridge capacity every two years and allowed scalability in conjunction with backward compatibility based on shingled tracks [3].

In this paper, an analytic expression for the transition response of TBS-based servo systems is introduced. In particular, a closed-form formula for the TBS transition response is given in the case of a Lorentzian response to magnetic transitions with 0° azimuth. Furthermore, an analytic expression for the pulse width at 50% amplitude of the TBS transition response is provided and a closed-form formula for the slope of the TBS dibit at the zero crossing is derived. The proposed analysis can be used to select the azimuth α and the minimum transition distance m of TBS servo patterns for future generations of LTO drives supporting higher track densities, and to determine the width W of the servo reader. Moreover, the characterization of the TBS transition response allows accurate simulations of the overall TBS servo channel.

The derivation of the servo transition response at a distance x from the transition measured in the longitudinal direction (parallel to the tape edge) is based on representing the servo stripe lines at an azimuth angle α by a staircase function with infinitesimal step size dy in the lateral direction. Then for a given reader width W all contributions of time-shifted micro-responses are added by linear superposition, i.e., by integration over the variable y , where y is the displacement across the track (lateral direction perpendicular to the tape edge). The general expression for the servo transition response is thus given by

$$h(x; \alpha, W, f(\cdot)) = \int_{[-W/2, W/2]} f(x - y \tan \alpha) dy$$

where $f(x)$ is the transition response corresponding to a magnetic transition with 0° azimuth. In the following it is assumed that $f(x) = 1/[1+(2x/P)^2]$ is the Lorentzian response, which is fully characterized by the pulse width at 50% amplitude P . In this case, the following closed-form formula for the TBS transition response is obtained

$$h(x; \alpha, W, P) = (P/(2 \tan \alpha)) [\arctan((W \tan \alpha - 2x)/P) - \arctan((-W \tan \alpha - 2x)/P)] .$$

Note that $h(x; \alpha, W, P)$ is the well-known Lorentzian function for $\alpha=0^\circ$. Figure 1 shows the TBS transition response for $\alpha=6^\circ$, $W=8\mu\text{m}$, and $P=0.27\mu\text{m}$, as well as the Lorentzian response.

The pulse width at 50% amplitude of the above transition response can readily be expressed by $PW50(\alpha, W, P) = P [1 + ((W \tan \alpha)/P)^2]^{1/2}$.

Note that $PW50(\alpha, W, P)$ is an increasing function of α , with $PW50(\alpha, W, P) = P$ for $\alpha=0^\circ$. For the response shown in Fig. 1, $PW50(\alpha=6^\circ, W=8\mu\text{m}, P=0.27\mu\text{m})=0.87\mu\text{m}$.

Recalling that the minimum transition distance in longitudinal direction is m , the dibit response is given by

$$g(x; \alpha, W, P, m) = h(x; \alpha, W, P) - h(x-m; \alpha, W, P) .$$

For the TBS format used in LTO, the minimum distance between transitions in a dedicated servo band is $m=2.1\mu\text{m}$ [2]. In general, the slope of the TBS dibit at the zero crossing can be expressed by

$$s(\alpha, W, P, m) = [-8m W P^2] / [(P^2 + (W \tan \alpha)^2 + m^2)^2 - 4m^2(W \tan \alpha)^2] .$$

It is found that analytical and experimental TBS dibit responses are in good agreement.

Evaluation of printed servo patterns.

B. Baker
Redwood Technology, Redwood City, CA

Printed servo patterns offer a significant decrease in the manufacturing cost of hard disk drives (HDDs). In 1998 Matsushita Electric Industrial (MEI) proposed printing the servo patterns of HDDs they manufactured for Quantum Corporation. Disks would be patterned in only a few seconds in special MEI machines [1, 2] before being inserted into the HDD.

Since initial feature sizes were two microns or greater, a final printed servo pattern would occupy too much of the disk surface. The author proposed[3] using the coarse but accurate printed pattern as a reference similar to the function of a traditional Servo Track Writer (STW). To accommodate the expected eccentricity, position information would be derived from phase measurements of nested chevrons. Heads of the drive would be used, as in STWs, to write the final pattern. HDDs would be assembled in a clean room, but the self-write process would be completed in a less expensive self-test rack.

Patterns were designed and sent to MEI for fabrication. First tests were done on a spin stand so features were added for consistent triggering of an oscilloscope at the pattern index. Scope data were analyzed with Discrete Fourier Transform (DFT) calculations, as in the channel chip[4], to measure accuracy of position derived from the difference of phases of A and B bursts of the chevrons. Temperature variations of the lab air caused significant radial offsets of a test track. Spin stands were being modified to add servo capabilities in order to track the thermal expansion, but it was not practical to write the spin stand's reference bursts without erasing portions of the printed patterns. The solution was to capture a few successive revolutions of data to minimize thermal offsets.

The smooth, measured eccentricity could easily be followed or could be corrected by HDD firmware, so the interesting information was the small differences between the total position and the contribution of the known eccentricity. Those small differences, which might lead to track squeeze or incursions, were computed and found to be smaller than those of STW written drives. Standard deviations of differences of position information derived from nearby radii were useful in optimization of parameters such as the separation between the permeable pattern and the DC driving magnet of the printing system[1]. The measurement software was transferred to partners at MEI and Fuji Electric for quicker verification of masters and sample disks.

A channel modification[5] enables use of the low-frequency coarse pattern in HDDs that turn at lower RPM. A decimation filter allows the clock of the output pattern to run 8 times faster than the frequency of the coarse input pattern. The write procedure was extended to allow output of the final pattern. Successor HDDs have those more capable channels. Continuation runs of two Quantum HDDs were completed by using SSW from a printed reference pattern. Yields were equivalent to those of STW written HDDs.

Subsequent measurements of patterns with finer features using better heads show continued improvements of the position information. Major deviations of measurements at nearby radii are nearly the same. By releasing and clamping the disk at a different angle relative to the spindle those major deviations were shown to be due to wobble of the air bearing of the spin stand. Hydrodynamic spindle bearings of HDDs are much better. Even with the consistent deviations a simple simulation of the actuator servo, with scaling for noise as the tracks narrow, shows ample protection against adjacent-track incursions. The present analysis also shows good tolerance of phase demodulation to worst case eccentricity of the pattern.

New compound phase patterns[6] eliminate the SSW process and its potential to introduce track squeeze. Position information would be derived from a master written in an e-beam system and reproduced by NIL (Nano-Imprint Lithography) with features smaller than 100 nm. These patterns have the same frequency for both coarse and fine position information and can be read with contemporary channel chips during a full-speed seek. They are well suited for perpendicular recording since it is not necessary to use Gray codes or other DC fields in the servo wedges. Printing of perpendicular media by horizontal fields has been analyzed and demonstrated[7].

Overwrite performance change due to air-flow induced vibration of head stack assembly.

E. Jang, J. Chang

HDD R&D, Samsung Information Systems America, San Jose, CA

Overwrite (OW) performance of two types of head stack assemblies (HSA) were compared as a function of zone location of disk. They have the same types of head slider, suspension interconnect, and preamplifier but have different mechanical platform (Type A: 4 HGAs vs. Type B: 6 HGAs) and different arm structure. There is OW degradation by more than 2 dB at OD compared to ID for Type B HSA but not for Type A. This paper investigates the mechanism of OW degradation of Type B HSA at OD. It was found that the mechanical vibration of arm actuator is a key factor to the OW degradation.

Overwrite experiments were performed on a Canon RS-5220U spin-stand, RWA2003, at 7200 rpm, and in three zones (ID, MD, and OD) of 95 mm aluminum disks. Conventional OW test method was used with a narrow-band filter and LMR heads. The ratio of low frequency (LF) to high frequency (HF) is 1:7. The high frequency (1T pattern) of OD zone is 468.19 MHz and the linear density is 711.70 kfc. Testing was done with the same setup for both type HSAs except the number of disks (two disks for Type A and three disks for Type B). Fig. 1 shows typical OW performance for Type A HSA (2 disk platform) and Type B (3 disk platform). The sample size of HSA is 3 (12 heads for Type A and 18 heads Type B). As shown in the figure, the OD OW of Type B is worse than ID by 2.77 dB while OD OW of Type A is slightly better than ID by 0.91 dB. We also studied the variation of OW as a function of high frequency. Fig. 2 shows the test result for Type B at frequency of -15% ~ +45 % offset from the reference frequency. No OW degradation was observed up to 45% increase of the reference frequency. The better OW with increasing frequency may be due to thermal pole tip protrusion of the write head. These results indicate that the main origin of OW degradation of Type B at OD is of mechanical, rather than electrical.

In order to confirm mechanical vibration effect on OW, several experiments were performed. One of them is to monitor the OW performance at 3 different zones under only one disk test condition. Fig. 3 shows OW performance before and after removing the bottom disk for one HSA of Type A. There are no significant changes in OW between “Before” and “After” tests. Fig. 4 shows OW performance before and after removing the bottom two disks for one HSA of Type B. Originally, there were OW drops at OD compared to ID (by 5.7 dB for hd 4 and by 3.8 dB for hd 5). However, the OW of OD is higher than that of ID (by 3.8 dB for hd 4 and by 3.4 dB for hd 5) after removing bottom disks. Furthermore, there are increases in OW at OD compared to before removing the bottom disks (by 6.7 dB for hd 4 and by 7.1 dB for hd 5). Additionally, we investigated the arm damper effect on OW performance. There are remarkable increases in both OW and amplitude at OD/MD zones after attaching big size dampers, but there is still overwrite drop at OD compared to ID.

There are some differences between Type A and Type B – number of arm, number of disk, and thickness of arms. The arm thickness of HSA E-block is one of the critical factors for the off-track motion of the head slider during the spin stand testing. The experimental results indicate that both disk flutter and arm vibrations are root causes for OW drop of Type B HSA at OD. The followings are possible explanations. 1) Disk flutter caused by air disturbance due to disk rotation. 2) Interaction between head (or HSA) and disk results in flow-induced vibration. 3) Axial displacement is converted to radial track misregistration (TMR). Arm bending modes of HSA and servo bandwidth are also discussed.

Reduced Order Models for Efficient Simulation of Hard Disk Drive Operational Shock Responses.

W. Lin¹, E. Ong¹, J. Mou¹, E. Ong¹, S. Hu²

1. Data Storage Institute, Singapore, Singapore; 2. Nitto Denko Corporation, Kameyama, Japan

The shock resistance of hard disk drive (HDD) under operational condition is one of the key challenges to the HDD industry with the increase applications of HDD in our daily life. Numerical study of HDD shock resistance will provide guidance to the designer in terms of design verification, performance prediction and optimization. However, due to the structural complexity of the HDD, inherent nonlinearity, as well as a large number of simulation in transient shock responses computed at sub-micro second time increment over a few milliseconds resulting in couple of ten thousand or hundred thousand time step computations; the traditional time-dependant fully meshed models, such as finite element method (FEM) which normally results in a large number of degrees-of-freedom (DOF), are usually computationally very intensive and time consuming or even prohibitive for designer to carry out the simulations. The remedy to this difficulty is the application of model order reduction techniques that allow the original problems with large number of DOF to be replaced with the models with substantially smaller DOF while capturing the behaviors of the original problems faithfully.

Projection-based model order reduction (MOR) uses the techniques of projecting the large DOF of the original system onto an orthogonalised subspace to form models with much smaller DOF. There are many research works in the area of projection-based model order reduction techniques. A well-known one is the Krylov subspace method which matches moments between the transfer function of the original system and that of the reduced order model to a given order. The Krylov subspace method has the advantages of numerical robustness and convenience in implementation. This paper presents the first time successful application of a projection-based Krylov subspace to generate accurate and efficient reduced order models for efficient and accurate simulation of HDD transient shock responses when the HDD is subjected to shock pulses. The reduced order models are generated directly from the HDD system structural matrices obtained from its finite element discretization and the Arnoldi algorithm to extract the subspace basis that spans the Krylov subspace from these structural matrices. Reduced order models are verified and validated with the commercial FEM software Ansys results and the experimental data in both time and frequency domains, as shown in Figs 1-4, for suspension shock transient dynamic responses when the HDD is subjected to half sine shock pulse of magnitude of 25G with the pulse width of 5 ms. It is also demonstrated in Table I that the reduced order model can achieve as high as significant four thousands computational speed up when compared with the traditional FEM simulations.

Model	DOF	Computation time (CPU second)	Root mean squared error
FEM (Ansys)	138,211	126,000	-
Reduced order model	50	32	2.1e-3

A Case for Redundant Arrays of Hybrid Disks (RAHD).

F. Wang¹, N. Helian¹, D. Deng¹, S. Wu¹, C. Liao¹, M. Rashidi¹, A. Parker²

1. Centre for Grid Computing, Cambridge-Cranfield HPCF, Cranfield, United Kingdom; 2. Cavendish Laboratory, Cambridge University, Cambridge, United Kingdom

1. Innovations & inheritance of prior work

Hybrid Hard Disk Drive was originally conceived by Samsung, which incorporates a Flash memory in a magnetic disk [1]. The combined ultra-high-density benefits of magnetic storage and the low-power and fast read access of NAND technology inspires us to construct Redundant Arrays of Hybrid Disks (RAHD, Fig.1) to offer a possible alternative to today's RAID (Redundant Array of Independent Drives) [2] and/or MAID (Massive Array of Idle Disks) [3]. We have designed two separable working modes for RAHD arrays: (1) High-Speed (HS) mode targeting at displaying the full potential speed of hybrid disks; and (2) Energy-Efficient (EE) mode targeting at reducing the energy consumption while maintaining acceptable performance.

2. High Speed (HS) Mode and internal management of hybrid disks

In the HS mode, the Flash memory always contains frequent data objects. We have designed two schemes to move the frequent data blocks into the Flash memory: (1) Using Decision Tree from Data Mining to predict the frequencies of data blocks (file attributes of a newly-generated file are used to predict its frequency). Blocks with high (predicted) frequency are then written onto the Flash memory [4]; (2) Tracking the frequencies of data blocks (when the disk is being used) and then migrating the most frequently-accessed data blocks into the Flash memory during the system idle periods [5]. Because of the high skew in common application loads, most of the requests are likely to be satisfied in the Flash memory without bothering the slower disks.

Three real-system traces (Cello-96, TPC-D, and Cello-99) [6] are used to investigate the data access patterns. These traces capture all low-level disk I/O performed by the system at Hewlett-Packard Laboratories. Our simulator combines the modified DiskSim simulator [7] with an integrated Object Mover to simulate an array of hybrid disks. We use the above modified DiskSim to configure an 8-hybrid-disk RAHD. Reads and writes in Flash are processed in terms of pages. The page size for the Samsung Flash memory used in the work is (2K + 64) Byte. Note that the page size is intended to fit a disk sector in size, hence a disk (Seagate Cheetah Ultra SCSI) in a RAHD is formatted to have a sector size of 2KB. Based on the observation that the majority of the disk I/O's (including both writes and reads) are probably going to less than 10% of the total disk space [5], a Flash memory is conservatively designed to occupy the first 10% of an enlarged disk space that is virtually continuous (inset of Fig.1).

3. Energy Efficient (EE) Mode

In the EE mode, some "active drives" remain constantly spinning whereas the remaining "passive drives" are allowed to spin-down following a period of inactivity. A request is directed to the Flash in the first instance. If the request is fulfilled by hitting the Flash memory, there is no need to awaken the sleeping disk. Otherwise, the request will be forwarded to the disk that is already active or needs to be awakened from sleep.

4. Real-system-trace-driven results

The trace-driven experimental results show: in the high speed mode, a RAHD outplays the purely-magnetic-disk-based RAID's by a factor of 2.4 – 4; in the energy-efficient mode, a RAHD4/5 can save up to 89% of energy at little performance degradation. The highest performance comes from either Level 4 or Level 5. Considering that RAHD4 has an inherent bottleneck on the parity drive, Level 5 looks best in terms of the trade between the performance and the power-saving.

Hybrid disks are specially designed for personal and mobile applications whereas the proposed Redundant Arrays of Hybrid Disks (RAHD) can be used more broadly. It is found that a RAHD will provide improvements in performance, power consumption, and scalability. It is a conceptually simple technique for dramatically improving disk array performance, which is desirable for supercomputers and transaction processing.

Fig.1 Redundant Arrays of Hybrid Disks (RAHD). Hybrid Disk schematic is also shown Based on the observation that the majority of the disk I/O's are probably going to less than 10% of the total disk space, a flash memory occupies the first 10% of an enlarged disk space that is virtually continuous. Accordingly, the most frequently-accessed data blocks are migrated into the flash memory periodically.

What is the future of hard disk drive, death or rebirth?

Y. Deng¹, F. Wang¹, N. Helian²

1. School of Engineering, Cranfield University, Bedfordshire, United Kingdom; 2. London Metropolitan University, London, United Kingdom

1. Introduction

Due to the thermal envelope, it is a challenge to further improve the performance of disk drives. There are many emerging Non-volatile Semiconductor Storage (NSS) techniques including flash memory [1], Magnetic Random Access Memory (MRAM) [2], and MicroElectroMechanical System (MEMS) [3]. Will the disk drive survive? The advances in the NSS techniques enable us to reconsider the disk architecture. This paper proposes a New Disk Architecture (NDA) which integrates a relatively small-size NSS into a traditional disk drive to boost disk performance.

2. Design and implementation

The NDA consists of a NSS module, a frequency tracker, a mapping table, and a data migration mechanism (Fig.1). The storage spaces of the NSS and the magnetic storage media are in the same linear space in terms of Logic Block Address. Many data access patterns indicate that a few blocks are frequently accessed, others much less often [4]. We used two fixed length Least Recently Used (LRU) lists including a hot list and a recent list to identify the most frequently and recently accessed data blocks. The mapping table contains a list of frequently accessed data blocks and their original locations and the locations after data migration. Newly incoming requests are compared against the list and redirected to the new location if the requested data resides there. A process running in the background periodically migrates the frequently accessed data from the magnetic storage media to the NSS, and vice versa.

3. Performance Evaluation

We augmented DiskSim [5] and employed real traces including Cello-96, TPC-D, and Cello99 [6] to evaluate the NDA. A Quantum Atlas 10k disk is employed as a baseline system. We adopted NAND flash memory, MRAM, and MEMS as the NSS in the NDA. The parameters of flash memory are from Samsung K9F6408U0A. The random page read is 10 μ s and the page program time is 200 μ s. For simplicity, the garbage collection was calculated as a penalty: $\text{Penalty} = (\text{Page Size}/\text{Block Size}) \times \text{Page Program time}$. The parameters (16 I/Os and 25ns cycle time) of MRAM are from [2]. The average access time of a MEMS device is 0.5 ms. Fig.2 shows the average response time of the baseline system and the NDA which employs different NSS. Fig.2 demonstrates that the performance speedup ranges from 2.85 to 3.03 with Cello99. By using Cello96, the NDA achieves performance speedup ranging from 2.30 to 2.53. However, the NDA only obtains performance speedup of about 1.1 for the three different NSS with TPC-D trace. We investigated the skews of the three traces. We found that Cello96 and Cello99 have skews of higher than 90%, whereas only 44% data accesses in TPC-D go to 10% storage capacity. The performance results indicate that the speedup is closely related to the skew. According to Fig.2, the NAND flash memory and MRAM have similar performance impact on the NDA. Compared with the NAND flash memory and MRAM, the MEMS has performance degradation of 9.76%, 1.10%, and 6.30% with the three different traces, respectively. This is reasonable because MEMS is slower than the NAND flash memory and MRAM. Fig.3 depicts the disk cache hit ratio of the baseline system and the NDA. It shows that the NDA achieves about 5.41% increase for the three different NSS with Cello99. For the Cello96, there is a negligible decrease (smaller than 1%) with three different NSS. The NDA incurs 0.30%, 3.57%, and 3.57% decrease of hit ratio for the three different NSS, respectively. The reason is that it is difficult to further improve the hit ratio with a small disk cache (Quantum Atlas 10k

has a disk cache of 2MB) even though we attempt to accumulate the frequently accessed data into a relatively small NSS.

4. Conclusion

NSS such as flash memory is likely to replace disk drives in more and more systems where either size and energy or performance is important. We argue that the NSS cannot be used in the data intensive environments and is not suitable for large capacity storage (e.g. bigger than 100GB). By combining a traditional disk drive and a relatively small-size NSS, NDA achieves significant performance speedup and maintains large capacity.

I Introduction

The radiation treatment is one of the cancer treatments and it is used together with other cancer treatments. Recently, the irradiation accuracy has improved by advance of the image diagnosis processors such as CT and MRI and the external irradiation machines. But the real-time data of the internal dose near the focus is required to treat the cancer effectively. Thus the implantable dosimeter and the wireless signal transmission system (Fig. 1) is needed. We use CdTe detector that is a semiconductor detector as the dosimeter. When X-ray is irradiated to CdTe detector, current flows in proportion to the irradiation energy and we can find out dose rate from the current. And the wireless signal transmission system is realized by a magnetic coupling with the structure of two coils located in the inside and outside body stable and is unique. We made the internal and external coil and examined the characteristic of communication area in communicating from the inside to the outside.

II Experimental methods and result

We made the solenoid coil as the internal coil, which is put into the focus by injector and the plane coil with ferrite core as the external coil. Our modulation method is PSK and the carrier frequency is 3MHz. We use the original signal data consisting of 10000 bits digital data prepared by PC and send them by the internal coil. The external coil receives the signal data and it is demodulated and input to PC again. It is compared with the original signal data and BER is measured. We defined successful communication as BER being 0. The transmission rate is 19200bps and we measured communication area in moving the external coil in the direction of X-axis or Y-axis and rotating the external coil. (Fig. 2) The result was shown in Fig. 3. When the external coil is located on the origin, communication distance is 300mm in the direction of Z-axis. When the communication distance is 200mm, which we need, the permissible dislocation is 90mm in the direction of X-axis and is 200mm in the direction of Y-axis. And communication is possible in any angle. The digital signal that we assume the irradiation dose information, the sending wave, the receiving wave, and demodulation wave are shown in Fig. 4.

We examined how communication area changes in the physiological salt solution where we assume inside the body when communication distance is 200mm. As a result, communication area is same as in air and it is not affected by the physiological salt solution. Then we confirmed that communication distance inside the body is 200mm.

III Conclusion

By using this wireless signal transmission system, we can transmit the data of the irradiation dose inside the body to outside the body. In the future, we will examine the influence of the linkage by the power transmission coil on the signal transmission coil.

Imaging of electric permittivity and conductivity using MRI.

M. Sekino, S. Tatara, H. Ohsaki

Department of Advanced Energy, Graduate School of Frontier Sciences, The University of Tokyo, Kashiwa, Japan

Introduction

Imaging of electric permittivity and conductivity distribution in biological tissues gives valuable information on physiological and pathological parameters which are not obtained by anatomical imaging. Measurement of these properties is obviously important for numerical simulations of electromagnetic fields in humans and other living bodies. Electrical impedance tomography (EIT), in which surface potentials are measured during applications of currents via surface electrodes, has been applied to non-invasively obtain conductivity distribution. Some new methods use magnetic resonance imaging (MRI) to obtain conductivity distribution to achieve a high spatial resolution [1,2]. However, these conventional techniques only aimed at the imaging of conductivity. In the present study, we propose a method for imaging permittivity as well as conductivity using MRI.

Principle of permittivity and conductivity imaging

In addition to conventional MRI hardware, a radiofrequency (RF) transmitter is used to apply an electric current to a sample, as shown in figure 1(a). The current is applied to the sample from a pair of surface electrodes with the magnetic resonance frequency (Larmor frequency). Figure 1(b) shows an operational diagram for obtaining permittivity and conductivity images. While the transmitter (A) produces two RF magnetic fields in opposite directions via the RF coil, the transmitter (B) applies a current to the sample. The succeeding transmission and reception of signals are the same as in conventional spin-echo imaging. Two images, θ_{1x} and θ_{1y} , are generated from the phase angle of magnetic resonance signals with RF magnetic fields applied in the x and y directions to the sample, and with the application of current to the sample. In addition, two images, θ_{0x} and θ_{0y} , are obtained with the application of RF magnetic fields in the same directions, and without the application of current. We generated an image of $-\nabla^2(\theta_{1x}-\theta_{0x}-i(\theta_{1y}-\theta_{0y})) / (\theta_{1x}-\theta_{0x}-i(\theta_{1y}-\theta_{0y}))$. The real and imaginary parts of this image divided by $\omega^2\mu_0$ and $\omega\mu_0$ result in permittivity and conductivity images, respectively.

Methods

The proposed algorithm for calculating permittivity and conductivity was evaluated using numerical simulations and experiments. We assumed a cylindrical sample with a diameter of 30 mm, relative permittivity of 40, and conductivity of 0.14 S/m. In the simulation, the electromagnetic fields in the sample during an MRI acquisition were calculated by solving a wave equation of the magnetic vector potential. Magnetic resonance signals were estimated by solving the Bloch equation. The experiments were carried out using a 4.7 T MRI system. A cylindrical test tube was filled with a liquid consisting of an NaCl solution and ethanol to exhibit the above electric properties. Platinum electrodes were attached to the ends of the tube.

Results and discussion

Figure 2(a) shows the results of the numerical simulation. The images of permittivity and conductivity were generated by a pixel-by-pixel processing of the $\theta_{1x}-\theta_{0x}$ and $\theta_{1y}-\theta_{0y}$ images. The permittivity and conductivity values estimated by the proposed algorithm were in good agreement with those in the model at the center of the sample. The estimated permittivity and conductivity were 40 and -0.25 S/m, respectively. The inhomogeneity appearing at the edge of the sample was attributable to an inhomogeneity in the RF magnetic field, which is distinctive in a high-field MRI system. Our algorithm assumed that the RF magnetic field was homogeneous in the sample. Figure 2(b)

shows the experimentally obtained phase images, permittivity image, and conductivity image. The permittivity and conductivity values were close to those in the liquid sample. We found errors in the bottom left part of the sample, which were caused by the lead wire used for injecting current to the sample. The results suggested that a reduction of error is necessary for practical applications. However, the proposed method has the advantage of noninvasively obtaining high-resolution images of the electric properties of a sample, and is easily applicable to biological tissues.

Optimization of coil structure in resonant circuit implant for hyperthermia using MRI.

J. Kunisaki, M. Shimizu, K. Kamio, S. Hiroe, T. Yamada, Y. Takemura

Division of Electrical and Computer Engineering, Yokohama National University, Yokohama, Japan

Hyperthermia is cancer treatment of raising the body temperature. It has an advantage that there are not major side effects as compared with various established treatments, such as surgical operation, radiotherapy and chemotherapy. The hyperthermia using implants, one of the warming methods in hyperthermia, has been reported in term of its ability to control the temperature and heat localized tissues [1]-[2]. A resonant circuit for the implant is heated efficiently by an external magnetic field [3].

We have reported preliminary results on a temperature rise of resonant circuits excited by a magnetic field from commercial MRI equipment [4]. A weak RF pulse of the magnetic field with a low duty ratio under normal diagnosis sequence of the MRI operation could raise the circuit temperature up to 13 deg. C. A combination of the hyperthermia using heated implants and diagnostic functions of MRI offers significant advantages such as human safety. At this point, size of the implants is dimension in 5-15 mm. In order to deliver them through catheter into the human body, miniaturization of the implant down to 1-3 mm is required. In this paper, the optimization of structure of the coil inductor in resonant circuits for implant hyperthermia is discussed.

Resonant circuits were heated by applying an ac magnetic field of 0.034 Oe as low as that of the RF pulse field of 1.5 T type MRI. The direction of the magnetic field was aligned as to penetrate the inductor coil. A temperature rise of the circuit was measured by an optical thermometer. The circuit was covered by polyurethane material as a thermal insulation. Three types of resonant circuits were fabricated from capacitor and different inductors in their coil structures. Two of the inductor coils were prepared with using a single wire (0.3 mm ϕ), and the other was with using a litz wire (15 strands with 0.08 mm ϕ). Effective cross section areas of these wires were same. Winding pitches of the single wire coils were 0 mm and 0.3 mm, and that of the litz wire coil was 0.3 mm. The diameter and turn of the coils were fixed at 6 mm and 10 turn, respectively. A resonant frequency of the resonant circuits was designed to 64.3 MHz, which was close to a RF field frequency of 1.5 T type MRI. Figure 1 shows a temperature rise of the resonant circuits measured at 40 min after applying the magnetic field. The frequency in the figure is indicated by a frequency shift from the resonant frequency. The temperature rise depended on the field frequency as shown in the figure. The maximum rise was obtained at lower frequency than the designed resonant frequency of the circuits. It was because that both of the inductance and the capacitance increased with increasing the temperature, and that the resonant frequency was decreased during the measurements [4]. The highest temperature rise among the three circuits was obtained from the circuit consisted of the litz wire coil. In order to obtain higher temperature rise from the circuit, a lower residual resistance and a higher induced electromotive force in the inductor are essential. However, resistance of the inductor is significantly increased by skin effect and proximity effect under the high frequency measurement. As the induced electromotive forces in the examined three inductors were equivalent, it was considered that the temperature rise was determined by the resistance of the coils.

Figure 2 shows frequency dependence of resistance of the coils used in the resonant circuits measured by using an impedance analyzer. It was found that the lowest resistance among the three coils was the litz wire coil, and the highest was the single wire coil wound closely. The effect of skin effect was suppressed by using the litz wire, and that of proximity effect was suppressed by using the coil wound with pitch.

The high temperature rise shown as Fig. 1 was achieved by the applied field strength and frequency within the reported guideline for human safety [5]. By optimizing the circuit structure, the circuit is expected to be miniaturized down to 1mm order, which is significant for realizing the hyperthermia treatment using MRI.

Calculation of Minimum Parameters Required for Low-Field Low-Size Nano Nuclear Magnetic Resonance (NanoNMR)

ABSTRACT

This paper addresses the minimum parameters required to make Low-Field Low-Size NanoNMR a viable technology and potentially, one of the future Lab-On-Chip technologies. Low-field means an externally applied magnetic field less than 0.5 T and Low-Size means a magnet whose largest physical dimension does not exceed 5 cm. The goal is to develop adequately small and cost-effective NMR spectrometers that can be used at room temperature in a small office environment. In this study, tunneling magneto resistance (TMR) devices are used to sense the NMR signal. The parameters that are calculated are: minimum sample size and concentration required to obtain an adequate NMR signal, TMR sensor size and its distance to sample, RF coil size, RF frequency and RF power. The nanoscale TMR sensors designed in this research using in-house developed simulation software have an area of 100 nm x 100 nm [1] and the permanent magnet that was evaluated has a maximum dimension of 20 mm.

INTRODUCTION

Current NanoNMR technology makes use of ultra-high magnetic fields (> 7 T) that require excessively high frequencies (> 400 MHz). As a reference, the latest NMR Spectrometers from Varian® use frequencies of 500 and 600 MHz with magnets weighing 1 ton and 1.6 tons respectively [2]. These spectrometers need a special room with a minimum ceiling height of 3 m and several additional requirements such as unconventional cooling, power and shielding conditions. The proposed technology, Low-Field Low-Size NanoNMR seeks the goal of downsizing the NMR Spectrometer to the point in scale when it is portable and cost-effective.

Figure 1 shows schematically the proposed NanoNMR sensor which was optimized throughout computer simulations using MATLAB®. The sensor consists of:

- A permanent hollow cylindrical shaped magnet with uniform magnetic field in the hole
- A sample container
- A RF Helmholtz coil
- TMR devices

Figure 1. NanoNMR Sensor

SUMMARY

In brief, to design a Low Field Low Size NMR Sensor, we need the following components with their respective characteristics:

- A ring shaped permanent magnet made of Neodymium Iron Boron Grade N35 with an inner radius of 5 mm, an outer radius of 20 mm and a thickness of 16 mm to produce a homogeneous magnetic field of $\frac{1}{2}$ Tesla at its center
- A TMR sensor with pinned-layer (PL) and free-layer (FL) made of Fe50Co50 with a 0.3 nm Al₂O₃ barrier, an area of 100 nm x 100 nm and biased at 200 mV. This sensor was optimized using in-house developed software. A magneto resistance (MR) of 40% was obtained with this design with a resistance of 135 ohms at 1.5 mA.

- A maximum distance between the TMR sensor and sample of 100 μ m was obtained through MATLAB® simulations.
- A minimum sample volume of 100 nL. The volume requirement is inversely proportional to the sample concentration
- An operating frequency of 10.65 MHz
- The RF coil is a Helmholtz pair with a coil radius of 5 mm made of copper 22 AWG. The coil radius and wire gauge are not critical, but the coil should fit in the hole at the center of the magnet
- RF power < 100 mW

CONCLUSIONS

In this paper, the guidelines to design a Low-Field Low-Size NMR Sensor are developed through analytical calculations and numerical simulations. The results show that this is a feasible, economical and promising technology. Not only NanoNMR will make possible to measure NMR signals from relatively small samples but also the dramatic reduction in acquisition costs will make it affordable to every researcher in biochemistry.

Nanotechnology is rapidly emerging as a necessity in the biomedical industry and research and therefore, the right tools need to be provided for this purpose. Low-Field Low-Size NanoNMR is one such technology we have explored and found to be a realistic and cost-effective solution.

Microwave radiometry for early breast cancer detection.

M. P. Costin^{1,2}, O. Baltag²

1. Computer Science Institute, Romanian Academy, Iasi, Romania; 2. Faculty of Biomedical Engineering, University of Medicine and Pharmacy, IASI, Romania

Abstract — Noninvasive methods have already proven their usefulness in medicine, therefore new techniques are all the time researched. Our approach is using microwave radiometry in breast cancer detection. The technique is in order to be implemented in a national excellence research project.

Keywords — early cancer detection, noninvasive technique, microwave radiometry, microwave medical imagistic.

I. INTRODUCTION

The microwave radiometry is a measurement technique for inner temperature of biological structures. The interest for the microwave radiography [1], [2] (also named microwave thermography), derives from the actual trend to find out, to innovate new noninvasive and without contact techniques [3]–[5], in order to monitor inner physiologic parameters. Regarding cancer detection, the actual research is directed towards new techniques discovery, other than mammography, which is using penetrating radiations, ionogen.

The paper presents the basic principles of microwave thermography, the radiation measuring technique for biologic structures, using very low microwaves receivers in the domain 1-10 GHz, applying the laws of worm body radiation, in the domain of microwaves.

II. MEASUREMENT AND EXPERIMENTAL RESULTS

The practical implementation used a radiometer that we designed on a schema similar to Dicke radiometer, in order to detect tumor tissues, breast abnormal developing structures. The measuring technique resides in applying a skin-contact dielectric antenna and measuring the electromagnetic radiation level in seconds over a specified time interval. The measured value constitutes an inner temperature indicia showing up the breast structure. The systematically data are cyclically taken, alternatively applying the antenna of the transducer on the same symmetrical positions on the right and on the left breast. The values corresponding to temperatures are represented on a diagram as a thermic map.

III. DEDICATED SOFTWARE FOR IMAGE PROCESSING

The processing is realized with special designed software that represents temperature level curves. The difference between these two kinds of thermo-images resides into the different depth of the site where we obtain the information from (the infrared thermography is sensitive to surface temperature, resulted both as effects to inner temperature and from temperatures close to surface).

Even if the image resolution, obtained by microwave thermography is relatively small, due to the imposed fan dimension of the antenna (which is not possible to be very small)—on one hand, and due to the wavelength on another hand, the advantages related to the other means of detection and diagnosis are pertinent. The images are transformed and a gradient computing relevantly plot and to illustrate the regions with high thermo-activity, often corresponding to breast cancer.

Microwave resonator devices for ferromagnetic resonance detection of magnetic beads.

S. Ghionea, P. Dhagat, A. Jander

Department of Electrical Engineering and Computer Science, Oregon State University, Corvallis, OR

Immunosensors using magnetic beads for antigen labeling are being widely investigated for applications in medical diagnostics and monitoring the presence of bioterror agents [1-6]. In our previous work, we demonstrated the feasibility of ferromagnetic resonance (FMR) based inductive detection of beads immobilized in an immunoassay, using a slotline and a coplanar microwave waveguide as shown in Fig. 1 [7]. Here we present a new approach to FMR detection (Fig. 2a) using a resonant slotline excited by a microstrip. This design allows simultaneous excitation of two or more junctions using a single source. Multiple resonators can be added, allowing a single microstrip to drive several slotlines for detecting multiple antigens. Further, it can be used for differential measurement where one junction serves as the control.

In Fig. 2a, we illustrate the principle using a single slotline resonator. A radio frequency (RF) signal is applied to a microstrip on the bottom metallized layer of a dielectric substrate (Fig. 2a). The top metallized layer has the slotline resonator and coplanar waveguides (CPW), and additionally acts as a ground plane for the microstrip. A microstrip-slotline transition is formed between the top and bottom layer, with maximum signal coupling to the slotline resonator when the slotline electrical length is $\lambda/2$, where λ is the wavelength in the slotline [8]. The slotline resonator has an RF current node at the center and antinodes on the end. The ends of the slotline form short-circuited junctions, as shown in Fig. 2a, with CPWs as outputs. The surface metal at junction 2 is functionalized with antibodies specific to the antigen of interest and serves as the sensitive area. In the absence of a bead at the junction, no signal couples from the slotline to the CPW. When a magnetic bead is immobilized at the junction, FMR is excited in the bead when the RF frequency matches the FMR frequency as determined by a dc bias magnetic field. The precessing magnetization in the bead couples the signal from the slotline to the CPW. Thus an output signal is obtained only in the presence of a bead at the junction. Key advantages of the microwave resonator are compatibility with standard CMOS (complementary metal oxide semiconductor) processes, single source drive, and improved signal to noise ratio due to differential measurement.

Ansoft High Frequency Structure Simulator software was used to simulate S-parameters of a resonator device designed for 6 GHz frequency. A bead, with physical and magnetic properties modeled after a commercial Invitrogen M-450 Dynalbead, was placed at junction 2, as indicated in Fig. 2a. The dc field was applied along the out-of-plane axis. Plotted in Fig. 2b is the difference in the simulated S-parameter at each junction with and without the bead placed at junction 2. These data show signal coupling from the slotline to the CPW at junction 2 when there is a bead at junction 2. Due to the symmetry of the two junctions a differential measurement can be made by measuring the signal independently at the CPW of the two junctions, detecting beads at junction 2 using junction 1 as the reference. This eliminates any common-mode signal that may be present in the device, giving just the bead signal. This is an important technique in integrating the sensor within a lab on a chip platform.

The detected signal for varying resonator configurations will be detailed at the conference.

Magnetic Immunoassays – New Methods of Biochemical Diagnostics Based on Detection of Magnetic Nanoparticles by Non-Linear Magnetization.

P. Nikitin¹, P. Vetoshko², M. Nikitin³, T. Ksenivich¹

1. Natural Science Center, General Physics Institute, Russian Academy of Sciences, Moscow, Russian Federation; 2. Institute of Radioengineering and Electronics, Russian Academy of Sciences, Moscow, Russian Federation; 3. Department of Molecular & Biological Physics, Moscow Institute of Physics & Technology, Dolgoprudny, Moscow Region, Russian Federation

Recently using of superparamagnetic particles or magnetic beads (MB) as labels in biosensing has become very popular. We introduced a highly sensitive method of MB counting based on non-linear behavior of MB in magnetic field [1-3]. It consists in exposing MB to an alternating magnetic field at two frequencies f_1 and f_2 . The response is measured at combinatorial frequencies $f = mf_1 + nf_2$, where m and n are integers (one of them can be zero). The integers can be varied in order to get the best signal-to-noise ratio, e.g. $f = f_1 \pm 2f_2$ [1]. The method allows very sensitive and robust detection of non-linear magnetic nanomarkers for different biosensing [2,3] and life science applications [4]. The Magnetic ImmunoAssay technology (MIAtek™) based on non-linear magnetization of MB is compatible with different assay formats (3D capillary and filter structures, lateral flow strips, biochips, etc) and with both heterogeneous and homogeneous immunoassays, where probe volumes with MB labels are formed, respectively, on a solid surface or by grouping of MB using inhomogeneous magnetic field or sedimentation directly in liquids or by filtration [1].

The first part of the present research is devoted to extension of 3D heterogeneous MIAflow™ format for detection of several biological agents simultaneously. For this purpose, a multi-channel BioMag readout device has been designed to count non-linear MB in several recognition zones with deferent capture antibodies. The threshold sensitivity of each channel is about 1 ng of total weight of magnetic nanoparticles. The sensing area per detectable magnetic particle is 3 orders larger than that reported for the other techniques. The first configuration for the multi-analyte assay shown in Fig. 1 consisted of several sequentially connected recognition zones with porous or multi-capillary structures. Different capture antibodies were immobilized on the large surface (up to 40 cm²) of the structures. The antigens from large range of volumes (0.1 - 100 ml) of tested liquids were immunofiltrated by antibodies on these structures. Then blocking bovine serum albumin, second tracer antibodies, MB and washing buffer were pumped via flow channel forming sandwich immunocomplexes. The resulting number of magnetic labels in each zone was read by the BioMag device. Another multi-analyte setup was based on recording of parallel biochemical reactions in spatial syringes, where porous filters or multi-capillary structures were sealed as shown in Figs. 2,a-d. The antigens and reagents were delivered using an automated liquid handling system based on step motors.

The second part of the present paper is devoted to optimization of the MIAtek™ technology for homogeneous immunoassays to detect agglomeration of biomolecular complexes of antigens and antibodies with MB directly in liquids under test. Some of these assays do not require washing steps. As proposed in [1], three methods were tested for grouping of immunocomplexes in the probe volume, namely: by inhomogeneous magnetic field, by sedimentation directly in liquids and by filtration. It has been observed that separation of immunocomplexes by inhomogeneous magnetic field also accelerates binding of immunoreagents by active attraction of interacting particles and decreases assay time. An optical biosensor Picoscope™ [5] was used for measurements of kinetics at each step of reagent binding as well as for rapid selection of protocols, reagents, magnetic beads and buffers for highly sensitive detection of biochemical reactions. The magnetic

immunoassays have been developed for detection of bacteria (*Salmonella typhimurium*, *Legionella pneumophila*) and soluble proteins (lipopolysaccharide of *Francisella tularensis* and F1 antigen of *Yersinia pestis*).

The developed magnetic biochemical diagnostic platforms and formats are promising for medical diagnostics, points of care, food pathogen detection.

The work was supported by Magnisense Company and RFBR grant.

Giant magnetoresistance sensors for lateral flow tests.

C. Marquina¹, J. M. De Teresa¹, J. Sesé², V. Grazú², B. Velasco³, P. Freitas⁴, R. Ibarra^{1,2}

1. Instituto de Ciencia de Materiales de Aragon, CSIC-Universidad de Zaragoza, Zaragoza, Spain; 2. Instituto de Nanociencia de Aragon, Universidad de Zaragoza, Zaragoza, Spain; 3. CerTest Biotech, Zaragoza, Spain; 4. INESC, MN, Inst Engrn Sistemas Computadores Microsyst & Nanot, Lisbon, Portugal

A great effort is currently being made in the research on lateral flow tests due to their wide use nowadays in Life Sciences. Their simplicity, low cost and the large variety of analytes that can be detected by means of this technique make them suitable for a large number of applications. However, the conventional tests based on immunorecognition and the use of coloured colloidal particles have still some drawbacks that limit their use: they do not provide a quantitative determination of the analyte, and their sensitivity is limited. Our strategy to overcome these disadvantages consists in the use of superparamagnetic core-shell nanoparticles to tag the analyte, instead of the coloured colloid. The use of these magnetic labels allows us to quantify the amount of analyte present in a problem sample with a very high sensitivity, detecting their magnetic response by means of the suitable magnetic sensor.

Our method is based on measuring the magnetoresistive response of a giant magnetoresistive (GMR) sensor placed in proximity to the magnetic nanoparticles present in the lateral flow strip. Our GMR sensors are of the spin-valve type, consisting of (6.5nm)NiFeCr/(4nm)NiFe/(2nm)Co₈₀Fe₂₀ as free electrode, (2.2nm)Cu as non-magnetic spacing, and (3.5nm)Co₈₀Fe₂₀/(30nm)MnNi/(5nm)NiFeCr as pinned top electrode, grown by ion-beam deposition. These sensors have a maximum magnetoresistance of 7% at room temperature and linear response around zero magnetic field. Laser lithography techniques are used to define the active part of the sensor and the contact pads. Besides the GMR sensor, our prototype consists of a permanent magnet to polarise the superparamagnetic nanoparticles, the electronic system to process the sensor output signal, and the mechanical system necessary to horizontally sweep the lateral flow strip containing the magnetic beads through the active region of the GMR sensor. This mechanical system allows also moving the strip vertically so that the sensor output is obtained by differential measurements, measuring the sensor resistance when strip and sensor are in soft contact and when they are separated a fixed distance in the vertical direction. In the figure we show the output signal of the magnetoresistive sensor corresponding to a test performed in a solution containing 25 mIU/ml of hCG hormone. Preliminary assays using our biosensor to detect the hCG pregnancy hormone in a solution show that the sensitivity of this method is thirty times higher than in the conventional pregnancy tests being able to detect tenths of nanograms. Several strategies to further increase the sensor sensitivity are currently being attempted.

The properties of the magnetic beads to be used in our test are also important to improve its performance. Therefore, different types of core-shell nanoparticles are being tested our group, in order to make a comparative study of their magnetic response at low magnetic fields, their agglomeration, etc. Other crucial aspect to take into account in order to increase the sensitivity is the proper functionalisation of the nanoparticle shell, in order to achieve an oriented immobilisation of the antibodies to be used in the immunorecognition process. Different functionalisation and immobilisation protocols are currently being studied in our group.

Output signal of the magnetoresistive sensor in d.c. configuration corresponding to a lateral-flow strip where a biorecognition test has been performed with a solution containing 25 mIU/ml of hCG hormone. The black curve corresponds to a single measurement and the red curve to the average of 5 measurements.

Magnetic-Entasis Biorecognition Platform: Self Assembly of Magnetic Nanoparticles for Detection of Magnetically Labeled Biomolecules.

Introduction

Biorecognition platforms based on the detection of magnetically labeled molecules are being developed for high speed, high sensitivity and inexpensive, point of care diagnosis of heart diseases, cancer and even for testing if drivers are under the influence of drugs [1-5]. Currently, GMR, spin-valve and Hall effect devices are widely used to detect 200-1000nm diameter superparamagnetic beads.

However, there is increasing demand for the detection of single, sub-100nm diameter particles in order to improve the resolution of biomolecular detection. The sensitivity of magnetoresistive devices may not enable the accurate and reproducible detection of single superparamagnetic labels of less than 100nm over large surface areas.

Here, we describe the main features of the 'magnetic-entasis platform'(MEP), a versatile approach for the rapid detection of single magnetic nanoparticle labels for large surface area biorecognition. Our method is based on inducing magnetic self assembly of columns of micrometer sized magnetic bead onto immobilized 'target' magnetic nanoparticles. We demonstrate that 'magnetic-entasis' will enable the detection of single nano-magnetic particles immobilized over 5mmx5mm areas within several seconds.

Experimental

The nano-magnetic beads ('targets') were detected as follows (Fig.1):

- (1) Optical photolithography was used to define gold thin film/silicon dioxide stripes with a five micrometer pitch on 5mm x 5mm sized silicon substrates.
- (2) Functionalized 130nm diameter superparamagnetic beads ('targets') were selectively immobilized at differing concentrations onto the gold stripes. Scanning electron beam microscopy (SEM) was used to determine the areal density of the 'targets' immobilized on the gold stripes.
- (3) The test substrate with the immobilized 'targets' was positioned under the objective lens of a digital microscope. The nanobeads were not visible even at x3000 magnification.
- (4) A pipette was used to apply a drop of water containing micrometer sized superparamagnetic beads onto the test substrate. These 'columnar' micro-magnetic beads moved under the action of gravity over the sample.
- (5) Magnetic field gradients were applied to the sample and the motion of the micro-magnetic beads monitored with the digital microscope.

Results

In the absence of the magnetic field gradient, the micro-magnetic beads moved smoothly across the gold/silicon dioxide patterned substrates. However, when the magnetic field was applied, the micro-magnetic beads were captured by the immobilized nanomagnetic 'target' beads and formed convex columns ('magnetic-entasis') estimated to be several tens of micrometers in height. The capture and formation of columns occurred within 30 seconds.

Approximately four, 130nm diameter nano-magnetic beads captured a single one micrometer columnar bead. In contrast, it required approximately 11 of the 'target' nanobeads to capture a single columnar bead with a diameter of 2.8 micrometers.

Conclusions

Magnetic self assembly of magnetic beads was used to detect 130nm 'target' nanobeads over large sampling areas. This method will find applications for monitoring biorecognition processes where detection of sub-100nm magnetic labels is a critical factor.

Introduction:

For the detection and identification of biomolecules of interest, especially DNA fragments, a common technology is to generate an array of the target molecules on a microarray [1]. The dominant technology is to create an array of probe molecules with each node of the array having probe molecules matched to a particular target molecule. The array may be lithographically formed, as in the Affymetrix array, or by spotting, as in the Agilent array. These arrays are single-use and relatively expensive.

Arrays have also been generated in which paramagnetic beads, to which target molecules have been bonded, are ordered on a magnetic substrate [2, 3]. In these arrays the surface of the bead is typically covered with target molecules, fluorescently tagged. Here we report on a new variation of the paramagnetic bead technology. The target molecules are bonded to the paramagnetic bead using a "linker" molecule on the bead. The paramagnetic beads attach to the gaps of a micron-sized magnetic bars array (Fig. 1(a)). Under these circumstances the large molecules order in form of an array and can be observed for a substantial period of time for analysis and identification. In addition, the array can be reused after flushing away the magnetic beads with a high-velocity fluid.

Experiments:

The magnetic bar arrays were formed on 4" Si wafers with lithographic patterning technology common to the hard disk industry with a process sequence including (1) sputter deposition of a 150 nm SiO₂ base layer, (2) sputter deposition of a metallic multilayer comprising a hard magnetic material, (3) bi-layer photolithography, and (4) ion milling. The magnetic bars were arranged in rows, with bars typically 20 µm long and 2 µm wide with gaps between bars from 1.5 µm to 4 µm wide. The paramagnetic beads are captured by the fringing fields in the gaps between bars. The rows of bars were typically spaced by 20 µm (see Ref. [3] or Fig. 1(b) in this paper). The hard magnetic material for the bar structures was either formed by a single CoPt (70 nm) on a Cr seed layer or a [Cr (5 nm)/CoPt (10 nm)]₇ multilayer. The coercivities of these films were about 550 Oe and 670 Oe, respectively. After processing, the bars were magnetized parallel to the long axis of the bar geometry by applying an external 13 kOe magnetic field. Earlier experiments with bars of the soft magnetic material CoTaZr were less than fully successful since closure domains often formed at the bar ends due to demagnetization effects.

Microfluidic channels were then patterned on a 4" Pyrex wafer, and the glass wafer bonded to the silicon substrate through anodic bonding. The particles to be captured in the array were then flowed over the magnetic bar array through the microfluidic channels.

Results:

The capabilities of the system were demonstrated by creating an ordered array of immobilized yeast molecules. A group in the Stanford Genome Technology Center is studying the relationship between certain yeast DNA segments and the reproduction of the associated yeast molecules. The experiment requires observing specific yeast cells through a microscope for many hours, a very tedious task for mobile yeast cells. With the yeast cells immobilized in an array, time-lapse pho-

tography can be used to monitor a number of cells without continuous observer presence. For our experiment, we used streptavidin-coated paramagnetic beads 5 µm in diameter and Concanavalin A (Con A) as the linker molecule. Fig 1(b) shows the array of captured particles. Paramagnetic beads have been captured on nearly every gap in the array. The paramagnetic beads typically capture only one yeast molecule, though occasionally two or even three yeast cells bind to a single paramagnetic bead. The yeast cells can be pre-mixed with the paramagnetic beads and the binder, or flowed over the paramagnetic beads after capture. The pre-mixing is found to be more efficient.

Discussion:

We have demonstrated the capture of non-magnetic molecules of biological and perhaps medical interest in an ordered array. The technique is applicable to a wide range of molecules, and so is of general applicability. All that is required is a linker molecule like Con A which will bond the target molecule to the streptavidin-coated bead. For larger molecules, paramagnetic bead arrays can be made with trios (arranged in a triangle) or quads (arranged in a square) of paramagnetic beads, affording multiple capture sites for larger molecules. The magnetic array is inexpensive and reusable. We envision wide applicability for this technology.

Voltage control of magnetic anisotropy in an ultrathin Fe film.

T. Maruyama, K. Ohta, N. Toda, T. Nozaki, T. Shinjo, M. Shiraishi, Y. Suzuki
Engineering science, Osaka university, Toyonaka, Japan

Recently, voltage controlled magnetization switching which has high potentiality for spintronic devices has started to attract a lot of attention because of its low energy consumption. Several kinds of approaches have been suggested so far, such as the voltage controlled interlayer exchange coupling [1, 2] and the electric field induced anisotropy change [3]. Very recently, Weisheit et al. reported that the coercivity of ultrathin FePt and FePd films can be changed by an applied electric field [4]. However, they used a liquid electrolyte to apply a large electric field. So as to apply this for practical spintronic devices, the effect should be realized in an all solid state device.

In this study, we focused on a structure which consists of a solid insulator and an ultrathin ferromagnetic layer (see Fig.1). All layers except for the top thick polyimide layer were prepared by a molecular beam epitaxy method. Since the influence of the electric field to the perpendicular anisotropy is effective only at the interface, the ferromagnetic layer should be composed of several monatomic layers. Besides, the ultrathin Fe layer deposited on an Au buffer layer exhibits a transition of magnetic anisotropy from in-plane to perpendicular depending on the film thickness [5]. This feature is suitable for the observation of the anisotropy change by the electric field. Therefore, we employed an ultrathin Fe film. The insulating layers consist of MgO, Al_2O_3 and polyimide. The polyimide was used to cover pinholes in the MgO/ Al_2O_3 layers. A bias voltage was applied through the top ITO (Indium Tin Oxide) electrode. When a high voltage is applied to the system, the electronic state of the ultrathin Fe layer changes, leading to the change of magnetic anisotropy. From symmetry, a perpendicular magnetic anisotropy is expected to be induced/suppressed by an electric field. A change of the hysteresis loop induced by a voltage application was detected by the polar MOKE system shown in Fig.2.

In order to detect the small signal changes, a lock-in technique was used. A lock-in amplifier 1 is used to measure the Kerr ellipticity η , and a lock-in amplifier 2 is for the measurement of minimal change of lock-in 1 amplifier output caused by the voltage application. In the measurement, we needed to apply an ac high voltage to the sample, so the oscillation output from the lock-in 2 voltage (3.13V, 213Hz) was amplified up to 160V peak to peak by a high speed amplifier. Using this measurement system, we could observe a considerable modulation of magnetic anisotropy when the thickness of Fe was from 0.4 to 0.6nm. In the presentation, we will discuss about the Fe thickness and the bias voltage amplitude dependence of this effect. This result has a significant meaning from a viewpoint that we can control the magnetic anisotropy, which is commonly considered as a fixed material intrinsic constant, by an applied electric field even in the all solid state devices.

We develop a theory to describe on a quantitative basis two magnon relaxation process in ultrathin ferromagnets. By extending an earlier formalism [1] to the case where the magnetization is tipped out of plane, one may extract information on the angular dependent time response of a system, as well as investigate the role of sample anisotropies or defects geometry in ultrathin films. It is known that surface or interface defects activate two magnon scattering and therefore we can manipulate the magnetic damping properties by controlling two magnon linewidth through defects. The nature of the damping of spin motions realized in such structures controls their response time and it is of interest to know whether the mechanisms well known in bulk materials are operative, and if there are new damping processes present unique to the nanoenvironment.

Our theory will be focused on the motion of the magnetization of ultrathin ferromagnetic films, under circumstances where the wavelengths involved are very long compared to the lattice constant, which is the domain probed by FMR spectroscopy and Brillouin light scattering. We provide explicit expressions for the two magnon contribution to the FMR linewidth and the two magnon induced frequency shift of the FMR line, in a form sufficiently general for application to a diverse array of defect structures. We also provide complete expressions for the frequency and wave vector dependent susceptibility tensor. This will allow the reader to analyze the influence of defect induced spin wave scatterings on Brillouin light scattering spectra as well, if desired. It is our view that to have the full form of the response functions in hand will prove useful in a variety of contexts. As an illustration of our results, we present in Figs. 1-3 numerical calculations of the angular and frequency dependence of the two magnon linewidth $\Delta H^2 = \Gamma \Phi^6$, for rectangular defects. It is interesting to note that both quantities (Γ and the critical angle Φ^c) depends on frequency, field angle, anisotropies and material parameters, and the defects details are contained only in Γ . This allows us to manipulate two magnon scattering rates by controlling defects geometry, in addition to the angular degrees of freedom. We see that the dependence of the two magnon contribution to the linewidth can show striking behavior, as the magnetization is tipped out of plane. It should be kept in mind that these calculations employ a particular model of the defect structure, and the behavior may change if the defect structure which activates two magnon scattering deviates substantially from the picture utilized in these calculations. The notion that the two magnon contribution to the linewidth cuts off when the angle between the magnetization and the film plane is greater than 45 degrees is supported nicely by the data reported in Ref. [2]. Of course, it will be of great interest to see detailed studies of the influence of tipping the magnetization out of plane. It is our hope that the results presented here will stimulate new and more detailed studies of the influence of tipping the magnetization out of plane on the response characteristics of ultrathin ferromagnets.

[2] R. D. McMichael et al., J. Appl. Phys. 83, 7037 (1998).

The frequency dependence of the two magnon contribution to the FMR linewidth, for the situation where the angle between the externally applied field and the plane of the film is held fixed, as the external field is increased. The parameters employed in these calculations are the same as those utilized in Ref. [1]

We illustrate the frequency dependence of the linewidth, as the angle between the magnetization and the film plane is kept fixed, as the external field is varied. The parameters are the same of Fig. 1

For various frequencies, we show the variation of the two magnon contribution to the FMR linewidth as a function of the angle between the external magnetic field and the plane of the film.

CEMS study of epitaxial $\text{Co}_2\text{Cr}_{0.6}\text{Fe}_{0.4}\text{Al}$ thin films.

V. Ksenofontov¹, C. Herbolt², M. Jourdan², C. Felser¹

1. Institute of Inorganic and Analytical Chemistry, Johannes Gutenberg-University Mainz, 55099 Mainz, Germany; 2. Institute of Physics, Johannes Gutenberg - University, 55099 Mainz, Germany

The Heusler alloy $\text{Co}_2\text{Cr}_{0.6}\text{Fe}_{0.4}\text{Al}$ (CCFA) attracts large interest as a potential half-metallic ferromagnet [1]. In this compound a high tunnelling magnetoresistance (TMR) is expected as a result of a high spin polarization at the Fermi level [2].

For the spin polarization the degree of structural disorder of Heusler compounds plays a crucial role. The preference of CCFA to grow in the $B2$ structure with disorder on the Cr/Fe and Al positions instead of the fully ordered $L2_1$ structure is a known fact. Calculations predict that $B2$ type of disorder has only a minor effect on the spin polarization, whereas additional disorder on the Co sites ($A2$ structure) is predicted to strongly reduce the spin polarization [3].

Epitaxial thin films of the Heusler half-metallic compound CCFA were investigated using conversion electron Mössbauer spectroscopy (CEMS) in order to get insight into the structural and magnetic properties. Thin films of 100 nm thickness were deposited by rf magnetron sputtering on MgO substrates without and with 10 nm Fe buffer layer. CEMS spectra of non thermotreated samples with Fe buffer layer show distinguishable α -Fe and CCFA subspectra (Fig. 1a). The latter can be described as a broad distribution due to reduced crystalline quality. Subsequent thermal treatment improves the thin film crystallographic order and morphology and causes the diffusion of Fe atoms from the buffer layer into the CCFA (Fig. 1b). Apparently, the related diffusion of Cr atoms from the CCFA thin film into the Fe buffer layer also takes place. Thus the thermal treatment influences the Fe to Cr ratio of the CCFA, and obviously the position of the Fermi level. Increasing of treatment temperature intensifies a central peak in the Mössbauer spectra, which means enhancement of antisite Co/(Fe,Cr) disorder. Samples with Fe buffer layer prepared at the optimal annealing temperature of 550 °C, as determined by tunneling magnetoresistance measurements, reveal some degree of $A2$ disorder (Fig. 1b). Thermal treatment at 600 °C reduces the magnetoresistance [2] and according to the CEMS data is associated with higher degree of $A2$ disorder (Fig. 1c).

CEMS spectra of CCFA thin films without Fe buffer layer are presented in Fig. 2. A sample annealed at 450 °C indicates almost no Fe atoms occupying Co sites and consequently no $A2$ disorder (Fig. 2a). Thermal treatment at 550 °C increases a degree of the antisite Co/(Fe,Cr) disorder (Fig. 2b). The $A2$ disorder fraction in CCFA thin films without Fe buffer treated at 600 °C (Fig. 2c) is similar to the degree of disorder found in thin films with Fe buffer layer (Fig. 1c).

Hyperfine magnetic fields on iron atoms (H_{hf}) in CCFA thin films deposited on MgO substrates as a function of annealing temperature show the following trends. For samples without Fe buffer layer H_{hf} monotonously decreases with increasing of annealing temperature due to the $A2$ disorder. For samples with Fe buffer layer similar decreasing of H_{hf} competes with increasing of H_{hf} due to an enrichment of Fe atoms which diffuse from the Fe buffer layer into CCFA. One can suppose that among others these two factors could determine the maximal value of magnetoresistance observed in CCFA films deposited on MgO substrates with Fe buffer layer after annealing at 550 °C [2].

Morphology-induced oscillations of the electron-spin motion in Fe films on Ag(001).

*L. Tati Bismaths*¹, *L. Joly*², *F. . Scheurer*¹, *W. Weber*¹

1. Institut de Physique et Chimie des Matériaux de Strasbourg,, Strasbourg, France; 2. Swiss Light Source, Villigen, Switzerland

It is well known that magnetic properties of thin films are inherently connected to the morphology and the structure of the films. It is in particular the strain arising from different lattice parameters of the film and the substrate which induces for instance additional magnetic anisotropy contributions. Here we report on spin-polarized electron reflection experiments in which the electron-spin motion, comprising an azimuthal precession and a polar rotation around the magnetization direction of the ferromagnet, is studied in Fe films on Ag(001). Apart from quantum-size induced oscillations, the period of which depends on the electron energy, we observe also oscillations with a period of one monolayer independent of the electron energy. We assign the latter to oscillations of the surface lattice parameter when going from a filled to an incompletely filled Fe layer.

Ferromagnetic Resonance of Disordered FePt Thin Films.

J. Gómez, M. Vásquez Mansilla, A. Butera

Centro Atómico Bariloche and Instituto Balseiro, Bariloche, Argentina

The intermetallic alloy FePt has received considerable attention in the last years due to the potential application as ultra high density storage media. Equiatomic FePt alloys have been intensively studied in the form of thin films and nanoparticles because of their unique magnetic and magneto-optical properties, especially the extremely large magnetic anisotropy, the very high coercivity, and the large polar magneto-optical Kerr effect. However, these properties are only observed when the alloy is atomically ordered in the L10 FCT crystalline phase, which is obtained after thermal treatment at high temperatures. Due to this fact, most of the research was devoted to the understanding of the physical properties of the ordered phase, while less attention was paid to the metastable disordered FCC phase which generally forms when films are fabricated at room temperature.

In this work we have analyzed the magnetic properties of a set of nominally equiatomic FePt films grown on oxidized Si (100) substrates. Samples of four different thicknesses ($t = 10, 30, 60$, and 100 nm) have been fabricated by dc magnetron sputtering at room temperature. The real atomic film composition was close 45% Fe, 55% Pt, as revealed by EDX studies. X-ray diffraction analysis confirmed the absence of atomic order and showed a moderate texture along the (111) direction. The dc magnetic response of the films was measured either in a VSM or a SQUID magnetometer. In Fig. 1 we present the in plane hysteresis loops for the four films. Loops perpendicular to the film plane show the typical linear variation of the magnetization due to the demagnetizing field of a planar sample. In all cases the in-plane loops show that the films are relatively soft, but we have observed a notorious change in the shape of the loops and an increment in the coercive field when the film thickness is increased. For $t = 10$ and 30 nm the coercive field is around 10 Oe, the remanence is almost equal to one and the magnetization reverses in a very narrow range of fields. On the other hand, the magnetization in the thicker films starts to decrease gradually at positive fields of 1kOe and the reversal occurs in a two step process. These measurements have been correlated with ferromagnetic resonance data (see Fig. 2) taken at both X-band (9.5 GHz) and Q-band (34 GHz). In the thinner films (10 and 30 nm) we have observed a single resonance absorption that can be related to the uniform precession of the magnetization. From the out of plane angular variation of this line we have deduced the effective demagnetizing field which is around 700 Oe for all films. This value correlates very well with the saturation field deduced from the perpendicular hysteresis loops. From Q-band measurements we obtained an average g -value of 2.09 which is coincident with the value of ferromagnetic iron. As expected, the linewidth of this resonance increases approximately by a factor of three with frequency and tends to be larger for thicker films. The two thicker films show an additional resonance line when the magnetic field is applied at, or very close to, the film plane normal. This line is shifted 400-700 Oe to lower fields from the main resonance and is observed at both X and Q-bands with approximately the same field separation from the uniform mode. These additional resonances, together with the change in the behavior of the magnetization, can be originated in the presence of stripe-like domains in the thicker films which are not present in the thinner ones.

Magnetization per unit volume as a function of field with the applied field parallel to the film plane. The four loops correspond to the different thicknesses investigated.

Ferromagnetic resonance spectra measured at X-band (9.5 GHz) with the applied field perpendicular to the film normal. The four spectra correspond to the different thicknesses investigated.

Magnetization processes in ultrathin Co film grown on stepped Si(111) substrate.

1. University of Białystok, Białystok, Poland; 2. Institut d'Electronique Fondamentale, Université Paris XI, CNRS, UMR 8622, Orsay, France

Self-organized ultrathin magnetic materials are the object of intensive investigations due to applications in magnetic storage media with perpendicular recording of the information. The magnetization reversal process of ultrathin Co film deposited on Au or Pt layer is strongly correlated with the film preparation. Especially, the domain wall (DW) propagation is sensitive to the magnetic anisotropy. In the present work, we demonstrate influence of periodical Si(111) stepped substrate surface on domain structure and magnetization processes in Au/Co/Au films.

Samples were prepared by molecular beam epitaxy in a ultra-high vacuum chamber. Substrates we used are 2° misoriented vicinal Si(111) misoriented toward the opposite [11-2] direction gives rise to an array of steps bunches alternated with 7×7 reconstructed terraces with about 80 nm length [1]. The in-situ STM images show the surface after the preparation of the substrate, Cu and Au buffers. The following structures were deposited on stepped Si(111) substrate: (i) a Cu buffer layer of 4 monolayer (ML) deposited at T=100°C; next layers were deposited at room temperature (ii) 30 ML thick Au(111) underlayer, (iii) d=3, 5, 7 and 15 ML thick Co layer and (iv) 30 ML thick Au cover layer. The hcp Co(0001) crystallographic phase is expected for cobalt deposited on Au(111) surface.

The magnetization reversal process were investigated at room temperature using the magneto-optical Kerr effect (MOKE) based magnetometer. Magnetization curves were registered as a function of perpendicular magnetic field H_{\perp} or in plane H_{\parallel} field applied along various azimuthal ϕ_H angles with respect to the [1-10] Si direction. L-MOKE loops were registered as a function of both H_{\parallel} amplitude and ϕ_H angle.

The P-MOKE hysteresis loops for selected Co thicknesses are shown in Fig.1A. The thickness driven evolution of loops corresponds to spin-reorientation transition (SRT) from the out-of-plane to the in-plane magnetization and a decreasing of coercive field to zero with increase of Co thickness. Angular ϕ_H dependence L-MOKE hysteresis loops shows two fold symmetry. Easy and hard in-plane axis are parallel to [11-2] and [1-10] Si directions (perpendicular and parallel to the steps on the surface respectively), respectively. So, increasing d the spin reorientation undergoes from the axis perpendicular to in-plane. The SRT easy magnetisation axis – easy magnetization plane was discussed [2]. For d>7ML, the P-MOKE magnetization curve was observed (see Fig.1A) indicating the easy magnetization direction in-plane orientation known as the SRT in Au/Co/Au films on flat substrates [2]. The shape of the both P-MOKE and L-MOKE loops is an evidence for the uniaxial magnetic anisotropy. Figure 1B shows the in-plane hysteresis loops measured in the magnetic fields oriented at various directions in the sample plane by L-MOKE. Curves illustrating magnetization process when magnetic field is applied along hard and easy. Azimuthal L-MOKE symmetry is related to the presence of the uniaxial in-plane anisotropy induced by steps. The vectorial MOKE magnetometry allowed us the determination of the magnetic anisotropy constants in a phenomenological model, including an additional uniaxial anisotropy energy term related to the vicinal substrate [3].

Fig. 2A and B shows the remnant domain structure image registered for 3 ML and 5 ML thick Co film, respectively. Strong preference of domain wall orientation along the [1-10] Si is well visible. The preference could be explained by the step-induced in-plane magnetic anisotropy determined

from L-MOKE measurements. The domain size decreases while approaching the SRT – compare Fig.2A and Fig.2B. Such decrease can be explained using the theory [4].

In conclusion, in this study it was shown that domain wall propagation and the perpendicular magnetic anisotropy in Au/Co/Au sandwich can be modification by morphology of the stepped substrates.

The work was supported by the Marie Curie Fellowships for “Transfer of Knowledge” (No. 2004-003177).

(A) - Polar Kerr rotation hysteresis loops for 3, 5, 7, 15 ML thicknesses of Co. (B) - Hysteresis loops measured by L-MOKE for 15 ML Co thickness in the easy ($\phi_H=0^\circ$ – close points) and hard in-plane directions ($\phi_H=90^\circ$ – open points), respectively.

Remnant domain structure image observed for different Co thickness: (A) - 3 ML and (B) - 5 ML. Image size is 270x215 μm . Stripes of domains correspond to steps orientation along [1-10] Si. The sample was initially saturated by $H_{\perp}>0$ (“white” area) and then “black” domains were created by $H_{\perp}<0$ pulse magnetic field.

Effects of Co/Sm composition on the ordered phase formation in Sm-Co thin films grown on Cu(111) single-crystal underlayers.

Y. Nukaga¹, M. Ohtake¹, F. Kirino², M. Futamoto¹

Thin films with high magnetocrystalline anisotropy have attracted much attention to the applications such as ultra-high density magnetic recording, micro-electro-mechanical systems, etc. SmCo_5 is a magnetic material with high K_u of $1.1 \times 10^8 \text{ erg/cm}^3$ and it is one of the candidates as the recording layer in realizing such ultra-high density magnetic recording. Recently, SmCo_5 polycrystalline thin films with (0001) preferred texture have been prepared using Cu underlayers on glass substrates [1,2]. Formation of (0001) texture is interpreted to be favored by a small lattice mismatch with the Cu(111) plane. The lattice mismatch between $\text{SmCo}_5(0001)[1-100]$ and $\text{Cu}(111)[1-10]$ is -2.2%. In the present study, we fabricated Sm-Co thin films on Cu(111) single-crystal underlayers by changing the composition and the effects of Co/Sm composition on the ordered phase formation are investigated.

Thin films were prepared on $\alpha\text{-Al}_2\text{O}_3(0001)$ substrates at a substrate temperature of 500 °C using an MBE system under base pressures lower than 7×10^{-9} Pa. The film layer structure was Sm-Co(20 nm)/Cu(10 nm)/Co(2 nm)/ $\text{Al}_2\text{O}_3(0001)$. The Cu(111) single-crystal underlayer was prepared by hetero-epitaxial growth on the Al_2O_3 substrate [3]. Sm and Co were co-deposited on the Cu underlayer and the thickness of Sm-Co layer was fixed at 20 nm. The composition of Sm-Co layer was varied from Co-rich to Sm-rich region (12–35 at. % Sm) including the SmCo_5 stoichiometry (16.7 at. % Sm). The composition was confirmed by EDX. The surface structure during film deposition was studied by *in-situ* RHEED. The film structure was investigated by XRD with $\text{Cu-K}\alpha$ radiation. SmCo_5 epitaxial thin films were obtained on Cu(111) single-crystal underlayers for all compositions. The epitaxial orientation relationship of $\text{SmCo}_5(0001)[1-100]$ and $\text{SmCo}_5(0001)[11-20]/\text{Cu}(111)[1-10]$ were determined from RHEED analysis. The SmCo_5 layer has two different types of domains whose orientations are rotated around film normal by 30 degrees to each other. Figure 1 shows the XRD patterns of SmCo_5 epitaxial thin films with different Co/Sm compositions. The superlattice (0001) peak of SmCo_5 ordered phase is observed in addition to the fundamental $\text{SmCo}_5(0002)$ peak for all samples. The peak shift toward low angle direction is recognizable for the $\text{SmCo}_5(0001)$ reflection with increasing the Sm composition, which indicates expansion of lattice constant, c_{SmCo_5} . Cu atoms are known to substitute the Co site in the SmCo_5 structure forming an alloy compound of $\text{Sm}(\text{Co,Cu})_5$ [4-6]. The SmCo_5 epitaxial thin films prepared in the present study are considered to include Cu atoms, since the thin films were grown at a high substrate temperature of 500 °C where Cu atom diffusion into the Sm-Co layer would take place. Figure 2 summarizes the change in the lattice constant estimated from the $\text{SmCo}_5(0001)$ XRD peak. The lattice constant of SmCu_5 thin film was determined to be 4.08 nm from a SmCu_5 epitaxial thin film prepared under a similar experimental condition. The Sm-Co thin film with 16 at. % Sm which is close to SmCo_5 stoichiometry has a larger lattice constant than that of bulk SmCo_5 alloy. The measured lattice constant value indicates that the alloy composition is $\text{SmCo}_{2.6}\text{Cu}_{2.4}$. The lattice constant of Sm-Co thin film with 35 at. %, Sm is close to that of SmCu_5 alloy thin film. Large amount of Cu atoms are diffusing into the SmCo_5 epitaxial thin films forming alloy compounds of $\text{Sm}(\text{Co,Cu})_5$. The Cu(111) underlayer and the Cu atom diffusion into the Sm-Co layer are considered to assist the formation of ordered structure.

3. Centro de Excelencia en Nuevos Materiales, Cali, Colombia

The term multiferroic has been coined to describe materials in which two or all three ferroic properties ferroelectricity, ferromagnetism, and ferroelasticity coexist in the same phase [1]. It means that these materials have spontaneous magnetization. It also means that these order parameters can be regulated by the application of electric fields and/or magnetic fields, and/or using mechanical stresses. These compounds have gained renewed and ever increasing research interest in the last three years [2]. Especially those in which magnetic and ferroelectric orderings exist simultaneously, called magnetoelectric materials, it is possible to find a coupling between the magnetic and ferroelectric properties through the magnetoelectric effect that is the induction of an electric polarization using a magnetic field or vice versa [3]. Moreira dos Santos et al reported on the synthesis of BiMnO₃ thin films, which show the coexistence of ferromagnetic and ferroelectric properties [4]. Recent theoretical calculations also suggest that it is likely to be both ferromagnetic and ferroelectric because of the covalent bonding between bismuth and oxygen atoms [5]. These properties make this material potentially interesting for both technological applications and for the study of magnetoelectrical interactions.

In this work, BiMnO₃ thin films were deposited by r.f. magnetron sputtering on single-crystal SrTiO₃ (001) and Pt/TiO₂/SiO₂ substrates. X-ray diffraction was used to analyze the crystal structure of the thin films, indicating that the films were monoclinic with two dominant orientation relationships along the substrate. The first is (111) BiMnO₃ || (001) SrTiO₃; the second is (222) BiMnO₃ || (002) SrTiO₃. Fig. 1 Film roughness was analyzed by AFM; quantitative values of grain size are in the range between 300 and 500 nm. Electrical measurements via R vs. T were taken from 450 K to 15 K. Magnetic characterization was carried out by using a Vibrating Sample Magnetometer (VSM) for magnetization versus temperature and for hysteresis loops at different temperatures. The saturation magnetic moment of 3.2μ_B per Mn ion (still fairly smaller than that of the bulk, 3.6μ_B) was observed at 5 K, decreasing with increasing temperature fig. 2. Ferroelectric characterization was carried out at low temperatures and at 300 K by using a cooling system, a temperature controller Cryodine model 22C of the LTS cryosystems series, the VISION™ software, and an RT66 test system from Radiant TechnologiesInc™. Hysteresis loops (Polarization v-s Voltage) were obtained and they show saturation polarizations of 1.51μC/cm², 2.21μC/cm², and 0.7μC/cm² at 105 K, 122 K, and 300 K. Fig. 3

1. Physics, Universidad del Valle, Cali, Colombia; 2. Centro de Exelencia en Nuevos Materiales, Cali, Colombia

Multiferroic materials exhibit both ferromagnetic and ferroelectric polarizations along with coupling between them. The magnetic polarization can be switched by applying an electric field; likewise, the ferroelectric polarization could be switched by applying a magnetic field. Consequently, multiferroics offer rich physics and novel device concepts, which have recently become of great interest to researchers [1]. Perovskite BiFeO₃ (BFO) has attracted much attention given the coexistence of ferroelectric and magnetic orders. It possesses a rhombohedrally distorted perovskite structure at room temperature, with space group R3c [2] and an antiferromagnetic / ferroelectric phase with high Curie ($T_C \approx 1100$ K) and Neel ($T_N \approx 673$ K) temperatures, in bulk. Yttrium manganese oxide YMnO₃ (YMO) exhibits two stable crystallographic modifications – orthorhombic and hexagonal [3]; while magnetic ordering occurs in both phases, ferroelectric ordering occurs only in hexagonal, which belongs to systems without central symmetries with the P63cm space group, besides displaying a ferroelectric transition with Curie temperature, $T_C \approx 914$ K, and a rather low antiferromagnetic Neel temperature $T_N \approx 80$ K [4].

In the present work we report the preparation of BFO and YMO thin films grown on Pt/TiO₂/SiO₂/Si substrates by using a magnetron sputtering technique assisted by radio frequency in a pure oxygen atmosphere. BiFeO₃ and YMnO₃ targets were self-made by the usual solid-state reaction method. The presence of bismuth oxide (Bi₂O_{2.75}) impurity phase was detected in the X-ray diffraction (XRD) pattern in addition to the major BiFeO₃ phase. Also, we detected phases at trace levels of (Bi₂₄Fe₂O₂₉) and (Bi₂₅FeO₄₀). The presence of major yttrium manganese oxide (YMO) in hexagonal phase was detected in the X-ray diffraction (XRD).

We investigated the effects of deposition temperature and crystallization on morphology, magnetization, and polarization of BFO and YMO thin films.

The crystalline phases of the films were determined by X-ray diffraction (XRD). Surface morphology was obtained by atomic force microscopy (AFM), polarization electric field (P-E) measurements were performed by using the Ferroelectric Testing system (RT66a). We used a VSM technique on the Physical Property Measuring System (Quantum Design™) to measure magnetization of thin-film samples. Polarization as a function of electric field in capacitor structures based on our BFO films shows hysteretic behavior with a coercive field of 90 kV/cm and a remnant polarization of 37.2 $\mu\text{C}/\text{cm}^2$ (Fig. 1a). Magnetization measurements of the BFO samples evidence weak magnetization fig 2, corroborating the behavior of the magnetoelectric coefficient observed in a previous work for bulk material [5].

For YMO, we found an optimal deposition temperature of 850 °C. Surface morphology is improved when deposition temperature increases from 750 °C to 850 °C. Polarization as a function of electric field in capacitor structures based on our YMO films show hysteretic behavior with coercive field of -2.69 kV/cm, remnant polarization of 1.39 $\mu\text{C}/\text{cm}^2$, and saturation polarization of 4.17 $\mu\text{C}/\text{cm}^2$ (Fig. 1b).

1. TU Dresden, Dresden, Germany; 2. University of Konstanz, Konstanz, Germany

The ability to manipulate a single-electron spin using external electric field is one of the long-sought goals in attempt to develop alternative device technologies. The control over electron spins would be invaluable for nanoscopic spintronics [1-3] and related applications, such as quantum information processing using individual electron spin qubits. The main paradigm for the researches in this field is a spin-based field effect transistor (spin-FET) device introduced by Datta and Das [4] where the spin of injected electron can be modulated via application of only electrical field without any additional magnetic field. An ideal spin-FET should combine an effective spin transfer with spin manipulation via electrical field.

However, a high efficient spin-FET device requires long spin relaxation time as compared to the mean time of transport through the channel combined with a sufficient difference of the spin rotation angles between two states (“0” and “1”) as well as an insensitivity of spin rotation to the carrier energy. In the recent theoretical work [5] spin-FET was proposed on the basis of a single graphene layer, a novel material consisting of a flat monolayer of carbon atoms packed in a two-dimensional honeycomb-lattice, in which the electron dynamics is governed by the Dirac equation [6,7]. Long electronic mean paths [7] and negligible spin-orbit coupling of the carbon based system [8], i.e. large spin relaxation times, make graphene a best-choice material for the observation of near ballistic spin transport.

Here, we report on the first unambiguous experimental observation of a controlled spin-manipulation in a graphene layer epitaxially grown on Ni(111) substrate [9] (Fig.1). We use photoemission spectroscopy of the electronic π states of epitaxial graphene layer on the Ni(111) surface to observe a strong dependence of binding energy of these states, $E(\mathbf{k})$, on the direction of magnetization of the sample. Since the explanation of this effect is based on consideration of the system of three orthogonal vectors in the system: wave vector of electron, magnetization of the sample, and electrical vector perpendicular to the surface, we conclude that the observed extraordinary high “splitting” up to 225meV of the π band in the graphene layer is a manifestation of the Rashba effect which provides a direct possibility to a flexible control of an electron spin in a graphene-based spin-FET.

The inert properties of grapheme layer were studied by means of spin-polarized electron emission of secondary electrons from graphene/Ni(111) system before and after exposure to oxygen [10] (Fig.2). It is shown that the spin-polarization of secondary electrons at zero kinetic energy from graphene/Ni(111) system is reduced by about 1/3 with respect to one from the clean Ni(111) surface, but contrasting to the latter it remains practically unaffected upon oxygen exposure. These experimental observations open technical perspectives for application of graphite layers in spintronic devices.

Epitaxial growth of SrM(00l) film on Au(111).

A. Kaewrawang, G. Ishida, X. Liu, A. Morisako
Information Engineering, Shinshu University, Nagano, Japan

Introduction

For the preparation of hexagonal Sr-ferrite (SrM) thin films as a high density perpendicular magnetic recording medium, perpendicular c -axis orientation to the film plane has been concentrated. However, the c -axis oriented SrM thin films can be deposited at substrate temperature over 600°C [1]. Crystallographic and magnetic properties of SrM thin films can be improved by using the appropriate substrate or underlayer [2]. For c -axis orientation preparation of the film, Au underlayer with (111) orientation seems to be effective for promoting c -axis orientation because a misfit ratio between (111) plane of fcc Au and c -plane of hexagonal SrM is 2.1%. In this experiment, the SrM films on Au layer with various substrate temperatures were prepared by a DC magnetron sputtering system. Their crystalline and magnetic properties of SrM thin film deposited on Au(111) underlayer have been studied.

Experiments

The preparation of SrM/Au films deposited on thermally oxidized silicon wafers was performed at the base pressure below 2×10^{-6} Torr. For the sputtering of Au underlayer film, deposition was performed in an argon pressure of 2.0 mTorr, and 7 W of sputtering power. The underlayer substrate temperature, T_u , was varied in the range from room temperature (r.t.) to 500°C. For the sputtering of SrM film, the sintered target with stoichiometric composition of $\text{SrFe}_{12}\text{O}_{19}$ was used. The mixture gas of Ar and O_2 with ratio of 1.8 and 0.2 mTorr, respectively, was used as sputtering gas. The substrate was heated up to 525°C and the sputtering power was 20 W. In this study the thickness of SrM and Au was 95 nm and 75 nm, respectively. The crystal structure of the films was determined by X-ray diffractometer (XRD) with Cu K α radiation. The magnetic properties were measured by vibrating sample magnetometer (VSM).

Results and Discussion

Fig.1 shows the X-ray diffraction diagrams of the film prepared on an underlayer at various T_u . When the film has Au underlayer without heating, strong (111) peak for Au. Consequently, the presence of the strong (00l) peaks for SrM indicates that the film has good perpendicular orientation. For the heated underlayer film, the intensity of Au(111) line becomes weak with increasing T_u . On the contrary, Au(200) becomes strong with increasing T_u . For T_u above 500°C, there are no obvious SrM peaks. The saturation magnetization, M_s , decreases with increase of T_u as shown in Fig.2a. Fig.2b shows the dependence of perpendicular and parallel coercivity, H_c , on T_u . $H_{c\perp}$ reaches a maximum of 3.6 kOe at $T_u=300^\circ\text{C}$ and $H_{c\parallel}$ increases with increasing T_u after T_u above 300°C.

Fig. 1 XRD diagrams of SrM/Au films prepared for different T_u .

Fig. 2 (a) Dependence of M_s on T_u . (b) Dependence of H_c on T_u .

Conclusions

SrM thin films with apparent c -axis orientation were successfully prepared on Au(111) underlayer by epitaxial growth. The substrate temperature for Au underlayer has strongly effect on the (111) peak for Au and c -axis orientation for SrM which attains in the SrM films at substrate temperature for Au underlayer below 300°C.

Surface characteristics of atomic-level Co-Cu thin film system : Molecular dynamics simulation.

B. Kim, K. Chae, Y. Chung

Department of Materials Science and Engineering, Hanyang University, Seoul, South Korea

1. Introduction

The understanding of thin film growth mechanism has been an essential issue to optimize device characteristics for technological application. For application in magnetic devices, ordered and uniform thin film is especially required for the coherency of the device [1]. In this paper, the growth behavior of the Co atoms on the Cu substrate for two different crystallographic orientations, (001) and (111), was extensively investigated by using molecular dynamics simulation.

Interatomic potentials were based on the Embedded Atom Method, and Zhou, et al. [2] were adopted to LAMMPS code. The size of the Cu(001) and Cu(111) substrates was $(60 \times 30 \times 5) a_0$ with the surface perpendicular to the z-axis. The temperature of substrates was isothermally maintained at 300 K. The incident energy of adatoms was set to 0.1 eV. The positions of the adatoms were randomly selected in the x, y-plane and the incident angles were set to be normal to the surface. The MD time step was fixed as 1 femto-second.

2. Results and Discussion

When the Co atoms are deposited on the Cu substrate at 300 K up to 20 monolayers (ML) with low incident energy of 0.1 eV, the tendency of growth behavior for the Co/Cu system turned out to be varied with the substrate orientation. The corresponding root-mean-square roughness W , during 20 ML deposition, was compared Co/Cu(001) with Co/Cu(111) (Fig. 1). The film roughness for the case of Co/Cu(111) was appeared to be significantly higher than the case of Co/Cu(001). The film roughness for the case of Co/Cu(111) was appeared to be significantly higher than the case of Co/Cu(001). To substantiate the differences of surface characteristics for Co films on Cu and Co surface, the net distance moved by Co adatoms from the release point in x-y plane for the deposition of 200 atoms was calculated and illustrated in Fig. 2. The degree of lateral displacement of Cu(001) and Co(001) was much less than that of Cu(111) and Co(111). Consequently, because of higher cohesive energy of Co ($E_{\text{coh, Co}} = 4.41$ eV, $E_{\text{coh, Cu}} = 3.54$ eV), high diffusivity of Co atoms on the Cu(111) or Co(111) substrate leads that Co atoms can be more agglomerated than the case of Cu(001) substrate.

The actual position of impact turned out to largely depend on the small distortions in the attractive potential due to the local acceleration [3] coming from the strong affinity between the Co adatom and substrate Cu atoms or between the Co adatom and surface Co atoms grown on the Cu substrate. The maximum value of locally accelerated energy of Co/Cu(001), Co/Co(001), Co/Cu(111), and Co/Co(111) was measured to be 2.3 eV, 1.9 eV, 1.6 eV, and 2.3 eV respectively. Consequently, in the initial stage of deposition for the Co/Cu(001) system, a Co adatom toward the Cu(001) substrate experiences larger locally accelerated energy than a Co adatom toward existing deposited Co atoms. When a Co adatom approaches to the vicinity of the edge between the Cu(001) substrate and deposited Co atoms, the Co adatom is affected by the steering effect caused by higher local accelerated energy from the Cu(001) substrate to fill the exposed Cu(001) substrate. Besides once a Co adatom is settled on the Cu(001) substrate, it hardly moves further due to the relatively lower diffusivity than the case of Co/Cu(111) (Fig 3(a)). On the other hand, for the Co/Cu(111) system, the behavior of approaching Co adatom seems to be steered to the deposited Co atoms. Moreover, it causes strong agglomeration of Co adatoms due to the high cohesive energy of Co atoms and the high diffusivity of Co/Cu(111). Eventually, the surface roughness of the Co/Cu(111) system

increases rapidly and, consequently, the growth behavior follows the 3-D island growth mode (Fig. 3(b)).

Exchange pinning across a ferromagnetic interface has been studied using inductive magnetometry with frequencies up to 15 GHz in magnetic fields up to 4 kOe [1]. Two systems are reported. The first system is a Py/Co bi-layer where the magnetization in both films is assumed to lie in plane. These samples consist of permalloy films with thicknesses between 50 and 80nm directly coupled to Cobalt films with thicknesses between 0 and 5 nm. Secondly a Pt/Co multilayer with a strong out of plane anisotropy is coupled to a permalloy film through a thin Cu spacer layer. These samples have similar permalloy thicknesses as the first system with the Cu spacer layer varying in thickness from 0 to 4nm. All films were grown using DC magnetron sputtering on Si [100] substrates.

The resonant response at fixed frequency was determined by varying an externally applied magnetic field. Multiple peaks were obtained indicating excitation of standing spin wave modes in the bilayer geometry. The frequency of these high order spin wave modes were measured and values for interface induced pinning determined using a dipole-exchange theory for strip-line excitation of standing spin-wave modes (SSWM) [2]. The exchange mode frequencies are strongly dependent on film thickness and interface pinning from the Co layer. We show how this technique can provide sensitive estimates of interlayer exchange coupling and pinning parameters by exciting standing spin wave modes across the film thickness.

Shown in Figure 1 is a plot of the frequency versus field response of a single Py film where both the fundamental mode and the first exchange mode are observed. In the same figure it can be seen that in a Py/Co bilayer, two extra higher order exchange modes are also observed. The addition of Co to the Py film results in an asymmetrical excitation through the thickness of the film. This gives a nett magnetization which can be measured by the inductive technique. Interestingly, the intensities of these modes were found to vary dramatically with frequency as shown in Figure 2. Similar trends in intensity can be seen in our theory when the film is modelled with a weak interlayer coupling between the Py and Cobalt and a surface anisotropy present at the substrate. The surface anisotropy provides the necessary asymmetry to observe the first SSWM observed in the both the single and bilayer film. At higher frequencies the first SSWM of the Py overlaps the fundamental mode of the Cobalt. The weak interlayer coupling has the Py driving the Co increasing the observed intensity.

Since the earlier studies of MnAs epilayers grown over a GaAs substrates, the coexistence of two magneto-structural phases in a finite temperature range has been one of the most interesting topic of research. One of these phases is ferromagnetic (α phase) and the other one is non-magnetic (β phase). The bulk compound does not show such phase coexistence; on the contrary, it presents a magneto-structural first-order transition at 313 K from the low temperature α phase to the β one above this temperature [1]. In this contribution, we present results which were obtained for MnAs epilayers grown on GaAs(100). We have focused on the magnetization behavior as a function of temperature and the film thickness.

MnAs epilayers were grown by molecular beam epitaxy (MBE) as described in Ref. [2]. MnAs thin films of 66, 100 and 200 nm thick were grown on (100) GaAs substrates (with As termination), named M100-66, M100-100 and M100-200 respectively. The magnetometric curves were obtained through a SQUID magnetometer and the FMR ones were performed at $\nu \approx 9.45$ GHz (X-band) with the applied magnetic field perpendicular to the film surface.

In Fig. 1 we display the M vs. T curves for the three films and, for the powder sample which was taken as a reference of the bulk behavior. In that figure we can observe that all the films show a smoother loss of magnetization than the reference bulk. This behavior is the expected for the films that present the phase coexistence. However, among the studied films, the behavior is not exactly the same, i.e., for increasing thickness the transition becomes sharper as shown in Fig. 1. Then, the magnetization curve for the M100-200 sample is the most similar to the reference bulk.

In Fig. 2 we present the spectra obtained at different temperatures by FMR for the M100-200 sample. From that figure, we observe that all spectra have a complex structure. At 120 K, we can observe only a very wide mode. At 260 K, we can distinguish two modes, i.e., at higher fields the corresponding to the α phase and, at low fields, a wide mode that arises from the effect of the very small β phase regions [3] that remain within the α phase even at very low temperature [4]. At room temperature the low-field mode becomes narrower and better defined. For temperature greater than 303 K the two modes merge in only one.

By comparison with the FMR spectra shown in Ref. [3] of the M100-66 sample, in which the merging of the two mode occurs at 278 K, we can conclude that the FMR experiments present a similar behavior to the SQUID measurement; it means that the magnetic transition temperature for thicker films are closer to the bulk one.

Summarizing, we have shown that the magnetic transition temperatures for increasing film thickness are closer to the bulk one. However, the magnetic anomalies, which are related with the presence of β phase regions at very low temperature, are present even for the thickest sample studied.

Fe-doping Effect on Morphologic and Magnetotransport Properties of La₂/3Ca₁/3Fe_{1-y}MnyO₃ thin films.

In this work we have performed magnetotransport measurements as a function of temperature of La₂/3Ca₁/3Fe_{1-y}MnyO₃ ($y = 0, 0.01$ and 0.03) thin films, that present different morphologies depending on the ⁵⁷Fe-concentration and the substrates. The morphology was studied by atomic force microscopy (AFM) at room temperature in air and the mean grain size were obtained. A series of thin films growth by dc magnetron sputtering on LaAlO₃ (LAO) and SrTiO₃ (STO) single crystal substrate at high O₂- pressure (500mTorr), have been used as samples, with thickness between 50 and 80nm.

AFM images of the films shown a surface smoothing effect was noticed for undoped sample (rms between 1 and 3 nm), and a direct grain size (15 - 65nm) dependency regarding to Fe concentration was observed on doped films in both substrate. The films consists of numerous grains of rather rounded shape (see Fig. 1). This rounding effect is more pronounced in the 3% Fe doped sample on STO. During the Fe doping increase, the size and shape of the grains are changing (see Fig. 2).

On the other hand, the results of the magnetoresistance (MR) of LCMO, LCMFO-1% and LCMFO-3% films on STO and LAO, presented an increase of the MR in Fe doped samples regarding to the biggest Fe concentration and grain size (see Fig. 3). Probably, this increasing should be due to the fact that close to Curie temperature, the connectivity between grain, the disorder of spins and Fe doping effect at the grain surface, produces a significant increase of the resistance, but when a magnetic field is applied, this one suppresses the magnetic disorder causing in this way a decrease in the resistance, thus it is contributed that the MR reaches high values close to the transition metal-insulator temperature.

The maximum MR is still very sensitive to the substrate, even for the highest doping or grain size, although all magnetic properties are essentially similar. The maximum MR for the 3% sample is almost twice as high for sample grown on LAO compared to sample grown on STO.

In summary, we observed a direct grain size dependency and magnetoresistance vary non-monotonically with increasing of Fe concentration. This behavior can be understood in terms of competing influences from the strain relaxation, which enhance the tendency to order ferromagnetically, and reduce the double-exchange interaction.

A study on surface magneto-optical Kerr effect of ultra thin Fe films on various GaAs substrates.

W. Guan, T. Shen, G. Jones

Joule Physics Laboratory, University of Salford, Salford, United Kingdom

Ferromagnetic thin films on semiconductors have attracted a lot of interest in recent years due to the potential applications in spin-based devices, such as spin-LED and MRAM and many more [1]. Amongst these ferromagnetic hybrid systems, although Fe on singular GaAs (001) has been relatively well studied [2], there is still a lot of work needs to be done to study Fe's behavior on other substrates. Ferromagnetic thin films' magnetic characterizations show clear substrate dependence [2,3], therefore we carry out the detailed study of the magnetic properties of Fe thin film on different GaAs substrates.

Ultrathin Fe films were epitaxially grown on various GaAs substrates. Apart from singular GaAs (001), three types of substrates were used, which were GaAs (311)B, vicinal (001) GaAs substrates with a 3 degree and 6 degree offcut angle towards the [111]A direction. All the substrates consist of a 500 nm n+ Si doped ($2.0 \times 10^{18} \text{ cm}^{-3}$) GaAs epitaxial layer on an n+ GaAs substrate. Upon this epitaxial layer is a 350 nm undoped GaAs epitaxial layer, which was subsequently capped with a 1 nm of amorphous As as a protective layer. After decapping the As protective layer, Fe films were deposited at room temperature onto the GaAs substrates. The pressure during deposition was better than 4×10^{-10} mbar. In order to compare the contribution to Fe films' magnetic properties that are more likely to be affected by the substrate, the thickness of Fe layer was kept to 7nm. The magneto-optical Kerr effect (MOKE) has been used to investigate the magnetic properties of ultra thin Fe films. Using our newly developed dual photoelastic modulator system [4], all MOKE measurements were carried out at room temperature in the longitudinal geometry.

The coercivity of Fe film on singular GaAs (001) substrate is 40 Oe. However from Figure 1b and 2b, which are the Kerr ellipticity of Fe on 3 degree and 6 degree offcut GaAs respectively, the coercivities are both about 32 Oe, and the one on 6 degree offcut substrate may be slightly bigger compared to that on the 3 degree offcut substrate. From Figure 3b, the coercivity of Fe on GaAs (311)B is only about 20Oe, which is much less than those of the films on singular and vicinal GaAs (001) substrates. The results indicate a clear substrate dependence for the in-plane magnetic property of Fe films.

The ultrathin Fe films epitaxially grown on singular GaAs (001) substrate have been observed to exhibit a remarkable in-plane uniaxial magnetic anisotropy (UMA) with the easy axis along the [110] direction and hard axis along the [1-10] direction - this result is basically in agreement with the finding of Gester et al [5]. As to the films on vicinal (001) GaAs substrates, we observed similar UMA, but unlike the singular substrate, we have not found the cubic magnetic behaviour of Fe on vicinal GaAs substrates. As the hysteresis loops along [100] and [010] directions have same coercivities as in [110] direction, this finding suggests that Fe on vicinal GaAs is dominated by the uniaxial magnetic anisotropy with the easy axis along the [110] direction superimposed on a cubic anisotropy with easy axes along [100] and [010] directions. For Fe on GaAs (311)B, it is clear to see that [0-11] direction is the hard axis. This is in agreement with the findings of Muduli et al [6] on (311)A GaAs substrate. But unlike (311)A GaAs substrate, it is not so obvious that [-233] direction is the easy axis. The magnetic anisotropy of Fe on this substrate seems to be the combination of a UMA with easy axis along [-233] direction and a four-fold magnetic anisotropy with the easy axes toward the [-130] and [10-3] directions. The asymmetric hysteresis loops along hard axes (Fig-

ure 1a, 2a, 3a) can be explained by a 'mixing-in' of the transverse magnetisation contribution to the longitudinal measurement based on the second order magneto-optical effect, i.e. Voigt effect [7].

Composite oxide buffer layers for (002) Fe/MgO/Fe magnetic tunneling junctions.

H. Huang, P. Huang, C. Lai

Department of Materials Science and Engineering, National Tsing Hua University, Hsinchu, Taiwan

Recently, MgO-based magnetic tunneling junctions (MTJs) have been studied extensively due to the high tunneling magnetoresistance ratio (TMR ratio) of the fully epitaxial or highly textured (002) Fe/MgO/Fe MTJs [1], [2]. In this study, we proposed new composite oxide buffer layers (ZnO/MgO) with very thin thicknesses grown on Si/SiO₂ substrates rather than using expensive MgO single crystal substrates for the growth of (002) Fe/MgO/Fe structure. Furthermore, we introduced Cr as the bottom electrode. With the proper buffer layer thicknesses, a good Cr (002) crystal structure can be obtained and used as the structure template for the growth of (002) Fe/MgO/Fe structure due to the small lattice mismatch between Fe and Cr. The structural and magnetic properties of the top-type MgO (002)-based MTJs are discussed.

All samples in this study were fabricated by using an ion beam deposition (IBD) system. Buffer layers composed of ZnO and MgO were first grown on Si/SiO₂ substrates at room temperature. The crystal structures of the composite buffer layers were strongly dependent on the thicknesses of both ZnO and MgO. The XRD patterns of Si/SiO₂//ZnO *x*/MgO *y*/Fe 30/Ta 5 (nm) were shown in Fig. 1. Fe (110) and Fe (002) were both observed when the thicknesses of ZnO and MgO were relatively thick. As both thicknesses of ZnO and MgO were decreased to 2.5 nm, only Fe (002) was observed in the XRD patterns. Furthermore, the diffraction peak intensity of Fe (002) dramatically decreased when only 2.5 nm MgO was deposited as the buffer layer without any ZnO layer. When only ZnO of 2.5 nm was used as the buffer layer, Fe (110) would be the only diffraction peak observed. These results indicated that the existence of thin ZnO layer in the composite buffer layers was indeed very crucial for the growth of (002) MgO/Fe structure. Thinner ZnO layer exhibited better capability for the growth of MgO (002) layer, which might imply that the interface effects play an important role in the growth mechanism.

To integrate the ZnO/MgO composite buffer layers into devices, we introduced Cr as the bottom electrode due to its comparable electrical resistivity to that of Ta and the small lattice mismatch between Fe and Cr. All MTJ samples were deposited under a magnetic field of 100 Oe. The samples were then field-annealed at 250 °C for an hour under a magnetic field of 1500 Oe. The XRD patterns of Si/SiO₂//ZnO 2.5/MgO 2.5/Cr 30/Fe 3/MgO 2/Fe 3/IrMn 10/Ta 5 (nm) were shown in Fig. 2. The diffraction peak of IrMn (002) was observed, which implied that the (002)-oriented Fe/MgO/Fe trilayers were successfully fabricated. As shown in the insets of Fig. 2, MgO (002) diffraction peak can also be clearly observed for both the as-deposited and field-annealed samples, which indicated good crystallinity of MgO (002). After field-annealing process performed at 250 °C, enhancement of peak intensities and peak shifts toward high 2θ angles of MgO (002), IrMn (002) and Cr (002) were observed, which may result from the improvement of crystallinity and stress release. The magnetic properties of both as-deposited and field-annealed MTJ samples were shown in Fig. 3. The exchange bias fields were 225 Oe and 270 Oe for the as-deposited and field-annealed samples, respectively.

In summary, MgO-based MTJ samples with a strong (002) texture were successfully fabricated with the thin ZnO/MgO composite buffer layers. The Cr bottom electrode was introduced to keep (002) orientation and a top spin-valve (002) MTJ was obtained.

Stripe magnetic domains in sputtered permalloy films.

1. ICMAB - CSIC, Bellaterra, Spain; 2. FAO, University of Barcelona, Barcelona, Spain

Permalloy (Py) alloy ($\text{Ni}_x\text{Fe}_{100-x}$) with Ni content of about 78 - 82 percent is prototype of soft magnetic material. Most studied Py films are those with $x \approx 81$ because of the almost-zero magnetostriction and negligible magnetic anisotropy [1]. However, Ni rich films ($x > 81\%$) quite commonly exhibit a weak perpendicular anisotropy, which originates from the film internal tensile stress [2] combined with a negative magnetostriction. A remarkable property of these films is that above a critical thickness (t_{cr}) the in-plane magnetization loops display characteristic features like increased coercivity and steeped magnetization curve [3]. These changes reflect the appearance of a dense stripe domain pattern in the film plane [4, 5] which originates from competition between the shape anisotropy, weak perpendicular anisotropy, and domain wall energy. However domains width observed by Saito [5] is $w \sim t^{1/2}$ (for $t > t_{cr}$) contrary to his model which predict $t^{1/3}$ (for $t > t_{cr}$) dependence on film thickness. Although there are numerous studies of this stripe domain structure, there are only few focused on the dependence of domains width in function of the film thickness - particularly in sputtered films [6].

Here we report on the characterization of permalloy films displaying a weak perpendicular anisotropy deposited by RF sputtering. We have grown series of Py films on Corning glass using a target of nominal composition $\text{Ni}_{81}\text{Fe}_{19}$ at various RF power and Ar partial pressures. Here we present films grown at 50 W of RF power and 0.05 Pa of Ar pressure. Films with thickness (t) ranging from 6.8 to 400 nm have been grown by varying the deposition time. Film thickness was determined from low-angle X-ray reflectometry experiments and estimated average growth rate of 6.7 nm/min. We have used X-ray photoemission spectroscopy (XPS) to verify that the metal stoichiometry of films matches that of target. The intensity ratio of 3p-Fe and 2p-Ni photoelectric peaks, after Shirley background subtraction, allowed to determine a Ni:Fe concentration of $81.2 \pm 0.3 : 18.8 \pm 0.3$ which is closely coincident with that of the target.

Magnetization loops measurements were done at room temperature by magneto-optic Kerr setup (MOKE). Longitudinal MOKE loops (with magnetic field applied in-plane of the sample) were recorded for various sample orientations in order to identify the in-plane anisotropy. Polar MOKE loops (with field applied perpendicular to the sample surface) were also recorded.

In-plane magnetization loops of thinner films ($t < 100\text{nm}$) displays a well defined uniaxial anisotropy (Fig. 1a) with a clear - square shaped - hysteresis loop along one (in-plane) direction and a closed loop along a perpendicular (in-plane) direction. In contrast, thicker films ($t > 200\text{nm}$) display magnetization loops identical in each in-plane direction (Fig. 1b). This property is an indication of stripe domain structure and therefore the existence of a weak perpendicular anisotropy. The critical thickness t_{cr} for appearing of stripe domains should be between 100 and 200 nm.

In the figure 2 we show MFM images of corresponding films. There is no visible domain structure on the 59 nm sample (Fig. 2 left) thus confirming that magnetization lies basically in the film plane. In contrast, the stripe pattern is well visible in the 200 nm film (Fig. 2 right) reflecting the occurrence of an out-of-plane magnetic anisotropy. Thicker films show similar properties with larger stripes and stronger magnetic contrast. This correlates with both the domain size and the strength of the out-of-plane anisotropy of the films.

We found that the domain width is closely proportional to $t^{1/2}$ as found by Saito [5]. In the following we will compare this result with existing models for stripe domains formation and we will discuss the possible effect of variation of internal film stress with film thickness.

Influence of capping layers on magnetic anisotropy in Fe/MgO/GaAs(100) ultrathin films.

P. Wong¹, W. Zhang¹, Y. Xu¹, Y. Fu², Z. Huang², Y. Zhai², Y. Xu³, H. Zhai³, S. M. Thompson⁴

1. *Spintronics and Nanodevice Laboratory, Department of Electronics, University of York, York, United Kingdom*; 2. *Department of Physics, Southeast University, Nanjing, China*; 3. *Center for Materials Analysis, Nanjing University, Nanjing, China*; 4. *Department of Physics, University of York, York, United Kingdom*

The effects of two different nonmagnetic covering layers, Au and MgO, on the magnetic anisotropy of epitaxial Fe on GaAs(100) with an epitaxial MgO interlayer grown by molecular beam epitaxy (MBE) have been studied by ferromagnetic resonance (FMR) and magneto-optic Kerr effect (MOKE). GaAs(100) substrates preparation prior to sample growth can be found elsewhere [1]. Growth of the films and their structural characterization were done by *in-situ* reflection high-energy electron diffraction (RHEED) and a crystal monitor calibrated with ex-situ atomic force microscopy (AFM). The substrate was annealed at 780 K for 45 mins until a sharp (1 x 1) reconstructed GaAs surface was identified. The MgO layer was then grown by e-beam evaporation at a rate of 2 Å/min, while the substrates were kept at 673 K. Then epitaxial Fe film with thickness t_{Fe} ranging from 7.1 to 42 ML, was grown at the same rate as that of MgO at room temperature (RT). The RHEED images of the 3 nm MgO layer epitaxially grown on the GaAs(100) were streaky with several elongated spots indicating the presence of some small crystalline islands on the smooth surface of the MgO film. This could be explained by the fact that there is a large lattice mismatch (25.5%) between GaAs and MgO with an epitaxial relationship of MgO(100)[001]//GaAs(100)[001]. This is consistent with the findings from other groups [2-4]. It also suggests a cube-on-cube orientation of MgO on GaAs. A 45° rotation of the epitaxial Fe lattice cell was identified respect to the MgO lattice giving a small mismatch of 3.8% and an epitaxial relationship, Fe(100)[011]//MgO(100)[001]. Before removing the samples from the chamber for *ex-situ* measurements, the samples were capped with either 3 nm Au or MgO epitaxially grown at RT.

The magnetic hysteresis loops, as shown in figure 1, for Au capped samples show that the uniaxial anisotropy dominates for the thicknesses from 7.1 to 21 ML. The MgO capped samples, however, exhibit strong cubic anisotropy with a weak contribution from the uniaxial anisotropy term. This is consistent with the FMR data with theoretical fitted curves derived from Landau-Lifshitz equation without damping. There are two interesting results found in this study. 1) The uniaxial anisotropy was still present with the MgO interlayer and Au capping layer. It is generally believed that the uniaxial anisotropy observed in the Fe/GaAs system comes from the Fe-GaAs interface. We would suggest that the presence of an overlayer might actually alter the electronic properties of the Fe film such that the spatial distribution and orientation of its bonding orbitals at the interfaces are changed, as suggested by Mc Phail *et al* [5]. 2) The MgO cover layer appears to suppress the uniaxial anisotropy in a more pronounced way than the Au cap. This might be accounted by the fact that the two different cover layers induced and provided different surface roughness and wetting effect which need to be further studied. The FMR experimental data also shows that the magnitude of the in-plane anisotropy varies with t_{Fe} for both series with the in-plane four-fold cubic anisotropy a more dominant term than the uniaxial one. As t_{Fe} increases from 7.1 to 42 ML, the data obtained from the FMR alongside with the MOKE observations confirms that the global easy axes slowly rotated to align with $\langle 011 \rangle$ for all the samples studied.

Planar waveguide inductive resonance methods are emerging as a common tool in the study of high frequency properties of metallic ferromagnetic films and multilayers [1-3]. The geometry and method of spinwave excitation in this technique are very different from that used in resonant cavity experiments, and correct interpretation of results requires an analysis which takes into account a number of features associated with the use of strip-line microwave experiments. We present a theory for resonance modes in ferromagnetic bilayers measured by a broadband inductive technique in a coplanar waveguide geometry. The effects of finite conductivity of the magnetic sample and the screening action of the coplanar ground-planes on the spin wave dispersion are included. The theory also includes contributions to the measured response from finite wavelength spin waves excited in this geometry.

Magnetostatic contributions to the spin wave frequencies in the planar waveguide geometry are described by a Green's function technique [4]. We derive a Green's function of the magnetic field of a spin wave for an arbitrary in-plane wave number which includes dipole and eddy current contributions. Exchange energy contributions to the spin wave modes are included with appropriate boundary conditions describing pinning at free surfaces and interfaces [5]. We derive a system of integro-differential equations which accounts for dipole and exchange coupling of the layers and the field screening by the metal of the coplanar line. Numerical solution of the equations results in a spectrum of acoustical, optical and higher-order modes and their eventual splitting.

Our theory is applicable to dipole exchange spin waves in single and bilayered ferromagnetic films with uniaxial magnetocrystalline anisotropies, and interlayer exchange interactions. Figure 1 shows a calculated response for a typical Py thin film 100nm thick for different pinning levels due to a surface anisotropy at one surface. It can be seen that the fundamental mode does not change drastically in frequency as a function of surface pinning. As pinning increases, higher order standing spin-wave modes appear. These higher order modes require an asymmetry created by the pinning to give a net measurable magnetization. It is also seen that the frequency of these modes is dependent on the pinning parameter. This dependence makes the model particularly useful for extracting quantitative pinning values for microwave frequency excitations in thin ferromagnetic films and multilayers.

Figure 2 demonstrates both the effects of sample conductivity and of the coplanar waveguide ground planes on wavevector dispersion in the film. It can be seen if the sample is excited with uniform resonance ($k=0$) then these effects disappear. However, the finite width of the coplanar transmission stripline dictates that $k>0$, and with narrow striplines, k can become appreciably large. The change in dispersion due to conductivity is dependent on film thickness, with ultra-thin films showing negligible change.

Ion beam irradiation under weak or moderate fluence allows to modify and even control the magnetic properties of thin film structures [1–2]. So, this method stands now as an elegant technique for magnetic nanopatterning [3]. Moreover, irradiation at relatively high dose generates surface roughness and gives rise to surface etching, but also to a swelling effect [2].

In ultrathin film structures, ion irradiation produces essentially intermixing at interfaces. It usually reduces the Curie temperature, coercivity and anisotropy [1]. This can even induce an out-of-plane to in-plane spin reorientation transition (SRT) [2].

In this contribution we report on a new phenomenon, of a new type of in-plane to out-of-plane SRT under moderate Ga⁺ irradiation, opposite to that happening usually in Pt/Co(x)/Pt films. This happens when considering a Pt(4.5nm buffer)/Co(3nm)/Pt(3.5nm overlayer) film with an in-plane easy axis, grown by sputtering on an Al₂O₃ (0001) substrate.

Limited 100 μm x 100 μm square areas were irradiated through a Cu mask by 30 keV Ga⁺ ions at two different moderate doses of 0.5 x 10¹⁵ and 10¹⁵ ions/cm². This Cu mask was removed afterwards leaving non-irradiated zones between irradiated squares.

Topographic atomic force microscopy evidences a swelling of the film on irradiated square areas that increases with the dose, i.e. an effect similar to that found in Fe/Cr/Fe structures [2].

Polar magneto-optical Kerr (MOKE) microscopy, insensitive to an in-plane component of the magnetization, was used to reveal the spatial distribution of remnant perpendicular magnetization inside the irradiated areas and at their border (Fig. 1). The procedure was the following: a remnant MOKE image is first recorded after saturation of the sample under a large negative field. A second remnant image is obtained after submitting the sample to a positive field. The final MOKE image (Fig. 1) is deduced from the difference of the two previous ones. It shows a fine patchy domain structure with a partial perpendicular magnetization component.

More attracting is the presence of a sharp remnant highly magnetized out-of-plane ribbons at the boundary of irradiated squares (Fig. 1). The difference of images for two independent ac-demagnetized states (Fig. 2) clearly evidence the two opposite perpendicularly magnetized states in these sharp ribbon-like domains, meaning a non-reproducible reversal process in these ribbons.

Perpendicular remnant hysteresis loops of the irradiated squares and of their boundaries were deduced from remnant image snapshots recorded for increasing field values. Results are consistent with the coexistence of out-of-plane and in-plane magnetized small domains.

In ribbons at square boundaries, the magnetization reversal process occurs at a well defined coercive field value.

We will discuss about the possible origin of the ion irradiation induced out-of-plane magnetic anisotropy in Pt/Co/Pt films having an initial in-plane anisotropy. The swelling effect that relax strains into the film must give rise to an increase of the anisotropy. However strain relaxation can be non-uniform on the full square area providing the coexistence of small patches with in-plane and out-of-plane anisotropy. The presence of a rather huge perpendicular anisotropy and well defined coercivity in ribbons can also come in part from peculiar strain states at this boundary, but also from demagnetizing film limit conditions that tend to partly suppress the shape anisotropy term.

Introduction

CoFeB thin films have been widely used in MgO-based magnetic tunnel junctions (MTJs) to achieve a large tunneling magnetoresistance (TMR) ratio and low resistance-area (RA) spin-transfer devices [1]. In spin-transfer devices, how to reduce the switching current density is a challenging issue. According to the equation of intrinsic critical current density, $J_{C0} = \alpha M_s t_F (H + H_K + 2\pi M_s) / \eta$ [2], J_{C0} can be tuned by altering the damping constant (α), the saturation magnetization (M_s) or effective anisotropic (H_K). In this study, we prepared CoFeB films with different capping layers and investigated the factors affecting the Gilbert damping constant.

Experiment results & discussion

The samples were fabricated in the form of half-MTJ stacks: Sub// SiO₂/MgO (1 nm)/CoFeB (2.5 nm)/X (0-5 nm)/Ta (0-5 nm), where the capping layer X was Cu, Ag, Mg, or MgO respectively. We chose Co₇₂Fe₈B₂₀ as the material for the free layer due to its low magnetostriction. The damping constant (α) was obtained from the measurement of ferromagnetic resonance (FMR) by electron spin resonance (ESR) [3]. The magnetic properties were measured by vibrating sample magnetometer (VSM).

The damping constants of CoFeB with different capping layers of 5 nm are shown in Fig. 1. According to the spin-pumping theory [4], several metals such as Pt, Pd, and Ta were reported to enhance the damping constant of NiFe films when they were deposited on NiFe. In addition to spin-pumping effect, intermixing effect can be another important factor affecting the α value. To further understand how the damping constant was affected by the adjacent material, we changed the thickness of Ta (0-5 nm) and thickness of Cu and Ag in the composite capping layers (Cu/Ta (5) and Ag/Ta (5)). The dependences of M_s and damping constants of CoFeB on the capping layer thickness are shown in Fig. 2. Significant reduction of M_s was observed when the thickness of the capping layer Ta increased, which implied that the Ta capping layers caused the intermixing at the interfaces. On the other hand, the insertion of Cu and Ag effectively suppress the intermixing. Therefore, M_s increased with increasing the thickness of Cu and Ag. The damping constants showed opposite dependence on the capping layer thickness, that is, the damping constant decreased when M_s increased. These results suggest that the intermixing at the interface of CoFeB and capping layer may significantly increase the damping constants. From Fig. 2 (a), we observed almost the same trend of M_s vs. thickness of Cu and Ag, so we might expect to see the same variations of α values if the intermixing is only one dominant factor. However, the damping constants of CoFeB with the Cu/Ta capping layer are lower than those with the Ag/Ta in all thickness, as shown in Fig. 2(b). It was sufficiently indicated that the spin-pumping effect plays an important role on the damping constant in addition to the intermixing. Lower damping constants with Cu/Ta capping layers revealed that Cu exhibited a smaller spin-flip rate than Ag. Therefore, the spin electrons pumped out from CoFeB were easily accumulated at the CoFeB/Cu interface and then diffused back to CoFeB. The ferromagnetic precession can be preserved by the diffusion-back spins, which avoids the loss of angular momentum and reduces the damping constant. Consequently, the effective damping constant, α should be the summation of the intrinsic damping constant of α_0 and the spin-

pumping or intermixing enhanced damping constant of α' . In summary, we can adjust α by selecting various capping layer, and take this advantage of modulate the switching current density in spin transfer devices.

The experimental data on the properties of ferromagnetic GaMnAs thin films doped with ≈7% of Mn are in good agreement with the Zener mean field theory [1]. This model predicts an increase of the critical temperature T_c with the magnetically active Mn concentration and the concentration of the charge carriers ($p^{1/3}$). According to this model, it should be possible to obtain a Curie temperature above 300°C by increasing the Manganese doping level to 10% and conserving a hole concentration of at least 10^{21} cm^{-3} [1].

Considering the solubility limit of Mn in the GaAs matrix, such high doping requires special growth conditions which are still a real challenge. Very recently the successful growth of such highly doped layers has been reported by Ohya et al. [2]. They have also investigated the annealing procedure which avoid the formation of MnAs second phase. Nevertheless the layers did not show a significant increase in the critical temperature. This fact, considering the resistivity measurements of the annealed samples which present the samples as metallic systems, can be attributed to the existence of magnetic and charge compensating centers which are not out-diffused completely by low temperature annealing procedure [2].

In order to study in more detail the magnetic properties of such highly doped samples (15, 17 and 21%) we have performed ferromagnetic resonance measurements (FMR) on both as-grown and annealed samples and compared the results to those obtained for standard low doped samples with 7% of manganese.

From the angular variation of the resonance positions we have determined the anisotropy fields (H_i) as a function of the Mn concentration and the measuring temperature; using the relative magnetization values obtained from the intensity of the uniform mode spectrum, the magnetocrystalline constants (K_i) have been deduced from these values (fig.1). The anisotropy constants are known to vary with the strains and the hole concentration in the films. Although the low thickness (10 to 20nm) of the samples does not permit to measure the strain in the films by the XRD technique, the use of the mean field theory predictions [1,3,4] permits to separate the effect of each of these two parameters.

The numerical values of the static magnetization show that despite the magnetic homogeneity of the GaMnAs films, a large fraction of the introduced manganese ions is magnetically inactive probably due to a high concentration of interstitial Mn ions.

The hole concentration (relative) determined by a rough approximation: $T_c/x_{\text{effective}} \sim p^{1/3}$ for the annealed samples are shown in fig.1 as a function of $x_{\text{effective}}$. The three heavily doped samples show a gradual (nearly linear) increase in $[p]$ with the effective Mn concentration. The hole concentration is nevertheless (about 4 times) higher than the one related to the reference sample with $x_{\text{effective}}=0.043$. The Curie temperatures determined from the FMR measurements are in good agreement with those reported formerly for these samples [2].

The variations of the uniaxial strain in these samples can be deduced by comparing the perpendicular uniaxial magnetocrystalline anisotropy constants (the dominant one in these structures) and the relative hole densities in each sample to those previously measured for a 7% doped reference sample (fig.1). We see that both the effective x and the strains increase at the same time. Although these results may seem normal at first glance, considering the absolute concentration values of Mn

in the samples do not confirm the previous studies on the modification of the lattice parameter by the interstitial Mn ions (e.g. [5]). A more surprising aspect of the results is revealed when fitting this variation for samples with lower $x_{\text{effective}}$ (i.e. higher x) by a straight line. This line which well includes all three heavily doped samples passes by the origin point, yielding the absence of any parameter modifying the lattice constant other than the effective x.

In addition the variation of the linewidth of the FMR spectra and the Landé g-factors were studied.

Large scale surface magnetic domains in magnetite thin films studied by spin-polarized scanning electron microscopy.

E. Kaji, A. Subagyo, K. Sueoka

Graduate School of Information Science and Technology, Hokkaido University, Sapporo, Japan

Introduction

Half metallicity and fully spin-polarization of magnetic thin films are essentially required characteristics to realize high performance spin related devices such as magnetic tunnel junctions spin valves and spin controlled transistors. Magnetite (Fe_3O_4) is one of the promising candidates for the materials of half metallicity [1]. Magnetite has high conductivity and high Curie temperature of 858 K [2], therefore, fabrication of high quality magnetite thin films have recently been of great increased interest for technological applications. Magnetic and crystallographic studies have performed on magnetite epitaxial films grown on MgO substrate and it has been reported that crystallographic symmetry introduces antiphase boundaries (APBs) in the epitaxial films that prevent the magnetite thin films from generating magnetic single domain structure. Reported low magnetoresistance ratio of magnetic tunneling junctions employing the magnetite thin films is due to the existence of the APBs [3]. APBs with antiferromagnetic coupling pin the magnetization of antiphase domains (APDs) nearby in opposite direction to reduced the magnetic domain structures down into 100-300nm scale. We have investigated APBs on surfaces by means of a scanning tunneling microscopy (STM) and obtained atomic resolution images revealed stoichiometry of magnetite thin films and detailed structure of APBs. We have been investigate correlation between the surface structure and macroscopic magnetic structures, and magnetic domains of a few tenths larger than that of APDs have been observed by means of STM and spin-polarized scanning electron microscope (Spin-SEM) or SEM with polarization analysis (SEMPA)[4]. The previous results suggested the annealing presses in UHV makes the spin configuration of the thin film visible using the Spin-SEM system and large fluctuations of magnetic domain are in the order of a few micro-meter [4]. In this paper, further Spin-SEM study is reported, that shows careful post annealing process offers clear magnetic domains of which domain boundary runs along $\langle 110 \rangle$ direction.

Experiment

The ultrathin epitaxial magnetite films were prepared by growth on a MgO (001) substrate by deposition of Fe in the presence of oxygen. The oxygen background pressure was set to 7.0×10^{-5} Pa. The flux of Fe was set to about 0.11 nm/min. The Fe was evaporated by an electron beam. The growth temperature was maintained at 523 K. This growth procedure gives a good stoichiometry of magnetite films. The surface cleanliness and stoichiometry were confirmed by X-ray photoelectron spectroscopy (XPS). Detained crystallographic structures were investigated by in-situ STM system [5]. Since our home made Spin-SEM system is independent instrument of the growth system equipped with XPS and STM, the sample should be transferred from the growth system to Spin-SEM via ambient condition in a short period. Experimental conditions and cleaning procedure with out ion sputtering of the sample surface are described in the reference [4]. Only an UHV annealing process at 573 K for 30 min was employed to produce clean surfaces.

Results

Figure 1 shows an SEM image and Spin image observed on the sample. The SEM image shows no surface morphology that suggested the surface is flat. In contrast to that, a clear spin dependent image is obtained. Due to the geometry of our Mott-type spin analyzer, the spin image reflects spin polarization components along 45 degree off plain and magnetic domain structure in an as-annealed remanent state. Stray magnetic fields around the sample were reduced below 0.01 mT by

a magnetic shield attached over a pole piece of an SEM electron gun. Magnetic domain walls run along $\langle 110 \rangle$ direction and size of the magnetic domains is in the rage from a few hundred nm to a few micro meters. Since an easy axis of the film is expected along $\langle 111 \rangle$ direction, the magnetic domain structures are related to the crystallographic anisotropy. This result indicates that the large scale magnetic ordering similar to our previous observation exist in the magnetite thin films. Such ordering has not been reported in the transmission electron microscopy or magnetic force microscopy (MFM) studies. Although correlation of experimental condition of the UHV annealing process should be investigate in detail. This result suggests that the UHV annealing reduces the antiferromagnetic coupling at APBs to make the magnetic domain large and that the thin films of sub-micro meter may yield high spin-polarized electrode.

The Gilbert damping factor is an important parameter for the characterization of the dynamic properties of the magnetization in ferromagnetic thin layers and is inversely proportional to magnetization relaxation time along the applied field. It can be obtained from ferromagnetic resonance measurements via the variation of the linewidth of the uniform mode spectrum with the measuring frequency. The FMR linewidth is generally decomposed into two parts: a homogenous broadened one ΔH_{homo} which increases linearly with the microwave frequency for a specific system and an inhomogeneous one independent of the microwave frequency.

We report here the measurement of the damping factor by FMR spectroscopy in 50nm thick GaMnAs sample with 7% Mn, showing the critical temperature $T_c=157\text{K}$ after annealing in air at 200°C for 30 hours. The measurements were performed at 9GHz and 35GHz in the 4K to 150K temperature range. We further investigated the anisotropy of the α -damping factor for different orientations of the applied magnetic field along the crystalline high symmetry directions and as a function of the measuring temperature (fig.1). Our results are compared to the very few previous reports on GaMnAs layers with similar Mn concentrations [1,2]. The values found in our high T_c samples are at least 10 times less than those reported previously. In this sample the damping factor is as low as metallic thin films (Fe) studied by Heinrich et al. [3].

The inhomogeneous linewidths are deduced, as well, for different directions of the film and different temperatures (fig.2)

In addition, the spectra are studied from the homogeneity point of view and the values of anisotropy constants and g-factors are measured as the reference values to be compared with other GaMnAs structures.

Experimental evidence for bulk and interfacial contributions to static and dynamic properties of Py/Al₂O₃.

C. Le Graet, D. T. Dekadjevi, S. Pogossian, D. Spenato, J. Ben Youssef
Physics, LMB/UBO/CNRS, Brest, France

During the last decades, a phenomenon not yet understood is the damping mechanism in nanostructures. Saturated magnetization, anisotropic and structural properties should be considered to understand the damping mechanism. Moreover, the presence of interfaces in bilayers plays a key role in the damping. It is useful to distinguish the bulk and interfacial contributions to this mechanism [1-3]. We present an analysis of the static and dynamic magnetization properties of Si/Permalloy(t_{Py})/Al₂O₃(3nm) grown by rf sputtering as a function of the Permalloy (Py) thickness (t_{Py}). Py was chosen as the ferromagnet since it exhibits a very low anisotropy resulting in a small damping. Al₂O₃ was chosen since it is an insulator. We perform a study as a function of t_{Py} to discuss interfacial and bulk contributions. A dc magnetic field was used to induce an uniaxial anisotropy. Static and dynamic properties were studied at room temperature, using a conventional VSM and Ferromagnetic Resonance (FMR) at frequencies in the range 3-20GHz using a wideband resonance spectrometer with a non resonant microstrip transmission line. The keyrole of the interface in the static magnetic properties is demonstrated since the saturated magnetization (M_s) is proportional to $1/t_{\text{Py}}$. The anisotropic properties are also studied as a function of t_{Py} . Fig. 1 shows the normalized remanent magnetization versus t_{Py} . It reveals an inversion of the anisotropy axis at a critical thickness (t_c) of 7nm. Below t_c , the easy axis is in the plane but perpendicular to the direction of the applied field during growth (H_d) whereas above t_c , the easy axis is along this applied field. This effect on the anisotropy could be attributed to the bulk since no critical behaviour appears in M_s at t_c . The dynamic properties of our system should be influenced by these static properties. In the following, we measure the resonant field (H_{res}) as a function of the frequency (f) to determine: the gyromagnetic factor (γ), the effective magnetization (M_{eff}), the intrinsic and extrinsic contribution to the damping. γ and M_{eff} are deduced from the resonant condition. We find a negligible surface anisotropy. Also, a significant decrease in γ with decreasing t_{Py} is present. It suggests that an interfacial mixing results in a non negligible orbital moment altering the Landé factor, and consequently γ . Therefore, the interfacial structure does not bring a surface anisotropy but modifies the gyromagnetic factor. To understand the damping driving mechanism, we measure the evolution of the peak to peak parallel resonance linewidth (ΔH) as a function of f and t_{Py} : ΔH increases linearly with f in agreement with previous results. Two different contributions are then determined: the extrinsic and the intrinsic ones. Before t_c , the damping factor (α) is enhanced relatively to the refereed value of bulk NiFe. Above t_c , α values are in agreement with bulk NiFe. Concerning the extrinsic contribution, Figure 2 shows two different trends: one below t_c and one above t_c . Usually, this extrinsic contribution reflects the structural quality of the samples.

In this study, we have shown experimental evidence for the interface and bulk contributions to the Py/Al₂O₃ static and dynamic properties. The interface drives the gyromagnetic factor. However, there are no significant effects of the bulk structural properties (grain boundaries) on this factor. The bulk plays a keyrole in anisotropic properties and extrinsic part of the damping. A detailed structural analysis will also be presented.

The effects of substrates on structural properties of Fe thin films are thoroughly studied for many years. In many previous reports, Fe thin film is believed to grow with isotropic polycrystalline structure on a glass substrate. However, recent study [1] reveals Fe thin film can have asymmetric polycrystalline structure even deposited on an isotropic glass substrate. In present work, we have studied asymmetry of polycrystalline Fe films of 5, 50, 200 and 300 nm thickness on glass substrate. For the investigation of thin film crystal symmetry, optical second-harmonic generation (SHG) has been used. SHG technique has intrinsic sensitivity to surface structure as well as crystal symmetry of thin film. We found that the surface structure of Fe thin film possesses asymmetric Cs crystal structure pretty close to C2v through considering SHG intensities. As a proof of Cs symmetry, it is presented one-fold intensity profile with one mirror plane in SHG intensity. Cs and C2v surface symmetry are usually showed at the (110) surface of cubic crystal. Therefore the surface structure of the polycrystalline medium would be related to bcc (110) growth orientation coinciding with XRD measurement, which is consistent with recent report [1]. Further we normalized SH in-plan asymmetries with various thickness. It is observed that SH asymmetry increased with increasing thickness. From these results, it is concluded that the surface structure of ultrathin polycrystalline Fe film below 5 nm is almost isotropic, while in the case of the thicker Fe thin films, surface structure possesses the symmetry closer to asymmetric Cs structure close to C2v. Polycrystalline Fe thin films were fabricated on glass substrate in 300 K in DC magnetron sputtering system. Ar gas is used under 5 m Torr Under base pressure at 2×10^{-6} Torr in 500 Oe magnetic field. We covered Si3N4 on Polycrystalline Fe to keep the surface state.

We used a general SHG system setup to measure surface structure of ferromagnetic Fe films on glass substrate. We used femto-second terawatt Ti: sapphire laser, mode-locked at 780 nm, the center of wavelength as a pulse laser and 532nm Nd: YVO4 (Spectra, Millennia Vs J) continuous laser as pumping laser. Here we measured SH intensity from Fe sample at specified incident polarization at 80 mW and 0 mW~130 mW to get information on normalized SH asymmetry. Sample magnetization is fixed by external magnetic field 1kOe. The filter before sample is used for blocking unexpected SH wave from optical elements and the filter behind sample for blocking fundamental wave.

From previous report [1], Fe films have bcc (110) growth orientation would possess the symmetry class corresponding to (110) surface at its surface. We expected that the surface of the polycrystalline Fe showing (110) growth orientation would possess the lowest symmetry class Cs or C2v. We measured SH intensity by azimuthal rotation of the sample on the sample stage. There are four selected configuration. Frequency-doubled s-pole output is almost comparable with the noise due to Dark current. The each data in Fig 1. shows one asymmetric mirror plane for frequency-doubled p-output. For sp configuration SH intensity have 65° mirror plane and for pp configuration have 120° mirror plane. There are only three crystal classes Cs, C3h and D3h including one mirror plane

operator and except for inversion operator. The SH intensity profile shows a sine and only two symmetry classes, Cs and C2 can satisfy this condition in sp configuration. Therefore it is concluded that polycrystalline Fe on glass substrate showing (110) growth orientation possess Cs crystal class. For Fe films of various thickness, Cs asymmetry of SH intensity has been obtained and shown in Fig. 2. Normalized SH asymmetry is increased with increase of film thickness. Thus, it can be deduced that symmetry breaking in this system is closely related to bcc (110) growth of Fe with increasing film thickness.

Introduction

It is well known that there are several kinds of magnetic coupling, such as the exchange bias and interlayer coupling in SV films. However, nature of those magnetic coupling in SV films with the insertion of a nano-oxide-layer (NOL) have been not well discussed even though NOL plays a most important role in nano-constriction SV MR devices such as nano-contact MR, because the magnetism and structure of an ultra-thin NOL themselves were not clear, which NOL is formed by surface-oxidation of metal film layer such as $\text{Co}_{1-x}\text{Fe}_x$ alloy. Therefore, we have already reported the magnetism and structural consideration on $\text{Co}_{1-x}\text{Fe}_x$ -NOL in pinned layer, where it is revealed that AFM CoO-FeO ($T_B \sim 140$ K) and $\text{Cr}_2\text{O}_3\text{-Fe}_2\text{O}_3$ ($T_B \sim 220$ K) are dominant component in $\text{Co}_{0.9}\text{Fe}_{0.1}$ -NOL and the surface of $\text{Co}_{0.9}\text{Fe}_{0.1}/\text{Cr-NOL}$, respectively [1, 2].

In this paper, the interlayer coupling field (H_{in}) through Cu spacer for $\text{Co}_{0.9}\text{Fe}_{0.1}/\text{Cr-NOL}$ SVs [$x = 0.1, 0.3$ and 0.7] with/without Cr are discussed for confirming NOL magnetism and structure in more detail.

Experimental

The sequential sputtering method was used for the sample preparation. The typical design of the SV sample was seed/IrMn 5.5/ $\text{Co}_{0.9}\text{Fe}_{0.1}$ 1/ $\text{Co}_{1-x}\text{Fe}_x$ 1 ($x = 0.1, 0.3, 0.7$)/Cr 0, 0.08/N.O. (0, 2, 10 kL)/ $\text{Co}_{0.9}\text{Fe}_{0.1}$ 2/Cu 2/ $\text{Co}_{0.9}\text{Fe}_{0.1}$ 2/Ta 3 [nm] on a thermally oxidized Si substrate (N.O.: the conventional natural oxidation process). 0 kL sample means the full metal SV. Oxygen exposure 1 L is oxygen partial pressure 1 $\mu\text{Torr} \times$ oxidation time 1 sec. All of the films were annealed at 270°C for 1.5 h under a magnetic field of 10 kOe. After the magnetic field cooling from room temperature to ~ 3 K under a magnetic field of 10 kOe, the R-H curves in each temperature were measured by using the conventional four-terminal methods under the temperature range of 5 K to room temperature. H_{in} was estimated as a central field of hysteresis loop at free layer.

Results and Discussion

It has been known the interlayer coupling is related to both RKKY like antiferromagnetic coupling and the Néel ferromagnetic coupling [2]. Table 1 shows H_{in} through the Cu spacer for each sample at R.T. Here, positive sign shows the ferromagnetic interlayer coupling. Large positive H_{in} was observed in the case of full metal SVs both Co-rich and Fe-rich, which suggests the presence of the Néel ferromagnetic coupling field along with the oscillatory RKKY coupling field because H_{in} shows the second RKKY antiferromagnetic maximum at near 2 nm. In contrast, H_{in} decreased by inserting NOLs, especially, in the case of the SVs with $\text{Co}_{0.7}\text{Fe}_{0.3}$ -NOL and $\text{Fe}_{0.7}\text{Co}_{0.3}$ -NOL, the interlayer coupling changed from ferromagnetic to antiferromagnetic coupling. It is considered that the influence of the Néel ferromagnetic coupling was weakened by the insertion of both $\text{Co}_{1-x}\text{Fe}_x$ -NOL and $\text{Co}_{1-x}\text{Fe}_x/\text{Cr-NOL}$, which means that the interface between $\text{Co}_{0.9}\text{Fe}_{0.1}$ and Cu is more flat than without NOLs. The interfaces of the SVs with Fe-rich NOL were more flat than those with Co-rich NOL was also observed. In addition, from the results of the inserted $\text{Co}_{1-x}\text{Fe}_x/\text{Cr-NOL}$, it was obtained that the case of prepared by the stronger oxygen exposure had the more flat interface.

Figures 1 (a) ~ (c) show the temperature dependence on H_{in} for each sample at $x = 0.1, 0.3$, and 0.7 . The positive H_{in} for full metal SVs increase with decreasing temperature. It is caused by the magnetic moment contributing to the Néel ferromagnetic coupling enhances with decreasing temperature. On the other hand, in the case of the SVs with NOL, the positive H_{in} decreases with decreas-

ing temperature and the interlayer coupling of $\text{Co}_{1-x}\text{Fe}_x/\text{Cr-NOL}$ SVs changed from ferromagnetic to antiferromagnetic coupling. It is considered that the RKKY like antiferromagnetic coupling also enhances with decreasing temperature and its influence contributing to the interlayer coupling is stronger than the Néel ferromagnetic coupling. In addition, although interesting results, the particular tendency of temperature dependence on H_{in} for $\text{Co}_{0.9}\text{Fe}_{0.1}$ -NOL SV and $\text{Co}_{0.9}\text{Fe}_{0.1}/\text{Cr-NOL}$ SV was observed at T_B of those CoO-FeO and $\text{Cr}_2\text{O}_3\text{-Fe}_2\text{O}_3$, respectively.

The Effect of CoFe Surface Pre-Oxidation on Magnetic Tunnel Junctions.

P. Pong, W. F. Egelhoff

Magnetic Materials Group, National Institute of Standards and Technology, Gaithersburg, MD

Introduction

The ferromagnet/oxide interface plays a critical role in determining the tunneling magnetoresistance (TMR), the junction resistance, and the magnetic properties. Surface oxidation achieved by exposing the bottom ferromagnetic layer to oxygen before depositing the Al layer helps to suppress intermixing at the ferromagnet/Al interface [1, 2]. Initially, the deposited Al takes oxygen away from the ferromagnetic oxide to form Al₂O₃. After the oxygen is consumed and Al is deposited, the Al layer is oxidized in plasma to form Al₂O₃ barrier [1, 3]. This approach provides a very promising means of suppressing orange-peel coupling in magnetic tunnel junctions (MTJs) [4]. Further investigation illuminating the pre-oxidation effect on MTJ properties with a range of Al thicknesses is very important to the application of the technique.

Experiment

The thin films were deposited on thermally oxidized silicon wafers by dc magnetron sputtering in an ultrahigh vacuum chamber with a base pressure of 2×10^{-10} Torr. The metal films were deposited at room temperature in 2 mTorr argon. The oxide barrier layer was made by first depositing a thin Al metal and then oxidizing it in oxygen plasma (4 mTorr argon, 2 mTorr oxygen) for 2.5 minutes. The thicknesses of the Al metal cover a range from 4 to 18 angstrom. The sample structure is substrate \ 25 Ta \ 50 Au \ 100 IrMn \ 40 CoFe \ X Al: oxidized \ 50 CoFe \ 50 Ta \ 70 Ru. (X is shown next to the data, all units in Angstrom).

Results and Discussion

Figure 1 presents two sample sets with a range of Al thicknesses. One sample set was pre-oxidized with 1 mTorr oxygen for 30 seconds prior to the deposition of the Al layer while the other set was not pre-oxidized. The TMR of the pre-oxidized samples are all larger than the samples without pre-oxidation regardless of their Al thicknesses. Moreover, the RAs of the pre-oxidized samples are also in general higher. Thus pre-oxidation significantly improves the TMR, although it increases the RA of the junctions. We believe the improvement of the TMR is due to the fact that the pre-oxidation helps to suppress intermixing at the ferromagnet/Al interface, inhibiting the orange-peel coupling. This result shows that the pre-oxidation technique is applicable for Al₂O₃ MTJs regardless of their thicknesses. Further experiment involving a MTJ wafer with a wedge of Al₂O₃ characterized by current-in-plane-tunneling (CIPT) technique reinforced the validity of the usefulness of pre-oxidation. We have also studied the influence of the pre-oxidation time on the TMR and RA.

Conclusion

It was previously shown that pre-oxidation could suppress the orange-peel coupling and thus enhance the TMR in a series of MTJs with the same Al₂O₃ thickness. In this work, the technique was utilized on MTJs with a range of thicknesses and the result was compared with the MTJs without pre-oxidation. This study shows that the pre-oxidation technique is of general use and it is applicable on MTJs with various Al₂O₃ thicknesses.

For both fundamental and application points of view, the switching time and behaviour of a trilayer system consisting of a ferromagnetic/non magnetic/ferromagnetic trilayer (as used e.g. for magnetoresistive devices) is of utmost significance. In microstructured magnetic multilayer systems a clear view of the reversal dynamics has not been achieved experimentally because it needs a technique offering at the same time a high temporal and lateral resolution. Time-resolved XMCD-PEEM represents a state-of-the-art way of getting ultrafast time resolution (low picosecond regime) and simultaneously layer and spatially resolved information of the investigated magnetic multilayered structures. The magnetization can be excited by a short magnetic field pulse that can be achieved in principle through different pump-probe methods. In the actual applications we used a laser-induced electrical field pulse in a Au stripline.

The transient local magnetization dynamics was studied by time-resolved XMCD-PEEM in a stroboscopic pump-probe technique [1, 2]. Magnetic microstructures deposited on a Au stripline are magnetically disturbed by a short magnetic field pulse. The ultrashort magnetic field pulse is provided by an electric current pulse flowing through the stripline underneath the microstructure, triggered by an optical switch by means of a femtosecond laser pulse [3, 4]. This part of the technique, in combination with the length of the synchrotron bunch, is responsible for the time resolution of the experiment.

Fig. 1 presents the sample design (optical switch, stripline and magnetic microstructures) as well as static XMCD images of investigated Permalloy microstructures. To study reversible dynamics, the initial domain configuration has to be a Landau pattern. Therefore the domain configuration was characterized by high resolution static XMCD-PEEM measurements.

Time-resolved XMCD-PEEM measurement on the elongated Permalloy rectangle is shown in Fig. 2. It is striking that the Landau pattern changes irreversibly from a two vortex state in a four vortex state after pulsing. The pump-probe series, depicted on the left of Fig. 2, shows the time evolution of the system. The difference images indicate the domain wall movement. Integrating different areas in the black, white and grey domain, as shown on the right side, image the dynamic magnetic response of the microstructure to the incoming field pulse. As the magnetization of the grey domains are perpendicular to the incoming field pulse, the changes in contrast are most obvious. The dynamics observed for the rectangle shown in Fig. 2 will be discussed and compared to the dynamics of a permalloy square present on the same stripline. Correlations between shape and dynamics will be analysed as well.

Furthermore, we investigated the spinvalvesystem of Co/ Cu/ Py and will present first results.

Anisotropic x-ray magnetic linear dichroism at Fe, Co and Ni L edges: Interfacial coupling revisited.

G. van der Laan¹, E. Arenholz²

1. Diamond Light Source, Didcot, United Kingdom; 2. ALS, Berkeley, CA

The detailed knowledge of the spin arrangements in engineered magnetic nanostructures comprised of multiple magnetic species is essential to tailor their properties for device applications e.g. in information storage technology. Soft x-ray magnetic dichroism spectroscopies play a very important role in improving our understanding of complex heteromagnetic nanostructures since they provide elemental and chemical site-specific magnetic information with high sensitivity and tunable probing depth. X-ray spectromicroscopy techniques such as photoemission electron microscopy (PEEM), scanning transmission x-ray microscopy (STXM) or full field x-ray microscopy add spatial resolution down to a few nm.

We present the observation as well as theoretical description of anisotropic x ray magnetic linear dichroism (XMLD) on thin films at the Fe L_{3,2} edges in Fe₃O₄ [1], the Ni L_{3,2} edges in NiFe₂O₄ and NiO [2], and Co L_{3,2} in CoFe₂O₄ and CoO [3]. We show unambiguously that - contrary to current belief - spectral shape and magnitude of the XMLD is not only determined by the relative orientation of magnetic moments and x ray polarization but that their orientation relative to the crystallographic axes has to be taken into account for the accurate interpretation of the XMLD data.

The observed anisotropy of XMLD is a general phenomenon and is expected for any magnetic system. Consequently, conclusions based on the interpretation of XMLD spectra without accounting for the XMLD anisotropy have to be reconsidered. We will revisit some of the previous experimental results and reinterpret the experimental data based on our findings. Applying our results to Co/NiO(001) interfaces, we find perpendicular coupling between Ni and Co moments. The results are important considering the growing interest in understanding exchange-biased systems

Topological hysteresis in superconductors and ferromagnets.

R. Prozorov^{2,1}, P. C. Canfield^{2,1}

1. Physics and Astronomy, Iowa State University, Ames, IA; 2. Ames Laboratory, Ames, IA

Pattern formation in magnetic materials has been a subject of intense interest due to the desire to understand the behavior of complex systems where topological intricacy prohibits exact evaluation of the ground state. It is impossible to determine the equilibrium topology of magnetic domains in ferromagnets or the structure of the intermediate state in type-I superconductors from global free energy minimization. The pattern geometry has to be assumed and parameterized, and then the energy minimization can be used to find the best value of the free parameters. But is it the ground state pattern?

The situation is further complicated by magnetic hysteresis, which is usually caused by the imperfections and defects in the crystal structure resulting in pinning of magnetic flux in superconductors or domain walls in ferromagnets. The alternative cause of pinning is shape and surface - related energy barriers (e.g., geometric and Bean-Livingston) that result in a spatially nonuniform free energy and corresponding metastable states of the system. Yet, can there be magnetic hysteresis in perfect samples?

In this work we used Faraday and polar Kerr effects to conduct magneto-optical imaging of the flux distribution in a type-I superconductor (pure lead crystal, Fig.1) and a soft ferromagnet (CeAgSb_2 (Fig.2) with quite unusual spin structure and crystal electric field anisotropy). Kerr imaging was conducted directly by reflecting a linearly polarized light off the as grown surface of ferromagnetic crystal (see Fig.2). Imaging in superconductors was done by using bismuth - doped iron garnets with in-plane magnetization as magneto-optical indicators. By placing such indicator directly on top surface of the sample under study, we obtained real-time imaging of the magnetic induction (see Fig.1).

We find that tubular rather than lamellar structure corresponds to the equilibrium pattern in both systems. Although the microscopic physics is quite different, we find common points that determine pattern topology in these materials. The interplay between long-range and short-range forces as well as flux conservation play major role in determining the patterns geometry.

There are also results unique to superconductivity and to ferromagnetism.

In a type-I superconductor, evolution of the intermediate state can be mapped remarkably well onto coarsening of the conventional soap froth, but unlike it, the process is controlled by the reversible parameters – magnetic field and temperature rather than by the irreversible time.

In a ferromagnet on the other hand it is shown that apparent topological time-reversal symmetry breaking can be lifted on the scale of the entire sample by creating secondary dipolar magnetic domains.

Addressing the issue of magnetic hysteresis, we describe a novel type of magnetic hysteresis that is only observed in clean, pinning-free samples. Most importantly, this hysteresis cannot be annealed or removed by any sample improvement. We call this phenomenon *topological hysteresis* to indicate that the difference in the topologies of the intermediate state in type-I superconductors or ferromagnetic domains in soft ferromagnets upon cycling of the applied magnetic field can lead to a measurable hysteretic response of macroscopic magnetization.

Avalanches through windows: multiscale visualization in magnetic thin films.

G. Durin¹, A. Magni¹, S. Zapperi^{2,3}, J. P. Sethna⁴

1. Istituto Nazionale di Ricerca Metrologica, Torino, Italy; 2. Dep. of Physics, University of Modena and Reggio Emilia, CNR-INFM National Center on nanoStructures and bioSystems at Surfaces (S3), Modena, Italy; 3. ISI foundation, Torino, Italy; 4. Physics Department, LASSP, Cornell University, Ithaca, NY

The motion of domain walls in soft magnetic materials, a basic example of complexity in materials science, has been the subject of a long and continuing series of studies. In bulk systems, most of the statistical properties are understood in terms of a depinning transition [1]. In thin films, the motion is presumably dominated by depinning as well, but our understanding of the dynamics is still preliminary. Also, experimental data available are poor, although very promising. Puppini [2] found the critical exponent τ of the avalanche size distribution $P(S)=S^{-\tau} f(S/S_0)$ in a Fe film is about 1.1, less than for bulk systems. Recently, Ryu et al. [3] argued that in MnAs films ($T_c \sim 45^\circ\text{C}$) there is a cross-over between two universality classes, as τ changes from 1.32 to 1.04 with T increases from 20 to 35°C . These experiments rely upon measuring avalanches optically, in a small sub-window of the entire sample, and often comparing windows of varying sizes.

Here, we explore two issues associated with extracting avalanche statistics from images: good methods for extracting avalanche distributions, and a proper scaling approach to address the finite-size cutoff in the avalanche sizes induced by the observation window.

The determination of avalanche size from images is not as simple as in fluxometric measurements because it is far more challenging to separate signal from noise in the richer space-time information provided. This is particularly important for size distributions, where small avalanches are crucial for estimation of the exponents. To address this question, we acquired images of domain walls on Py films using an high-resolution MOKE, with a slow varying longitudinal in-plane field.

After background subtraction and contrast enhancement, we tried to determine a reliable procedure to identify the domains in the images. Edge detection routines, for instance, are not useful in determining the position of the walls; by analyzing single images, we lose the useful information provided by the time sequence. Indeed, an effective point is to ignore the spatial information and consider only the evolution in time for each pixel. A significant jump in the measured intensity represents the switching time for the magnetization at that point. Spatial information must be then used to correct for the small number of pixels which appear to switch at a wrong time. While it is essential to make these corrections, these methods are pretty delicate. An example of avalanche visualization is shown in fig. In this case, we applied a procedure which significantly depleted small avalanches. We are exploring alternative methods which may perform better, to ensure a reliable estimation of the critical exponents.

We then consider the effect of the window size of images. Generally, the windows size both suppresses the largest avalanches and can add extra truncated avalanches at smaller sizes. Given that one can measure up to three decades of sizes for a given window, it is valuable to combine information from several window sizes; to do so we must understand the finite-size effects with windowed boundary conditions. We thus considered a realistic simulation of an elastic line moving in a random environment, and made distributions with/without avalanches that touch the borders of the window — including/avoiding the extra truncated avalanches. The fig. shows the results where only the avalanches that did not touch the sides of a $L \times L$ window are incorporated.

The tricky part of analyzing this data is that the large avalanches near depinning transitions are increasingly anisotropic: an avalanche with width W will have typical height $H \sim W^\zeta$. If $\zeta < 1$, as in

our case ($\zeta=0.63$), large avalanches become short and fat. This means that the main effect of large windows is to cut off the widest avalanches, while at small window sizes a substantial number of tall avalanches may also be removed. Thus, unlike isotropic finite-size scaling, the effects of larger windows are not similar to the small windows: they are similar to smaller windows *of a different shape*.

We can analyze the data using the finite-size scaling form

$P(S,L)=S^{-\tau} P_w(S/L^{1/\sigma_v})$, appropriate for systems with a strip geometry of width L and infinite height. Doing so, we find that the fitted exponents $\tau=1.14$, $1/\sigma_v=1+\zeta=1.68$ are close to the theoretical expected values (1.13, and 1.63). In contrast, we found that the distribution including the avalanches touching the window borders has an exponent τ which continuously changes with window size, approaching the theoretical value only at the largest window sizes. This analysis enables us to conclude that the measurements at different window sizes must be taken with care, but at the same time, when statistical distributions are properly rescaled, offer other critical exponents which can better characterize the dynamics domain wall in thin films.

Direct observation on a systematic change of the magnetic domain structure with temperature in 50 nm-MnAs/GaAs(001).

J. Kim¹, Y. Lee¹, K. Ryu², S. Shin², H. Akinaga³

1. Quantum Photonic Science Research Center and BK21 Program Division of Advanced Research and Education in Physics, Hanyang University, Seoul, South Korea; 2. Department of Physics and Center for Nanospinics of Spintronic Materials, Korea Advanced Institute of Science and Technology, Daejeon, South Korea; 3. Nanotechnology Research Institute, National Institute of Advanced Industrial Science and Technology, Tsukuba, Japan

Epitaxial ferromagnetic (FM) MnAs film on GaAs(001) has received considerable attention because of the potential for spintronic devices such as spin injection [1], magnetic tunneling junction [2], and magnetologics [3]. Apart from its technical aspect, there has also been a tremendous interest in the fundamental aspect. The MnAs system exhibits the coexistence of FM α -MnAs and non-FM β -MnAs stripes according to a systematic variation of the relative volume ratio in a temperature range of 10 - 45°C via the strain stabilization. In this study, we present the direct observation on a systematic change of the magnetic domain structure with temperature in the MnAs system with a film thickness of 50 nm, investigated by magnetic force microscopy (MFM).

A MnAs film of 50 nm thick was epitaxially grown on a GaAs(001) substrate in a molecular-beam epitaxy system. Ahead of the growth of MnAs, the substrate was heated up to about 600°C in the flux of As₄ for thermal cleaning, followed by the deposition of an undoped GaAs buffer layer of 350 nm thick. Subsequently, the MnAs film was grown at 270°C with a growth rate of about 0.05 nm/s. The longitudinal Kerr rotation was measured in an incident angle of 45° by using a photoelastic-modulator method. The magnetic domain structure has been obtained by using a MFM system, which is basically a scanning-probe microscopy equipped with a magnetic tip. In our measurements, the MFM images were obtained in the interleave mode at a lift scan height of 50 nm. The contrast of the observed MFM images illustrates the interplay between the stray fields above the film surface and the magnetic tip. We also added a special heating/cooling stage to the MFM. The stage yielded a sample temperature ranging from 0 to 180°C in a controlled manner with a negligible thermal drift. This stable performance was achieved by employing the independent configuration for the z scanner of the xy scanner.

Figure 1 presents the Kerr hysteresis loops of the 50 nm-thick MnAs/GaAs(001) film, measured at several temperatures. It should be noted that the saturation magnetization increases as temperature decreases, which is ascribed to the grown FM α -MnAs phase with decreasing temperature. It was found that the film revealed an in-plane easy axis (perpendicular to the stripe direction shown in Fig. 2). Figure 2 shows the temperature dependence of magnetic domain structure in the 50 nm-thick MnAs film, observed on a sample area of 4×4 μm^2 at several temperatures ranging from 20 to 45°C. As temperature decreases, the width of FM α -MnAs comes to be larger while that of the non-FM β -MnAs decreases, which coincides with the enhanced Kerr rotation with decreasing temperature, as in Fig. 1. It should be noted that the magnetic contrast at the surface of FM α -MnAs is due to the stray fields from the end parts of the in-plane magnetic domains. As the temperature decreases, the magnetic contrast becomes clear and the simple domain structures were formed at 35°C. The simple domain is defined as the spin configuration having a single spin direction along the width of FM stripe. As the temperature further decreases, the domains gradually collapse to form larger simple domains, and finally at 20°C the whole film turns to a nearly single magnetic domain except for small unstabilized regions.

Bismuth ferrite with coexistence of antiferromagnetic and ferroelectric ordering at room temperature has attracted many researchers all over the world. We were successful in inducing ferromagnetism in BiFeO_3 without disturbing its ferroelectric properties by doping with Tb/Dy at Bi site in thin films at room temperature [1-2]. In the present work multimode atomic force microscope (Nanoscope IV from Digital Instruments) configured to provide, simultaneously, both the magnetic (magnetic force microscopy-MFM) and the ferroelectric domain structure (piezo-response force microscopy-PFM) in thin film, tens of microns in lateral width and a resolution better than 50 nm is used to study the coexistence of two order parameters at microscopic level. The magnetic domain images are taken in situ at different temperatures and also at different applied voltages using MFM in order to determine the coupling behavior.

Figure 1 directly demonstrates the phase coexistence of magnetic and ferroelectric domain structures at microscopic level in same spatial area (20 μm) of pulse laser deposited $\text{Bi}_{0.7}\text{Dy}_{0.3}\text{FeO}_3$ thin films grown on $\text{Pt/TiO}_2/\text{SiO}_2/\text{Si}$ substrate. The effect of temperature on magnetic domain patterns is clearly evident from the figure 2. As the temperature increases zig-zag domains start getting aligned to form stripe domains. However, around 300°C magnetic domains are disturbed. This is obvious since it crosses the magnetic transition temperature which is of the order of 265°C as seen in DSC curve (Fig. 3). More interestingly the magnetic domain pattern also starts aligning with applied voltage of about 12 volts and remanence is seen even if the voltage is removed (Fig. 4). Due to instrumental limitations it is not possible to increase the voltage further which otherwise could have brought more clarity in the behavior.

The direct evidence of ferroelectric and magnetic domains in same spatial area of $\text{Bi}_{0.7}\text{Dy}_{0.3}\text{FeO}_3$ thin films helps to rule out the chemical phase separation of both the phases at microscopic level. The observed coupling of magnetic properties with temperature as well as with applied voltage in these films is tremendously important since it opens up the area for novel devices.

Introduction

Magnetic dots are much attractive as promising materials for practical applications, including non-volatile magnetic random access memory (MRAM), magnetic storage media and so on. In particular, the magnetization reversal in a single magnetic dot has been studied intensively from both fundamental and applied points of view. An experimental technique to directly observe the detailed magnetization reversal in a single magnetic dot is required.

Recently, we have proposed a new magnetization measurement method, the magnetic field sweeping (MFS)-magnetic force microscopy (MFM)[1-4], which uses a MFM tip as a detector while the magnetic field is swept. In MFS-MFM, the MFM tip having low magnetic moment is fixed 10 nm above the surface at a point of interest within the dot, and then detects the phase changes (stray fields changes) in that point of the dot as the magnetic field is swept; That is, the precise magnetic state of a local point in a single magnetic dot can be directly observed at room temperature within one minute. We have successfully observed the magnetization reversal in a circular dot and the domain wall motion in a nanowire using MFS-MFM [1-4]. In this study, we report, using MFS-MFM, a detailed magnetization reversal in a single Ni-Fe elliptical dot with several sizes.

Experimental Procedure

Ni-20at.%Fe(Ni-Fe) elliptical dots were fabricated by electron-beam lithography, electron-beam evaporator, and a lift-off technique onto thermally oxidized Si (100) substrates. The thickness was 10 nm, the aspect ratio between the length of the major axis and that of the minor axis was 2 to 1, and the length of the major axis was varied from 200 to 1600 nm. The major axial distance between adjacent dots was 200 nm. The shape of the dot was observed by scanning electron microscopy (SEM). The magnetization process of dot arrays was investigated by magneto-optical Kerr effect (MOKE) magnetometry, while the magnetic state of a single dot was observed using our proposed measurement method, namely, MFS-MFM.

Results and Discussion

Figure 1 shows the curves of the phase vs. magnetic field (H) at various points in the 10-nm-thick Ni-Fe elliptical dots with the length of major axis of (a) 400 and (b) 1000 nm, as measured by MFS-MFM. The magnetic field is applied in the longitudinal direction of the elliptical dot. Here, Figs. 1(a-1) and 1(b-1) represent AFM image of each dot, and the position of each measurement is denoted in Figs. 1(a-1) and 1(b-1). Points 1-3 indicate measured points within each dot. For the dot with the length of major axis of 400 nm, points 1 and 3 [Figs. 1(a-2) and 1(a-4)] each displays a stepped hysteresis loop of the phase. These hysteresis loops are attributed to the change in the domain configuration at the dot edges with sweeping magnetic field. At point 2 [Fig. 1(a-3)], weak phase decreases are observed at approximately 100 and -100 Oe. These phase decreases might be due to the core of a closure domain at the center of the dot. These results reveal that the magnetization reversal in the dot originates from the change in the domain configuration. On the other hand, for the dot with the length of major axis of 1000 nm, points 1 and 3 [Figs. 1(b-2) and 1(b-4)] each displays a hysteresis loop of the phase. These loops are attributed to the magnetization reversal taking place at the dot edge. At point 2 [Fig. 1(b-3)], sharp phase decreases are observed at approximately 50 and -30 Oe. These phase decreases are considered to be ascribed to the domain

wall motion within the dot. These results reveal that the magnetization reversal in the dot originates from the domain wall motion within the dot. Thus, the magnetization reversal apparently differs according to the dot size. This difference is due to the fact that the magnetostatic energy is reduced with the increasing of dot size.

As a consequence, it is demonstrated that the detailed magnetization reversal in the elliptical dot with several dot sizes can be directly observed using MFS-MFM. From these results, it is concluded that the magnetization reversal changes from change in the domain configuration to domain wall motion with increasing dot size in the 10-nm-thick Ni-Fe elliptical dot.

High-resolution MFM imaging of in-plane magnetic field using transient oscillation.

I. INTRODUCTION

Magnetic force microscopy (MFM) is a powerful tool to investigate microscopic magnetic domain structures and further improvement of spatial resolution is required. We recently proposed a new MFM imaging method of in-plane magnetic field gradient using the transient oscillation of a tip [1]. When a MFM tip moves to a next measuring position under a constant driven frequency of the tip, its oscillation frequency shifts from the driven frequency due to the transient oscillation of the tip. Measuring of the frequency change during tip scanning can image in-plane magnetic field gradient. Using a monopole type MFM tip, in-plane magnetic field gradient of $\partial^2 H_x / \partial z^2$ is imaged by this method, where x and z are the in-plane and perpendicular directions to a sample surface. On the other hand, conventional phase detection images perpendicular magnetic field gradient of $\partial H_z / \partial z$. Therefore, higher spatial-resolution is expected for the present method because of the higher order differential effect of magnetic field. In this study, we evaluate the spatial resolution of the present method and discuss the possibility of high resolution magnetic imaging.

II. EXPERIMENT

Figure 1 shows the block diagram of MFM measurement of in-plane magnetic field gradient. We used a phase detection MFM (JSPM-5400, JEOL Ltd.) with a frequency measurement apparatus (easyPLL, Nanosurf®) for detecting the phase and frequency during a lift-mode scanning with a constant tip-sample distance. The tip was driven at a constant frequency near the resonant frequency of the tip in vacuum atmosphere. CoCrPt-SiO₂ perpendicular magnetic recording media was observed by using high-coercivity FePt tips (H_c : 8kOe) made by NITTO OPTICAL CO., LTD. The magnetized direction of the tip is perpendicular to the sample surface.

III. RESULTS

Figure 2 (a), (c) show the MFM images of the perpendicular magnetic recording medium measured by conventional phase detection and the present frequency detection, respectively. These images were observed at the same scan and the scanning direction was the horizontal direction of the image. The recording density of the media is 500 kfc/i and the mechanical quality factor Q is about 7000. Fig. 2 (a) is a conventional MFM image of perpendicular magnetic field gradient. Recorded bits and the track edges are observed. On the other hand, the frequency detection method images in-plane magnetic field gradient along the scanning direction and recorded bits are clearly observed without track edges in Fig. 2(c). The in-plane magnetic field gradient image was also obtained by making a differential picture of the phase detection image in the scanning direction. When the MFM tip is a monopole type tip, the signal of the phase image corresponds to $\partial H_z / \partial z$ and the signal of the differential picture corresponds to $\partial^2 H_x / \partial z^2$. This is the evidence that the present method can detect the higher order magnetic field gradient. The quality of the differential picture is worse than that of the present frequency detection image.

Figure 2 (b), (d) are the corresponding spectra of the recorded area of Fig. 2(a) and (c). These spectra were calculated by averaging the spectra of line profiles in the scanning direction. Here the peak signal corresponds to the recording signal of 500 kfc/i. For the conventional phase detection, the intensity of the spectrum decreases and takes a constant value with increasing spatial frequency k_x . Spatial resolution can be evaluated by the critical spatial frequency where the intensity of MFM signal equals to the noise [2]. The critical frequency is about 24 (1/ μ m) and the spatial resolution is

about 20nm. On the other hand, for the frequency detection, the intensity of the spectrum takes a maximum and gradually decreases with increasing k_x . The frequency decay of the signal is smaller than that of the phase detection. The behavior of MFM signal is consistent with the transfer function spectra of $\partial H_z / \partial z$ and $\partial^2 H_x / \partial z^2$. In addition, the noise is not white and the intensity decreases with increasing k_x . This character is thought to be suitable for high-resolution imaging. The spatial resolution is almost the same as that of the phase detection. The origin of the noise and the possibility of high-resolution imaging of the present method will be discussed.

Characterization of coercivity of magnetic force microscopy probes.

M. Jaafar, A. Jacas, W. Rosa, A. Asenjo

Instituto de Ciencia de Materiales de Madrid, ICMM-CSIC, Madrid, Spain

Magnetic Force Microscopy (MFM) reveals as a useful technique to analyze the local magnetic behavior of the materials. Sometimes, the MFM data are complementary to the magnetic characterization performed by using standard macroscopic methods. So far, in the case of nanometric devices, only few techniques can supply valuable information about the behavior of individual nano-objects, and the MFM presents highest resolution. In this work a Nanotec Electronica S.L. microscope has been conveniently modified to apply magnetic fields in axial direction (up to 1.5 kOe) and in-plane direction (up to 2.0 kOe). The application of a magnetic field during the MFM operation modifies the magnetic state of the tip as well as the magnetic state of the sample. In this concern, previous MFM tip characterization can help to improve the quantitative MFM image interpretation. Notice that the evolution of the MFM signal versus the externally applied magnetic field can be used to obtain the local hysteresis loop of the sample or the hysteresis loop of the MFM probes. In this work, axial and transverse hysteresis loops of the probes have been generated by measuring the changes in the standard MFM images observed when the magnetic field is applied. The variation of the MFM signal is ascribed to the modification of the magnetic state of the probes (Fig.1). This is enabled by the large coercivity (1.7 kOe) of the checked longitudinal recording media. The properties of the probes depend on the coating material, the macroscopic tip shape and tip radius (Fig.2). In addition to the standard MFM images, we have performed the so-called “3Dmodes” measurements. This is possible thanks to the main advantage of the Variable Field Magnetic Force Microscope (VFMFM) which is its mechanical stability under variable external magnetic field for both in-plane and out-of plane directions that allows the observation of spin dynamic in real time.

In the “3D modes” a magnetic image is acquired along a surface scan as a function of the “in situ” applied magnetic field. Images (a) and (b) of fig. 3 correspond respectively to the characteristic topography and magnetic signal of a hard disk with parallel domains written along the track. The figures 3c and 3d correspond to the frequency shift measured along the black line marked in (a) and (b) images for increasing (c) and decreasing (d) magnetic fields. The vertical scale in 3c image is the external magnetic field that is decreased at each scan line from +60 mT at the upper line (position 1) to -60 mT at the lower scan line (position 2). In figure 3d the magnetic field increases from -60 mT at the lower scan (position 3) to +60 mT at the upper scan (position 4). The switching of the contrast when pass thorough the coercive field of the MFM probe (around 40mT) is observed in both “3Dmodes” images. Measuring the contrast along the dashed lines in the figures 3c and 3d the hysteresis loop of the MFM probe is obtained. We can observe the mechanical stability of the system since the position of the magnetic walls of the hard disk remains constant when varying the magnetic field. In conclusion, we can use this technique to performed local hysteresis loops of nanoelements in situ with the VFMFM thanks to the mechanical stability in the 3Dmodes and the previous characterization of the different probes.

Calibration of MFM probe tips for measurements in external in-plane magnetic fields.

A. Ehresmann¹, T. Weis¹, D. Engel¹, V. Höink², J. Schmalhorst², G. Reiss²

1. Institute of Physics and Centre for Interdisciplinary Nanostructure Science and Technology (CINSaT), University of Kassel, Kassel, Germany; 2. Thin Films and Nanostructures, Department of Physics, University of Bielefeld, Bielefeld, Germany

The analysis of MFM measurements carried out in external magnetic fields H_{MFM} parallel to the sample plane, i.e. perpendicular to the effective magnetization direction of commercial MFM probe tips, is difficult due to the influence of the magnetic fields not only on the sample but also on the tip's magnetic properties. In the simplest approximation an external in-plane magnetic field tilts the effective tip magnetic moment from the perpendicular direction by a certain angle. This means that not only the magnetic state of the sample, but also the alteration of the tip magnetic characteristics affects the MFM image.

To measure the effect of the in-plane magnetic field on the magnetization state of the MFM probe tip dedicated calibration samples were fabricated and a method was developed to extract the change in the magnetization state of the probe tip from the MFM images. This information can be used to analyse MFM images recorded by this tip and disentangle magnetization state changes of the probe tip and the sample by an external field. The calibration sample consists of an exchange biased thin film magnetic bilayer of a ferromagnet and an antiferromagnet. Preferably the layer system is chosen to have a large exchange bias field. After initialization of the exchange bias by, e.g., field growth or field cooling homogeneously over the whole sample, the sample is covered by a resist film (e.g. PMMA) thick enough to stop 10keV He ions. The resist is then patterned by lithography in stripes with their long axes perpendicular to the exchange bias direction. A subsequent 10keV He-ion bombardment in an external magnetic field H_{IB} antiparallel to the original exchange bias direction leads to an effective antiparallel exchange bias in the areas not covered by the resist mask with respect to the initial exchange bias direction. Finally the resist is removed. This results in a sample with lateral magnetic stripes with mutually antiparallel effective exchange biases without a topographic contrast [1–4 and refs therein]. Between the two exchange bias fields of the neighbouring stripes the magnetization state remains essentially uninfluenced by the magnitude and direction of the external in-plane magnetic field, therefore delivering a calibration sample without topography contrast and stable magnetic patterns for certain in-plane magnetic fields. Fig. 1(b) shows an MFM image of the topographically flat, but magnetically patterned sample with a MOKE hysteresis curve (Fig 1(a)) for applied in-plane fields.

The domain walls between the adjacent artificially magnetized stripe domains may be modelled by an arctan function [5]. Then the magnetic force of the sample strayfields H_s on the MFM tip can be calculated when the following assumptions are made: 1.) The magnetic patterns of the sample are large compared to the MFM tip. 2.) The distance between the tip and the sample is large enough to allow the tip magnetization being modelled as a magnetic dipole moment. 3.) Applicability of the point-dipole approximation [6]. For MFM measurements in non contact mode the image contrast is not dependent on the force, but on the force gradient. If this is considered and with some further simplifications the response of the MFM for a measurement with a tip whose magnetization state is described by a magnetic dipole moment tilted by the angle θ between magnetic tip moment and the sample normal may be modelled by $R(H_{\text{MFM}}) \propto |\mu_{\text{tip}}|(\sin\theta(H_{\text{MFM}})d^2H_{s,x}/dz^2 + \cos\theta(H_{\text{MFM}})d^2H_{s,z}/dz^2)$

To calibrate a commercial non contact MFM tip by our calibration sample, MFM images have been taken at different values of the externally applied in-plane magnetic field H_{MFM} . The grey values of

the MFM response along the stripe direction have been summed up for each image and the resulting profiles were fitted by a function corresponding to the above equation for the MFM response. With this fit the angle θ can be determined as a function of the externally applied in-plane magnetic field. This can be used to separate the influence of the external magnetic field on the tip magnetic moment from its influence on the magnetization state of real samples.

An experimental investigation of the magnetically active volume in a magnetic force microscopy tip.

N. E. Mateen, *M. Gibbs*, M. Rainforth

Department of Engineering Materials, University of Sheffield, Sheffield, United Kingdom

The determination of tip active volume is a particularly long-standing problem for the quantitative interpretation of MFM images. Micromagnetic modeling has been used to estimate the image reproduced in MFM from different active volumes [1], but it has never been possible to confirm these calculations experimentally.

Using focussed ion beam milling, and a commercial pyramidal tip, we have explored changes in the fine scale resolution to be seen in atomic and magnetic force microscopy. On a single tip we have successively removed the magnetic coating, taking great care to avoid damage to the tip apex (see Fig.1). From this, using a reference sample (Veeco recorded tape) we have demonstrated that the active volume of magnetic material in magnetic force microscopy extends some distance beyond the immediate tip apex, and that when the effective diameter of material on the tip is reduced to be close to the critical dimension for single domain behaviour, there is a marked change in the amplitude of the tip response.

The AFM detail is not enhanced by the milling as the region at the tip apex was not involved during the milling process. In the MFM scans we demonstrate a slight increase in fine scale detail observed, but also a significant decrease in signal magnitude as the tip is milled (see Fig.2). We interpret this as changes in the micromagnetic configuration close to the tip apex, and ultimately to the removal of material decreasing the effective tip moment. This is the first time that there has been an experimental estimate of the magnetically volume in an MFM scan.

While magnetic devices were constantly scaled down, the spatial resolution achievable with commercially available magnetic force microscopy (MFM) probes remained almost the same, which makes it difficult to adequately study next-generation magnetic media. The state-of-the-art commercially available MFM probes promise an optimal spatial (or lateral) resolution of approximately 25 and 15 nm at ambient and ultra-high vacuum (UHV) conditions, respectively [1]. Our approach is to use silicon based plateau probes on which magnetic thin films, exhibiting magnetic properties similar to the ones found in various types of magnetic recording media, are effectively grown and then milled with focused ion beam (FIB) to fabricate high resolution magnetic force microscopy (MFM) tips [2]. The fabrication sequence is shown in Figure 1. Finally, the FIB-fabricated almost perfectly flat plateau-like tips with the radius ranging from 0.1 to several microns could be used as substrates for further thin film deposition with finely controlled deposition/growth properties. In this manner, not only the magnetic composition but also the orientation of the magnetization at the “tip” of the probe could be finely controlled. Such traditional thin films as CoCrPt based alloys, Co/Pd multilayers, and FePt L10 media were deposited on the plateau probes. Figure 2left shows an SEM image of CoCrPt granular media, which was sputter deposited on a plateau probe. Focused magneto-optical Kerr microscopy was used to directly compare the magnetic properties of media sputtered on a silicon substrate and on the plateau probes. Figure 2right shows a hysteresis curve for a FIB-fabricated MFM tip with Co/Pd multilayers with coercivity value of about 5000 Oe, which is an order of magnitude greater than the coercivity value of commercially available MFM probes. A detailed study will be presented to achieve MFM resolution of less than 10 nm at ambient condition.

Fabrication of Magnetic Force Microscopy Tips via Electrodeposition and Focused Ion Beam Milling.

O. Cespedes, A. Luu, F. F. Rhen, J. D. Coey

Physics Department, Trinity College Dublin, Dublin, Ireland

Summary:

In this work we describe a method for the fabrication of magnetic force microscopy tips via electrodeposition and focused ion beam milling. Very high aspect ratios and interacting magnetic moments of order 0.1 to 1 pAm^2 (10^{10} to 10^{11} Bohr magnetons) are possible without altering significantly the tapping resonant frequency of the cantilever. These tips can achieve high resolution ($5\text{-}10 \text{ nm}$) at room temperature and open atmosphere. They can also be fabricated into any shape, with applications for the patterning of nanostructures via atomic force microscopy.

Fabrication method and results:

Our method to fabricate magnetic force microscopy tips allows the deposition of relatively high amounts of magnetic materials without changing significantly the total mass of the tip. The process consists of four steps (see Figure 1 for schematics and images of the process):

- 1.- We deposit a 100 nm bi-layer Al/Ag on top of the tip. The aluminum layer is afterwards thermally oxidized / passivated.
- 2.- With a focused ion beam, we open a hole of some 100 nm where the deposition will be made (edge of the tip).
- 3.- An electric contact is made with the silver layer before the tip is put into a solution with the ions corresponding to the desired material. The only metallic area open to the solution is the gold layer where the hole has been opened. When an electric potential above the rest value is applied between the tip and the solution the ions flow into the previously milled hole.
- 4.- (Optional) Further patterning of the deposited material and increased aspect ratio is possible by using a focused ion beam as a sharpening tool (Figure 2).

With this fabrication method we have achieved the deposition of significant amounts of interacting magnetic material while avoiding big shifts and artifacts in the tapping resonant frequency. We must also emphasize that the geometry of the tip can be roughly controlled via the electrodeposition parameters at the step # 3. Electrodeposited materials from highly concentrated solutions at relatively low pHs and voltages give as result dense depositions of smooth surfaces and small grains [1]. As the applied voltage for electrodeposition is increased so does roughly the grain size. By decreasing the ionic concentration while working at low voltages we can also obtain elongated, thread-like or fractal-like structures.

The focused ion beam sharpening gives us the possibility to enhance the aspect ratio or to modify at will the tip geometry after the electrodeposition. This results into enhanced topographic images of samples with deep structures and high resolution magnetic images on smooth surfaces (Figure 3). Furthermore, the method allows the deposition and patterning of material in the desired position of an atomic force microscopy tip, which makes of them ideal tools for nano-stamp patterning.

Scanning Hall Probe Microscopy (SHPM) is a valuable tool for monitoring localized magnetic fields at the surfaces of ferromagnetic materials and vortices in superconductors [1-2]. Safely lowering the Hall probe to the sample surface without damaging the sensor is a critical stage of the measurement procedure. High spatial resolution SHPM imaging is carried out using Hall sensors with scanning tunneling microscope tips (STM-tip) integrated adjacent to the probes. In these systems, the Hall probes are attached to piezoelectric actuators and lowered to the sample surface until a tunneling current is detected, when feedback circuitry is used to control the sample to probe separation. Hall probes with STM-tips can only be used for conducting samples. Further, such systems require complicated electronics to monitor tunneling currents and control the position of piezoelectric actuators. SHPM systems could be made more robust and easier to use if probe positioning and movement could be achieved without STM tips and piezoelectric actuators.

Here, we describe the features of a SHPM system where the Hall probe is attached to a flexible cantilever and the moment of contact with samples is monitored using a simple strain gauge embedded into the cantilever. This 'contact-mode' SHPM is a simple means of measuring non-conducting samples over large areas and wide temperature ranges.

Fig.1 is a schematic diagram of the Hall probe, strain gauge and flexible cantilever. The Hall probe was a 2 micrometer x 2 micrometer AlGaAs/InGaAs 2DEG sensor fabricated by conventional photolithography. A protective layer of silicon nitride was sputtered onto the probe. In contrast to our previous devices, there is no STM-tip adjacent to the sensor.

The cantilever was lowered towards the surface of a sample using a high resolution stepping motor and contact with the sample monitored by the output from a balanced bridge circuit with the strain gauge as one of its arms. The contact mode SHPM was used to measure domains at the surfaces of 50 micrometer thick garnets.

Fig. 2 is 50 micrometer x 50 micrometer contact mode magnetic image of the garnet. The difference between the black and white regions is 212 G and the domains have a width of 10 micrometers.

The contact mode SHPM can also be used at cryogenic and elevated temperatures.

Variable Temperature-Scanning Hall Probe Microscopy (VT-SHPM) with GaN/AlGa_N Two-Dimensional Electron Gas (2DEG) Micro Hall Sensors in 4-400K range, Using Novel Quartz Tuning Fork AFM Feedback.

R. Akram, M. Dede, A. Oral

Department of Physics, Bilkent University, 06800, Ankara, Turkey

In this report, we present the fabrication and variable temperature (VT) operation of Hall sensors, based on GaN/AlGa_N heterostructure with a two-dimensional electron gas (2DEG) as an active layer, integrated with Quartz Tuning Fork (QTF) in atomic force-guided scanning (AFM) Hall probe microscopy (SHPM)[1]. Physical strength and wide band gap of GaN/AlGa_N heterostructure makes it a better choice to be used for SHPM at elevated temperatures, compared to other compound semiconductors (AlGaAs/GaAs and InSb), which are unstable due to their narrower band gap and physical degradation at high temperatures.

GaN/AlGa_N micro hall probes were produced using optical lithography and reactive ion etching. The active area, Hall coefficient, carrier concentration and series resistance of the Hall sensors were $\sim 1 \times 1 \mu\text{m}^2$, $10 \text{ m}\Omega/\text{G}$, $6.3 \times 10^{12} \text{ cm}^{-2}$ and $12 \text{ k}\Omega$ at room temperature and $7 \text{ m}\Omega/\text{G}$, $8.9 \times 10^{12} \text{ cm}^{-2}$ and $24 \text{ k}\Omega$ at 400K, respectively.

A novel method of AFM feedback using QTF has been adopted. This method provides an advantage over STM feedback, which limits the operation of SHPM the conductive samples and failure of feedback due to high leakage currents at high temperatures. Figure 1 shows the assembly of GaN Hall probe on a 32kHz Quartz Crystal Tuning fork for AFM feedback SHPM. Simultaneous scans of magnetic and topographic data at various pressures (from atmospheric pressure to high vacuum) from 4.2K to 400K will be presented for different samples to illustrate the capability of GaN/AlGa_N Hall sensors in VT-SHPM. Figure 2 shows the scan results of a hard disk sample at 77K.

Optical reading from videotapes using magnetic garnet film.

Introduction

In broadcasting stations, the recording media used to archive large volumes of content have mainly been magnetic videotapes. In the near future it will become necessary to transfer all this content from videotapes to new types of recording media. However, the time required to do so is prohibitive because videocassette recorders (VCRs) can only read data from videotapes at single (1x) speed. In order to greatly increase the speed at which videotape data are read, we propose an optical reading method using a magnetic garnet film; this will allow several data tracks to be read in parallel.

Magnetic garnet film

Bismuth (Bi)-substituted magnetic garnet films have a large Faraday coefficient and recorded patterns on a videotape can be transferred to the film simply by placing it in close proximity to the videotape.[1][2] Our trial films have a Faraday angle rotation of approximately 5 degrees per micrometer film thickness when a green laser (wavelength = 532 nm) is used. We observed the data pattern transferred from the videotape using a polarizing microscope. The thickness of the magnetic garnet film was 0.5 μm . A reflected film of thickness 50 nm and a protective film of thickness 20 nm were sputtered on the magnetic garnet film. A sample videotape in D-3 format was used and data were recorded using a D-3 VCR. The transferred data pattern, an example of which is shown in Figure 1, was clearly observed by the microscope. For the D-3 format (NTSC system), the track pitch is 20 μm and the bit length is between 0.385 and 1.3475 μm .

Reproduction of videotape data using laser and magnetic garnet film

We have designed an experimental setup to reproduce the signal from a videotape using a combination of a laser and a magnetic garnet film, as shown in Figure 2. The videotape is run using a VCR and is placed in contact with the magnetic garnet film. A linearly polarized laser beam is then directed onto the film. The plane of polarization of the reflected laser beam is rotated by the Faraday effect. Therefore, the data stored on the videotape can be reproduced using a polarizing beam splitter (PBS) and a differential amplifier. This data reproduction scheme is similar to the magneto-optical (MO) disk system.

In practice, the recording scheme adopted by VCRs involves a helical scan. However, in our demonstration we used videotape on which a data track was recorded horizontally. The tape speed was 1x with respect to the VHS system, which corresponds to 0.4x with respect to the D-3 system. Figure 3 shows the spectrum of the reproduced signal at the bit length of 0.385 μm . A carrier-to-noise ratio (CNR) of over 30 dB was measured. At a speed of 4x with respect to the D-3 VCR system, the CNR was again more than 30 dB. We expect that at higher speeds, for example 40x, the CNR will be almost as high.

Conclusion

We have proposed a method to read data optically from a videotape using a magnetic garnet film. Our trial film of thickness 0.5 μm is able to induce a Faraday angle rotation of approximately 2.5 degrees when a green laser is used. We achieved reproduction of a videotape with over 30 dB of CNR at the minimum bit length of the D-3 format. We believe that this is sufficient to reproduce

D-3 format videotapes optically. However, in order to apply this method to higher-density format videotapes, the resolution of the magnetic garnet film must be improved. It is also necessary to develop a parallel reproduction scheme for high-speed data reading.

The influence of the implantation on the magneto-optical properties of $(\text{YBiCaSmLu})_3(\text{FeGeSi})_5\text{O}_{12}$ surface.

L. Kalandadze

Batumi State University, Batumi, Georgia

We investigated the magneto-optical properties of the ion implanted $(\text{YBiCaSmLu})_3(\text{FeGeSi})_5\text{O}_{12}$ garnet films. The implantation process was carried out at the room temperature by Ne^+ ions with energy of 100 KeV and with various doses $(0,5\sqrt{2},5)\times 10^{14}$ ion/cm².

For investigating the magneto-optical properties of a garnet surface we have chosen the equatorial Kerr effect (EKE). The EKE consists in a change in the intensity of linearly polarized light reflected from the sample in the case of reversal of magnetization of the sample.

The research of the spectral dependences of the EKE for unimplanted and ion implanted with various dose garnet films has shown that the ion implantation significantly influences on the magneto-optical properties of the garnet films.

For examples, Figure 1(a) presents the dependences of the EKE on the quantum energy of incident light for the films before and after the implantation process with various doses. The angle of light incidence on the sample $\phi = 70^\circ$.

Fig.1. Dependences of the EKE on the quantum energy of incident light (a) and on the angle of light incidence (b) for the $(\text{YBiCaSmLu})_3(\text{FeGeSi})_5\text{O}_{12}$ films before (curve 1) and after the process of implantation with various doses: 0,5 (curve 2), 1,5 (curve 3), and 2,5 (curve 4) $\times 10^{14}$ ion/cm².

According to the Figure 1(a) the magneto-optical spectrum of the unimplanted garnet surface has the magneto-optical maxima in the region of light quantum energies 2,6; 3,4 and 4,5 eV. Most garnet films are characterized by the similar peaks (1). For the implantation with the minor doses the spectrum character of the EKE is practically the same. But it significantly changes when doses are $(1,5\sqrt{2},5)\times 10^{14}$ ion/cm². Specifically, an increase of the implantation dose causes a decrease of the magneto-optical maxima in the region of light quantum energies 3,4 and 4,5 eV, which may be connected with the split of FeO_4 and FeO_6 molecular complexes, where intensive electron transition takes place with energy more than 3 eV. But the increase of the implantation dose causes reduction of the negative magneto-optical maximum in the region of light quantum energy 2,6 eV with the effect reverse which gets in the end a new positive meaning.

Besides, the investigation of the dependences of the EKE on the angle in the region 2,6 eV (Figure 1(b)) has shown that specific implantation dose $(1,5\sqrt{2},5)\times 10^{14}$ ion/cm² makes the change of sign of the effect but it hardly have any influence on the position of Brewster angle. This result has also been born out by the optical measurement which only proves the weak relationship between the optical constants n and k and the implantation dose.

Present results in the region 2,6 eV might be explained by weakening antiferromagnetic ties between two iron sublattice and by turning over the magnetic moments of the iron ions which are responsible for the electronic transition in the external magnetic field.

In the proceeding, we have also researched the magneto-optical properties of ion implanted $(\text{YBiCaSmLu})_3(\text{FeGeSi})_5\text{O}_{12}$ garnet films after annealed at 270°C for 2 hours. This kind experiment is particularly interesting in the matter of annealing process as it reduces the implantation defects and restores crystalline structure of ferrite-garnet (2). The experimental results showed that after annealing process in the region 2,6 eV, the sign of the effect remains same like unimplanted garnet films and the value of effect increases in ultra-violet region of spectrum.

We have also determined the spectral dependences of the component of the tensor of dielectric permittivity for the surface of the above-mentioned ferrite-garnet films before and after implantation process. These calculations let us evaluate the influence of the implantation on an electronic energy structure of the surface layer for the sample.

On System Optimization for Magneto-Optic Switching: Material Considerations.

S. Kemmet, M. Mina, R. J. Weber

Electrical and Computer Engineering, Iowa State University, Ames, IA

Abstract

Optimization though material considerations of an all-fiber interferometric switch based on Faraday rotation is reported. The switch is a Mach-Zehnder interferometer (MZI) type. The interferometric action is controlled via Faraday rotation exhibited by magneto-optic (MO) material in the presence of an external magnetic field. To achieve optimal operation, domain behavior of the MO material is investigated. Results are presented that will lead to a switch with larger dynamic range with a low external magnetic field.

Introduction

As fiber optic and optical devices become increasingly utilized in high-speed communication networks, all-optical switching technologies have been proposed and developed.[1] A switch was proposed based on MO effect using bismuth substituted iron garnet[2]. The proposed fiber-based switch is based on a MZI setup utilizing Faraday rotation. The switch has shown promising ON-OFF dynamic range with reasonable applied external magnetic field. In this paper we investigate at the domain level the MO properties of bismuth substituted iron garnet $[(\text{Bi}1.1\text{Tb}1.9)(\text{Fe}4.25\text{Ga}0.75)\text{O}_{12}]$ samples[3] for optimization of a fiber-based MZI type optical switch. The MO Faraday rotator(MOFR) samples are $330\mu\text{m}$ thick and the refractive index is 2.344 at 1550nm . In the case of realizing the switch for single mode fiber (SMF), action of individual domains becomes the major contributing factor to the amount of Faraday rotation. Through domain level material investigation, switching with a greater ON-OFF dynamic range can be realized with significantly lower magnetic fields.

Switch Concept

The switch is a MZI type switch with a MOFR in each leg, shown in Fig 1. At the switch input a linearly polarized beam is split with a 3dB directional coupler, resulting in the state of polarization (SOP) in the upper and lower leg to be perpendicular. In each leg is a MOFR. The beams are recombined with a 3dB coupler. In the absence of an applied field, each beam is unaffected: an ON state. When the MOFRs are in an applied field Happ, the SOP is rotated by an angle θ due to Faraday rotation. The angle of rotation is described in the linear region by $\theta = \theta_{\text{sat}}(\text{Happ}/\text{Hsat})$ where θ_{sat} is the rotation at the saturation field Hsat. The output can be analyzed with use of simple matrix analysis and Jones matrices. If the SOP in one path is shifted 45° and the other by -45° , the output is 0, the OFF state.

Material Considerations

The relation $\theta = \theta_{\text{sat}}(\text{Happ}/\text{Hsat})$ holds when the diameter of the incident beam is large enough to sample many domains. However, when the beam size is smaller, contributions of individual domains affect the rotation of the SOP. The beam of a MMF, which has a diameter of about $62.5\mu\text{m}$, samples many domains and generally obeys the above relation. However a SMF, which has a mode field diameter of approximately $10\mu\text{m}$, passes through only a small number of domains. Individual domains align with an applied magnetic field at much lower field strengths than the bulk material. Therefore, by confining the beam to a single or small number of domains, switching can be accomplished at much lower fields.

Experimental Setup and Results

In order to determine the size of the beam on the face of the MOFR sample, the lateral offset method was used. With a separation of 1.25mm between the two fibers, the HPBW is approxi-

mately $16\mu\text{m}$. Using magnetic force microscopy a domain width was determined to be approximately $20\mu\text{m}$.

In Faraday rotators, if the beam width incident on the material is smaller than the domain dimensions then domains can be located in the material. By moving a sample between two aligned SMFs, one attached to a laser, with a polarization controller and power sensor, domains and domain walls can be identified as shown in Fig 2. Aligning the beam within a single domain, the Faraday rotation in the absence of a magnetic field was measured to be approximately 15° . A magnetic field was applied to the material. Individual domains aligned with the applied field as low as 10 Oe, well under saturation of 350 Oe.

Conclusion

Domain behavior of a magneto-optic Faraday rotator used in an all-fiber MZI type switch was investigated and reported. Domains within a MO thin film sample were differentiated and the rotation in the absence of a magnetic field was measured. Domain alignment with an external magnetic field was achieved at low field strength.

Practical magneto-optic spatial light modulator with single magnetic domain pixels.

K. Iwasaki¹, H. Mochizuki¹, H. Umezawa¹, M. Inoue²

1. Research and Development Division, FDK CORPORATION, 2281 Washizu, Kosai-Shi, Shizuoka, Japan; 2. Toyohashi University of Technology, 1-1 Hibarigaoka, Tennpakucho, Toyohashi-shi, Aichi, Japan

Spatial Light Modulators (SLMs) with a two-dimensional pixels array enable to modulate the intensity and the phase of light waves. Especially, Magneto-Optic Spatial Light Modulators (MOSLMs), which uses magnetization reversal for switching pixels, have advantages of high switching speed and non-volatility compared with other SLMs such as the liquid crystal type and the MEMS type. Therefore, the applications to the optical information processing like holographic storages using MOSLMs are developing [1].

J.Cho et al. reported the 128 by 128 MOSLM driving at 1 kHz frame rate in 1994 [2]. We have developed the improved 128 by 128 MOSLM to drive at higher frame rate and achieved to double the pixel density and to decrease the I2R losses in the metal drivelines by 70% [3]. In addition, we have enabled to operate without using external bias coil. This means that the pixels are switched in the state of a single magnetic domain by a magnetic field generated from the optimized drivelines on the pixel. Therefore our MOSLM is expected to drive faster than the one before.

In this study, we observed the magnetic domain structure of the pixel switched at high-speed drive condition and confirmed that there is a two-step process, the first step being pixel nucleation at the center of the pixel followed by a second step of pixel saturation. Then we measured the time of each step and estimated the frame rate under the optimized drive condition.

The pixels consist of Bi-substituted iron garnet film. As a polarized light ray enters the film, its polarization is rotated depending upon the orientation of the magnetization direction of the pixel. As a result, the pixels show up dark or light through an analyzer. Fig.1 shows the image of 128 by 128 MOSLM with checker pattern observed by polarization microscope. The pixel pitch is 16 micrometers. The magnetization direction is switched by the magnetic field generated from intersecting X and Y drivelines on the pixel as shown in fig.2. The dependence of domain structure on the pulse width of X and Y current was evaluated.

Fig.3 is a timing diagram to switch one pixel. Here, TX and TY denote the pulse width of X and Y current. TYD is the delay time of Y current from X current. Fig.4 shows the images of domain structure depending on various TYD under the condition of TY=1000nsec and TX=20nsec. When TYD=50nsec, there is a reversed domain at the center of the pixel where large magnetic field is generated from the X and Y drivelines. However, the pixel is not switched completely. The half of pixel area is magnetized oppositely when TYD=100nsec. Eventually, we confirmed that TYD should be longer than 200nsec to switch the pixel completely in the state of single domain. These results show that there is a two- step process, the first step being nucleation followed by a second step of domain wall motion. These steps need the time of 20nsec and 200nseconds respectively. We optimized the drive condition using these results and estimated the frame-rate of 128 by 128 MOSLM that repeats continuously between ON and OFF. As a results, it becomes 11kHz when 32 pixels are switched at the same time. It is ten times faster than conventional MOSLM. Furthermore, this MOSLM is able to turn the desired pixels on or off without external bias field. Therefore it would be expected to operate faster by using the best drive condition corresponding to writing pattern.

Department of Electrical and Electronic Engineering, Toyohashi University of Technology, Toyohashi, Japan

Recently, there has been intense searching magnetic nanostructures and novel magnetic materials, which exhibit enhanced magneto-optic response [1-3]. It was shown that magneto-optic phenomena can be significantly enhanced in the case of resonant interaction of light with magnetic materials or in the vicinity of phase transitions [4,5]. But in the most cases enhanced magneto-optics is accompanied by a degradation of optical properties and therefore the problem is far from being solved. In the presentation we discuss our recent theoretical and experimental results on magneto-optic spectra of various magnetic nanostructures, semiconductors and magnetophotonic crystals, in particular: (i) magnetic nanocomposites

$\text{Co}_x(\text{TiO}_2)_{1-x}$, $\text{Co}_x(\text{Sm}_2\text{O}_3)_{1-x}$, $\text{Co}_x(\text{NbLiO}_3)_{1-x}$, $\text{Co}_x(\text{CaF})_{1-x}$, $(\text{CoFeZr})_x(\text{SiO}_2)_{1-x}$, $(\text{CoFeB})_x(\text{SiO}_2)_{1-x}$, and $(\text{FePt})_x(\text{SiO}_2)_{1-x}$; (ii) discontinuous magnetic multilayers Co/SiO_2 and $\text{Co}_{0.45}\text{Fe}_{0.45}\text{Zr}_{0.1}/\text{Si}$; (iii) diluted magnetic oxides $\text{TiO}_2:\text{Co}$ and semiconductors $\text{Si}:\text{Mn}$; (iv) the interface of magnetic and non-magnetic photonic crystals.

Magnetic nanocomposites were fabricated by ion-beam and rf-magnetron sputtering. A special compound target allowed us to get a wide range of metal-to-dielectric ratios x (depending on the target composition and the mutual arrangement of the target and substrates) in one deposition cycle. Diluted magnetic oxides $\text{TiO}_{2.8}:\text{Co}_x$ with $x=0.5-8\%$ were fabricated by magnetron sputtering. Mn-implanted silicon plates of both n and p types were obtained by implanting 195-keV manganese ions with doses from 1×10^{15} to $2 \times 10^{16} \text{ cm}^{-2}$. Details of magnetophotonic crystals fabrication were described in [1]. The magneto-optic properties were investigated by studying the geometry of the transverse Kerr effect (TKE). The TKE spectra were measured by the dynamic method in the 0.5–4.5 eV energy range in the applied magnetic field up to 2.5 kOe.

It is shown that magneto-optic response of magnetic nanocomposites with compositions close to the percolation threshold at some specific frequencies of light is much larger than that for bulk constituent ferromagnetic metal. The magneto-optic response is also enhanced for discontinuous multilayers when the volume fraction of metal in each layer is close to the metal-insulator transition. Using experimental data on optical parameters and the TKE spectra we found both diagonal and off-diagonal elements of the dielectric permittivity tensor for nanocomposites and compared them with theoretical calculations carried out in the framework of the effective medium approach. The calculated magneto-optic spectra for nanocomposites are in a qualitative agreement with experiment but it is not the case for discontinuous multilayers.

Ferromagnetism in Mn-implanted Si wafers was studied by means of VSM and SQUID-magnetometer, and Faraday effect. The Faraday rotation exists in $\text{Si}:\text{Mn}$ at 80-305 K in the spectrum range 1-6 mm and is mostly pronounced near the absorption edge, where the specific rotation is about 500 grad/cm. The positive sign of Faraday rotation indicates on p-type conductivity in Mn-implanted Si.

Magneto-optic spectra of thin films $\text{TiO}_{2.8}:\text{Co}$ indicate on intrinsic ferromagnetism at room temperature both in anatase and rutile phases but in the limited range of charge-carrier concentration. The magneto-optic spectra are sensitive to the thin film thickness, Co volume fraction, annealing conditions. For small volume fraction of Co (<1%) the TKE spectra are characterized by 6 well-pronounced peaks, which are not typical for bulk Co and Co clusters. This fine structure disappears with increase of Co volume fraction up to 5-8% and magneto-optic response in reflection mode becomes larger than that for thick Co films. In combination with high transmittance at visible it opens up new avenues for the development of novel magnetophotonic crystals and advanced integrated magneto-optic devices.

Magnetorefractive effect [4] exists in a wide spectral range and is much larger than traditional magneto-optic phenomena. We discuss recent experimental results on magnetorefractive effect in magnetic nanocomposites and manganites in the framework of a simple theory of high frequency spin-dependent tunneling. It is predicted that magnetorefractive effect can be enhanced up to 60% in multilayered structures and magnetophotonic crystals.

We also propose the scheme of magnetophotonic crystals with simultaneously high Faraday rotation and transmittance close to 100%.

Temperature properties of magneto-optic film and the non-destructive testing of a paramagnetic specimen.

J. Lee¹, R. Wang²

1. Department of Information and Communication Engineering, Chosun University, Gwangju, South Korea; 2. Department of Information and Communication Engineering, Graduate School of Chosun University, Gwangju, South Korea

Faraday rotation is a magneto-optical effect. The plane of a polarized light beam is rotated when the beam is transmitted to a magneto-optic (MO) film. The Faraday rotation angle (θ_F) and direction is affected by the strength and direction of the external magnetic field (H_E). Therefore, the strength and direction of the H_E can be estimated using an optical system which includes a polarizer and analyzer. It has been reported that non-destructive testing (NDT) with the use of the magneto-optical effect can detect cracks [1-3]. The magnetic field is leaked around a crack on the magnetized ferromagnetic specimen. These magnetic flux leakages (MFL) can affect the magnetic domain in the MO film, and a crack can be detected using a polarized lighting system to observe the magnetic domains. The small width of the magnetic domain of the MO film enables a small crack to be detected. The MO film needs to be thicker to permit a smaller domain width. However, the saturated magnetic field (H_S) increases with respect to increasing thickness of the MO film [4]. As a result, the MO film for inspecting cracks on a ferromagnetic metal with a high spatial resolution, i.e., small domain width, cannot be used for the NDT of a paramagnetic specimen.

This paper proposed an NDT technique that can detect a natural crack in a paramagnetic specimen by the use of an MO film and its temperature properties. The induced currents are distorted around the crack when a sheet type current is induced in a specimen. The eddy current, which appears as a result of the distorted current, is the cause of the magnetic field around a crack. The crack can be detected with the use of an MO film, which is positioned on the surface of a specimen. This is because the magnetic field around a crack affects the MO film. An MO film, which has a small H_S , is used for the NDT of a paramagnetic specimen because of the low magnetic field strength around a crack. Likewise, the MO film will be saturated when the H_E is larger than the H_S .

The crack can also be detected if the MO film and optical system are submerged in a transparent liquid which has a definite freezing point at a fixed pressure. In order to verify the effectiveness of the proposed NDT method, which uses a submerged MO film in a transparent liquid, the dependence of the domain width on the external magnetic field strength in 4~100 °C distilled water environments was investigated. The following results were obtained:

Fig. 1 shows the relationship between the magnetic domain width and the temperature. The domain width is approximately 65.8 μm at 4 °C, and almost three times the width at room temperature. As mentioned above, the width of the magnetic domain represents the spatial resolution in the NDT which uses the MO film, and a small crack can be detected using a magnetic domain with a small width. Therefore, the ability to detect a crack increases at high temperatures because the domain width decreases with increasing temperature.

Fig. 2 shows the domain ratio with respect to the strength of the H_E and the temperature. The domain ratio was approximately 50% at room temperature, when the external magnetic field was 0 mT, as shown in Fig. 2 (a). The bright area expanded with the external magnetic field, as shown in Fig. 2 (b), which was 1 mT at the room temperature. The domain ratio changed at approximately the boiling point of water, as shown in Fig. 2 (c) and (d). On the other hand, the MO film can be saturated in a small H_E at low temperatures, as shown in Fig. 2 (e) and (f). The magnetic field due to the distortion of the induced current around a crack can be used to detect a crack in a paramag-

netic metal. However, the strength of the magnetic field due to the induced current is too weak to detect a crack with the use of an MO film, which has a relatively large saturated magnetic field. Therefore, a crack in a paramagnetic material can be detected with the use of an MO film at low temperatures.

Artificially fabricated magneto-photonic crystals can effectively lengthen the mean optical path of illuminated light thanks to the light localization in the vicinity of defect. An extraordinary magneto-optical (MO) effects in the bilayer system of a metallic film perforated with subwavelength-hole arrays and a uniform magnetic film can exhibit a MO enhancement, due to the coupling of surface plasmon polaritons with quasi-guided waves in the thin magnetic layer. The MO responses of diffracted beams are measured in the off-specular geometry, which is the so-called diffracted MO effect. This new technique has been utilized to analyze the magnetization reversal process. In addition, it can be used to change the amplitude and the sign of MO effects as illustrated by Antos et al. and Kim et al. [1-3] experimentally.

In this work, the rigorous coupled-wave approach implemented as Airy-like internal reflection series was employed to simulate the diffracted MO Kerr spectra presented in Ref. [1]. The simulation for the multilayered grating, as shown in Fig. 1, indicates a good consistency with the experiment in the zeroth- and the first-order diffractions for the polar magnetization. It was found that the magnitude of Kerr rotation in the zeroth order is one order smaller than that of the first one over a wide range of photon energy. In other words, it is likely to achieve the MO enhancement through the MO diffraction from gyrotropic gratings. In order to make it controllable, the comprehensive simulations on pure MO diffraction, excluding the dielectric layers, are carried out to elucidate the crucial influences upon it at a wavelength of a He-Ne laser. We found that this kind of MO enhancement is strongly dependent on the grating depth, and the ratio of Kerr rotation in the first order to that of the zeroth order monotonously decreases below unity with increasing the depth, as displayed in Fig. 2. This means that the shallow gratings give rise to the larger MO enhancement than the deep ones, which is of great advantage to the miniaturization and the integration of devices. Furthermore, it is believed that the absolute magnitude and the MO enhancement can be improved by designing the grating profile and selecting the gyrotropic materials elaborately.

A surface plasmon resonance is a collective excitation of conduction electrons at a metal-dielectric interface and is characterized by an electromagnetic wave strongly localized at this interface. This can be exploited in plasmonic systems made of noble metals, which can exhibit interesting light absorption, transmission and guiding properties.

One can incorporate this plasmonic character into magneto-optically (MO) active systems, by fabricating magnetoplasmonic structures made of ferromagnetic materials combined with noble metals. Here, the noble metal supports the plasmon resonance and the ferromagnet is responsible for the MO activity. This way, the MO response in such systems can be greatly enhanced when the plasmon resonance is excited, as has been shown in Au/Co/Au continuous trilayered structures [1,2,3] characterized by propagating or Surface Plasmon Polariton (SPP) resonances and nanoparticles [4], characterized by Localized Surface Plasmon (LSP) resonances. In both cases, the plasmon resonance endorsed by the presence of Au strongly affects the optical properties of the system and enhances the electromagnetic field in the spatial region where the MO active material (Co) is located, producing an enhanced MO effect that can be exploited practically in the development of surface magnetoplasmon resonance sensors of enhanced sensitivity [5].

Like gold, silver is another noble metal with even stronger and narrower plasmon resonances in the visible range [6] due to the optical properties of silver. In this work we have therefore carried out a systematic study on the MO properties of Ag/Co/Ag trilayers as a function of Co thickness when the SPP resonance at the air/trilayer interface is excited. Samples were grown by magnetron sputtering at room temperature on glass substrates. Co layers are sandwiched between a 16 nm thick buffer Ag layer and a 6 nm thick Ag top layer. Ag layer thicknesses were selected to optimize the SPP excitation. A 2 nm thick Pt capping layer was deposited to avoid any Ag deterioration, which is known to occur upon exposure to air after sufficient time. Co thickness was varied between 0 and 7 nm. Standard samples characterization included morphology studies by SEM and AFM, magnetic characterization by measuring polar and transverse Kerr loops, and MO characterization by measuring polar and transverse Kerr spectra in the visible range. Finally, both reflectivity and transverse Kerr effect were measured at 632.9 nm using the Kreschmann configuration [3], enabling SPP excitation at the air/trilayer interface. An example of these measurements can be seen in figure 1, where both reflectivity and transverse Kerr effect are shown to strongly depend on the light incidence angle, with intense resonances and specifically a large enhancement of the MO activity in the angular region where the SPP excitation occurs.

In figure 2 we have depicted a compilation of the experimental results (upper curve) and theoretical calculations (lower curve) of the Co thickness dependence of the transverse MO signal when the SPP is excited. A distinctive maximum in MO signal is observed both experimental and theoretically for a Co layer thickness around 2.5 nm, with decreasing values for lower and higher Co thickness. This clearly differs from the intuitively expected gradual increase of MO signal with magnetic layer thickness when no plasmon resonance is excited, and is due to the optimum reduction of the reflectivity and increase of the electromagnetic field at the Co layer for this specific thickness when the SPP is present. The differences in intensity and sharpness between theory and experiment are very likely due to the morphology of the actual samples originated by the tendency for a 3D growth

of Ag on glass under the used deposition conditions. We believe that the optimization of layers planarity and interface sharpness will allow to experimentally reaching the theoretically expected values.

(1) Introduction

II-VI based magnetic semiconductors (MSs) with a direct and wide optical band gap are expected to show high potential for optical applications utilizing short wavelength laser diodes (LDs), such as 532-nm green and 475-nm blue LDs. II-VI MSs $\text{Zn}_{1-x}\text{Mn}_x\text{Te}$ and $\text{Zn}_{1-x}\text{Mn}_x\text{Se}$ exhibit their absorption edges at 428-544 nm and 428-458 nm, respectively. The edge is not so influenced by the Mn concentration, as is typically observed in $\text{Cd}_{1-x}\text{Mn}_x\text{Te}$. We have confirmed that the Faraday rotation θ_F in the ZnMnTe films deposited on quartz glass (QG) substrates is large near the absorption edge [1]. This paper successively reports the magneto-optical characteristics of ZnMnTe and ZnMnSe films synthesised on QG, and shows the result of a direct Faraday rotation observation successfully made for the ZnMnTe film under ac magnetic fields.

(2) Band gap energy and Faraday rotation of ZnMnTe and ZnMnSe films

Using molecular beam epitaxy, ~2- μm -thick ZnMnTe and ZnMnSe films were prepared on 0.5-mm-thick transparent QG substrates. Crystallinity was evaluated using an x-ray diffractometer. The preferred (111) growth reported previously for CdMnTe films on QG substrates [1] was also observed in the ZnMnTe and ZnMnSe films with weaker peak intensities. $\text{A}^{\text{II}}_{1-x}\text{B}^{\text{VI}}$ MS alloys are direct-gap semiconductors whose band extrema occur at the Γ point, and a linear interpolation between $\text{A}^{\text{II}}\text{B}^{\text{VI}}$ and MnB^{VI} compounds gives a good first-order approximation of a value description of the dependence of E_g on x [2]. The interpolation on the energy gap of replacing the group II elements by Mn in $\text{Cd}_{1-x}\text{Mn}_x\text{Te}$, $\text{Zn}_{1-x}\text{Mn}_x\text{Te}$ and $\text{Zn}_{1-x}\text{Mn}_x\text{Se}$ is shown in Fig. 1. Values obtained from ZnTe-MnTe and ZnSe-MnSe interpolation are compared with those obtained from experimental $(\alpha h\nu)^2$ - E_g plots in Table I. Figure 2 shows the variation of the Faraday angle with wavelength measured at room temperature in $\text{Zn}_{1-x}\text{Mn}_x\text{Te}$ and $\text{Zn}_{1-x}\text{Mn}_x\text{Se}$ films. Although a negative peak value of θ_F at room temperature is typical for $\text{Cd}_{1-x}\text{Mn}_x\text{Te}$ films over the wavelength range of 600-650 nm, for $\text{Zn}_{1-x}\text{Mn}_x\text{Te}$ films, a shift of θ_F dispersion to higher photon energies was observed as a result of the increase in band gap energy. The negative peak of the Faraday rotation in $\text{Zn}_{1-x}\text{Mn}_x\text{Te}$ films that have an absorption edge at 520-530 nm is near the edge.

(3) Green laser application for ZnMnTe films

We developed an equipment for observing the Faraday effect directly under ac magnetic fields generated by a ring magnet. Figure 3 shows the Faraday-effect signal observed for the $\text{Zn}_{0.82}\text{Mn}_{0.18}\text{Te}$ film using the equipment that has the ring magnet and a 532-nm green LD. The results suggest that $\text{Zn}_{1-x}\text{Mn}_x\text{Te}$ films are useful for green lights.

Magnonic crystals-theory, experiment, parametric processes.

*S. A. Nikitov, S. Bankov, Y. Filimonov, A. Kozhevnikov, S. Vysotsky
IRE, RAS, Moscow, Russian Federation*

Magnetic films with magnetostatic spin waves (MSW) traditionally are considered as a perspective transmission medium that may be used for design of a wide class of miniature microwave electronic components. Application of periodic arrays combined with magnetic films opens new opportunities including creation of miniature bandgap structures so-called magnonic bandgap (MBG) crystals that have unique electromagnetic properties. The aim of this work is a rigorous analysis of different two-dimensional magnonic crystals, i.e. the structures with arrays of slots or strips or etched holes of a finite length. The main ideas and approximations of the analysis are presented below. It was supposed that the thickness of metal screen with slots or thickness of strips is considered as equal to zero. Also we suppose that conductivity of these metal elements is infinite. Width of strips and slots is much smaller than the period of an array. Thus we may take into account only longitudinal currents flowing along strips and slots (electric and magnetic, respectively). All slots and strips in an array are considered as identical. Electromagnetic field is a superposition of electric and magnetic waves. It corresponds to the quasi-static situation in which the fields of electric and magnetic waves are almost uncoupled. We also describe magnetic material in a conventional way applying tensor of magnetic permeability. Loss in magnetic material can be taken into account. Slots in the two-dimensional array are tilted along the Oy axis. The angle of incidence of the MSW has an arbitrary value. Solving the boundary problem one finally obtains the dispersion dependencies of MSW propagating in 2D and 1D periodic structures representing surface magnonic crystals. The main feature of dispersion dependence is appearance of MBG.

Experimentally we studied linear properties and parametric instability of propagating MSW in a magnonic film consisting of yttrium iron garnet (YIG) film with 2D periodic arrays of etched holes with rhombic and quadratic symmetries. The film thickness was 16 μm , the holes depth was between 1 and 2 μm , their diameter – 32 μm and the structures period was 40 μm . We studied also the angular dependencies of dispersion and parametric instability threshold with respect to the angle between the axis of the structures and the applied external magnetic field and the MSW direction of propagation. The angle is the angle between the MSW wavevector and the lattice axis. It was measured that when the pair of antennas was located outside the YIG film with the 2D lattice neither amplitude and phase and frequency curves (AFC) nor (PFC) showed any distinct features. The dispersion obtained in this case is typical for the MSW. However, when one or both antennas were located within the YIG film the band gaps appeared in the spectra. This band appeared at some value of the angle for some range of the ratio between the areas of the etched and unetched parts of the YIG film located between the antennas. Increase in the portion of the etched area led to increase in the MSW losses within the whole frequency spectrum. This increase in propagation loss has made it impossible to register the band observed previously. When the band was registered at a given angle and the etched area between the pair of antennas was increased the depth of the band increased as well. It should also be noted that the shapes of the AFC and PFC plots were practically unchanged as the propagation direction of the MSW or the direction of the bias magnetic field was varied. The wavenumber of the propagating MSW was calculated to be $k=860\text{ CM}^{-1}$. As the angle was varied the band was seen to move to the longer wavelength or the lower frequency of the MSW. The measured half-width of the minimum peak is equal to 16 MHz. The location of the minimum and its frequency width changed continuously as the angle increased. The above experimental results can be interpreted most simply for the angles and . In these cases due

to the symmetry involved the MSW propagates normally to the 2D periodic structure and the Bragg condition was fulfilled. In view of the fact that the existence of the band was caused by the Bragg reflection we may conclude that in the vicinity of the Bragg resonance condition frequency bands that forbid propagation of the MSWs can be engineered. Reflection of the microwave power from the input antenna increases within these forbidden bands. We studied also the first-order parametric instability of the MSW. We found that the power thresholds which are necessary to develop the instability in 2D magnonic crystals exceed essentially (almost in two times) the analogous values for a YIG film without etched structure (i.e. without magnonic crystal). This increase is a result of increase of relaxation velocity of magnetostatic spin waves due to scattering by the nonuniformities of 2D lattice. It was also measured that the magnonic bandgap is not destroyed up to quite big levels of supercriticality of threshold power. It was also measured that the magnonic bandgap is not destroyed up to quite big levels of supercriticality of threshold power. It was also shown that at the conditions of effective hybridization of magnetostatic spin waves with exchange spin waves propagating at the right angle to the bias magnetic field the parametric instability threshold increased essentially.

Hybrid noble metal-ferromagnetic heterostructures present optical and magneto-optical (MO) properties due to their individual constituents that, when combined, give rise to systems with enhanced optical and MO responses. For instance, it has been shown that the MO response of Au/Co/Au trilayered systems can be enhanced when its surface plasmon resonance is excited [1], enabling to develop new high sensitivity biosensors [2]. However, so far such enhancement has been only observed in continuous films that present simultaneously well defined propagating surface plasmon resonances and MO activity [1]. A discrete, nanostructured system exhibiting localized surface plasmon resonances (LSPR) may possess two advantages with respect to continuous structures: (i) the strong localization of the electromagnetic field associated to these resonances around the nanostructures can lead to a noticeable enhancement in the MO properties, and (ii) this spatial localization of the electromagnetic fields could be exploited to make such a system become a promising candidate for the development of high spatial specificity magneto-plasmonic sensing devices.

Even though complex onion-like nanoparticles made of noble metals and ferromagnets that exhibit LSPR have been obtained using different chemical methods [3], no MO activity has been reported in any of them. In this work we show that such active nanostructures exhibiting optical and MO properties can actually be obtained. The system analyzed consists of Au/Co/Au nanodisks prepared using a colloidal lithography procedure from continuous Au/Co/Au films grown onto glass by sputtering. This nanostructuring gives rise to strong changes in the optical absorption properties of the system. In figure 1 we show the absorption spectra of two samples with disk diameters of 60 and 110 nm, exhibiting a characteristic peak around 2 eV. The peak is due to the excitation of the LSPR of the Au/Co/Au nanodisks and its energy position depends on the nanodisk shape that is given by the trilayer thickness and the disk diameter. This resonance excitation in turn affects the MO response of the system. For example, figure 2 shows the Polar Kerr ellipticity spectra of the nanodisks (magnetic field applied perpendicular to the sample plane) compared to that of the continuous films. As it can be observed, the MO Kerr activity of the nanodisks shows an enhancement in the same energy region of the absorption peak. Its origin can be explained considering that the LSPR excitation induces a change in the complex reflectivity coefficients from which the MO Kerr activity is defined. The latter results are better seen in figure 3, where the Total MO activity (defined as the modulus of the complex Kerr rotation) of the d=110nm nanodisks normalized to that of the continuous layers is analyzed. The peak observed corresponds to that observed in the absorption spectra, illustrating the effect of the LSPR on the enhancement of the MO response. All these results will be finally understood with the help of theoretical simulations made with a scattering matrix formalism that takes into account the off diagonal terms of the dielectric tensor and consequently the MO activity.

Photonic crystals (PCs) are dielectric microstructures with periodic modulation of the refractive index in one or several directions and with a period comparable to the optical wavelength. This internal organization confers them with a unique property: a photonic band gap structure (PBG) for electromagnetic waves. The photonic band gap represents the prohibition of the light propagation inside the PCs for some wavelengths. This characteristic makes the photonic crystals suitable for several applications such as sensors, lasers, optical fibers, photonic components in telecommunication devices and optical filters. Opals are 3-dimensional photonic crystals built up by dielectric spheres that self-assemble in ordered fcc crystalline arrangements. The PBG position will depend on the particle size and the difference in refraction index between the spheres (usually silica, titania or polystyrene, among others) and the air that fills the voids between the particles (1).

It has been observed that when a magnetic material is introduced into the structure of a PC, either as a defect or as a full component of the material, the new PC acquires novel magneto-optical properties such as a PBG tunability or an enhancement of linear and non-linear optical effects (2) that could lead to new magneto-optic components.

We will report on the synthesis, magnetic and magneto-optic characterization of inverse magnetic opals. Inverse opals are the result of filling the voids of a direct opal with another material, removing the spheres and leaving holes in their places. Briefly, the synthesis was as follows: direct opals of different sphere diameter -and thus different spectral position of the PBGs- were built up of polystyrene spheres of various sizes (380 and 467 nm), assembled by vertical deposition onto a hydrophilic glass substrate. Afterwards, silica was infiltrated between the spheres by chemical vapor deposition and then the original organic spheres were removed by dissolution with toluene. The corresponding PBGs of the inverse opals are centered at: 550 nm and 800 nm, respectively. Finally, an aqueous solution of superparamagnetic nanoparticles (NPs) of maghemite was prepared. The silica inverse opal was subsequently filled up with the magnetic NPs by soaking it into the magnetic dispersion and pulling the opal out of it using a vertical stepping motor. Following this procedure, inverse silica opals infiltrated with different amounts of maghemite NPs were obtained (see Fig. 1).

The maghemite NPs were synthesized in organic media by thermal decomposition of iron pentacarbonyl and transferred to water by using sodium citrate as the stabilizer (3). They are 10 nm in diameter, with narrow particle size distribution ($\sigma < 10\%$) and superparamagnetic at room temperature.

In order to study the properties of infiltrated opals, magnetization measurements were first conducted using an SQUID magnetometer with the applied magnetic field perpendicular to the sample surface. The measurements allowed us to confirm that magnetic infiltration was successfully achieved. Moreover, it was shown that the magnetic moment of the opals can be controlled by the infiltration process. On the other hand, these experiments revealed that the infiltrated opals were superparamagnetic at room-temperature, as observed in the raw maghemite NPs. This observation indicates that infiltration does not produce any significant aggregation of NPs.

Magnetization loops were measured by magneto-optical (MO) setup in transmission (Faraday configuration) and in reflection (Kerr configuration). In both configurations the light beam is normal (or close to normal) to the surface of the sample. Experiments with s- and p- polarization were con-

ducted. The applied magnetic field was also perpendicular to sample surface. Experiments were done using low-power laser sources of different wavelengths (red 632.8 nm, 14 mW and green 542 nm, 1 mW). The incident laser beam was almost normal to sample surface and thus the polar component (parallel to the external field) of the magnetization was determined. Preliminary Faraday rotation experiments showed magnetization loops similar to those observed in the SQUID measurements, superimposed to a dominating diamagnetic contribution from the substrate.

Kerr measurements on the other hand, allowed observing magnetization curves also analogous to those extracted from SQUID. As expected, the Kerr rotation is found to increase with the NPs infiltration dose. Comparison of the values of the magnetic moment and Kerr rotation for samples with different NPs infiltration dose, suggest an enhancement of the magneto-optic response in the opals. In summary, we have shown that magnetic inverse opals can be fabricated by a simple infiltration method. Measurements have revealed a strong Kerr rotation and available data may indicate a non linear magneto-optical response. Perspectives for further development will be discussed.

Controllability of growth-induced anisotropy of thin garnet films grown on (210)-oriented substrates.

S. Tkachuk¹, D. Bowen¹, C. Krafft², I. D. Mayergoyz^{1,3}

1. Electrical and Computer Engineering, University of Maryland, College Park, MD; 2. Laboratory for Physical Sciences, College Park, MD; 3. UMIACS, University of Maryland, College Park, MD

It is well known that the sensitivity and magnetic field imaging range of garnet films as magneto-optical sensors are determined by the shape of the hysteresis loop which is controlled by the anisotropy properties. The anisotropy constants, in turn, depend on the chemical composition of a thin film, the crystallographic orientation of a substrate on which the film was grown and on the growth conditions, such as rotation rate or melt undercooling. In this respect, epitaxial films grown on (210)-oriented substrates are very attractive due to their unique anisotropy properties that allow for the existence of an easy plane of magnetization inclined to the film plane^[1]. It turns out that if the following condition on the anisotropy constants

$$\kappa = -4K_{\text{Ueff}} K_i / K_{yz}^2 = 1 \quad (1)$$

is fulfilled then the easy magnetization plane exists and the film will possess low saturation field and high magnetic field sensitivity. Here, K_{Ueff} , K_i , and K_{yz} are the effective out-of-plane uniaxial, in-plane uniaxial and canted orthorhombic anisotropy constants, respectively.

In this paper, we extensively study the dependence of the anisotropy properties of thin garnet films grown on (210)-oriented substrates on melt chemistry and growth conditions with the purpose to realize (albeit approximately) relation (1).

Several garnet film samples of composition $(\text{Bi, Pr, Lu, Gd})_3(\text{Fe, Ga})_5\text{O}_{12}$ have been grown by liquid phase epitaxy onto (210)-oriented $(\text{Ca, Mg, Zr})\text{-Gd}_3\text{Ga}_5\text{O}_{12}$ substrates. The anisotropy fields (anisotropy constants scaled by M_s) have been obtained through the ferromagnetic resonance (FMR) measurements using the appropriate equation for the resonance frequency^[2]. The anisotropy fields along with growth rates, film properties and values of κ are given for each grown sample in Table I, where H_{Kueff} is effective out-of-plane anisotropy field, H_{Ki} is in-plane anisotropy field, H_{Ki} is cubic anisotropy field, H_{Kyz} is canted orthorhombic anisotropy field, while H_s is the saturation field.

The design of the melts has been guided by the following requirements: crystallographic lattice matching between the film and the substrate, high Bi incorporation and canted magnetization. The epitaxial films were grown from a $\text{PbO-Bi}_2\text{O}_3\text{-B}_2\text{O}_3$ flux on substrates rotating at 196 rpm. The cation oxide percentages for the rare earths are given in Table II. The Fe:Ga ratio was 5:1.

It has been found (see Tables I and II) that by appropriately changing Pr content in the melt the desired control of anisotropy fields (constants) can be achieved. Indeed, the value of κ has been reduced almost by one order of magnitude and the clear correlation between the reduction in κ and saturation field has been observed. It has also been found that for $\kappa=2.7$ free energy deviations from energy values at $\kappa=1$ are relatively small and on the order of cubic anisotropy energy. Thus, the conclusion can be reached that by appropriate control of Pr content in the melt the garnet films with high magnetic sensitivity can be grown on (210)-oriented substrates.

Adjustable Faraday rotation by using one dimensional magnetophotonic crystals.

M. Hamidi¹, A. Bananej³, M. Tehranchi^{1,2}, M. Ghanaat Shoar¹

1. laser and plasma resurch institute, Shahid Beheshti University, Tehran, Iran; 2. physics department, Shahid Beheshti University, Tehran, Iran; 3. Laser and Optics Research School, Tehran, Iran

During recent years there has been great tremendous progress on one dimensional magnetophotonic crystal (1D-PMC) as a compact isolator element in future nanophotonic circuits. Because of strong confinement of light in the defect magnetic layer, the interaction of light with material and as a consequence, the Faraday rotation can be enhanced dramatically. On the other hand, according to the different users' requirements, adjustable 1D-MPC in both of magnitude of magneto-optic effect and its wavelength dependent is the crucial bottleneck. In this paper according to our best of knowledge, for the first time, we propose a new method for overcoming these limitations. By using the symmetric periodic multilayer to determine the equivalent refractive index, the magnitude of the Faraday rotation in wide range of wavelength can be adjusted.

In the present work, we consider the basic structure as $(\text{Ta}_2\text{O}_5/\text{SiO}_2)_m/\text{Bi:YIG}/(\text{SiO}_2/\text{Ta}_2\text{O}_5)_m$ which SiO_2 is as low index layer with $n=1.45$ and Ta_2O_5 as high refractive index layer with, in the Bragg stack with optical thickness and Bi:YIG layer as the magnetic defect layer with optical thickness. Where $\lambda = 720\text{nm}$ and $m=6$ is the repetition number. According to our simulation results, the Faraday rotation in this structure is 150 times greater than of a single layer of Bi:YIG.

It has been investigated the great dependence of Faraday rotation and transmission on the optical contrast ratio of dielectrics. But the choice of materials with refractive indices intermediate to those of the highest and lowest values is impossible in any spectral region; also, selection of materials is further limited by a number of other practical limitations. Now, in the case that, each of the low index layer replaced by a three symmetric multilayer as equivalent layer, the optical contrast ratio in the Bragg stack can be tuned continuously and as a consequence, the transmission property and Faraday rotation in the structure can be adjusted. Fig1.a shows the transmission of the 1D-MPC for different value of optical contrast ratio. It is evident by changing the optical contrast ratio from 1.43 to 1.09 by using the accessible and compatible a couple of materials, the light confinement in the defect point can be changed (Fig.1.a) and as a consequence, the magnitude of Faraday rotation vary from -3.35 to -0.74 in a wide range of wavelength (Fig.1.b).

Artificial structures composed of alternating dielectric materials with different refractive indices, known as photonic crystals (PCs), have been shown to affect the propagation of light, providing a new mechanism to control and manipulate the flow of light. Following the concept of photonic band gaps originating in light coupling to the spatially periodic structure and localization of light in the vicinity of defects introduced into the periodic structure [1], various one-, two- and three-dimensional PCs, photonic crystal fibers and waveguides, wave plates have been designed, and new fabrication technologies have been developed within the last two decades [2, 3].

Unique optical and magneto-optical properties are shown to exist when the constitutive materials of PCs are magnetic. For magnetophotonic crystals (MPCs), in which the constitutive elements are magnetic (or even only a defect introduced into the periodic structure is magnetic), there exists an additional degree of freedom to operate the photonic band structure, diffraction patterns, and the state of polarization of light, i.e., these characteristics can be influenced by the external magnetic field [4–6]. It is shown that MPCs enhance responses of known magneto-optical (MO) materials. Light confinement associated with the magnetic defect has been exploited to enhance and optimize MO responses and optical non-linearity of existing materials. In fact, the large enhancement of the Faraday rotation is demonstrated in one-dimensional (1D) MPCs composed of a magnetic garnet thin film sandwiched between dielectric Bragg mirrors [7]. The enhancement of the Faraday rotation can be also seen at the edges of photonic band gap appearing in multilayered magnetic structures [8].

In this work we present a new type of MPCs composed of two 1D PCs, namely, magnetic and non-magnetic Bragg mirrors with slightly different photonic properties [6]. Such MPCs exhibit the resonant transmission and are experimentally shown to enhance the magneto-optical response of known materials (see figure). The surface state, so-called the Tamm state, is originated by the interface between two 1D PCs, and supports multiple propagation (localization) of light within magnetic layers. When magnetic field is applied, the difference of the wave vectors for left- and right-circular polarized localized Tamm modes, multiple propagation of these modes within the magnetic layer and the nonreciprocal character of the Faraday effect result in an enhancement of the polarization rotation by one order of magnitude. It is worth mentioning that the Tamm structures are of benefit for localizing light within (or at) any active material introduced at the interface (or built in between two PCs).

Magneto-plasmonic nanostructures: a way to control surface plasmon excitation for Biosensor application.

D. Regatos¹, A. Calle², A. Cebollada², L. Lechuga¹, A. Armelles²

1. Nanobiosensor and Molecular nanobiophysics Group, Research Center on Nanoscience and Nanotechnology (CIN2: CSIC-ICN), Bellaterra, Spain; 2. Microelectronics Institute of Madrid (IMM-CNM), Tres Cantos, Spain

The use of surface plasmons (SP) in the development of optical components has drawn significant interest over the past decade, and the field is currently experiencing a dramatic growth. The future development of this field will depend on the ability to develop active devices whose optical response could be controlled applying an external agent such as, for example, a magnetic field. Very recently it has been shown that multilayers made of Co and Au has magneto-optical (MO) activity and well-defined plasmonic features [1]. These structures have been used to develop a new family of biosensors with enhanced sensitivity [2]. In this work, we analyse a new magneto-plasmonic nanostructure made of Fe and Au. A complete analysis of the Transversal Magneto-Optic Kerr Effect (TMOKE) in Au/Fe/Au trilayers will be presented. We will demonstrate how the Fe layer controls the propagation of the SP of the structure and we will analyse its implementation in biosensor devices.

Two sets of Au/Fe/Au trilayers have been grown on a glass substrate by magnetron sputtering at room temperature. The Fe thickness was 4.3 nm for one set and 2.7 nm for the other. For all the samples the thickness of the Au layer in contact with the glass substrate was 5 nm, whereas the thickness of the upper Au layer has been varied between 22 and 36 nm. In the inset of Fig. 1 we present a scheme of the experimental set up (Kretschmann configuration). The upper Au layer was in contact with liquids of different refractive index. We have measured the reflectivity of the p-polarized light (R_{pp}) as a function of the incident angle and the relative variation of the R_{pp} induced by a magnetic field applied perpendicular to the incident plane (TMOKE signal). In Fig. 1 we show the R_{pp} and TMOKE signal for a 30nmAu/4.3nmFe/5nmAu/glass and for a liquid with refractive index of 1.3326. As can be observed, close to 71 degrees, due to the excitation of the SP (see Fig. 1a) the value of the R_{pp} decreases and, at the same time, the TMOKE signal experiments a sharp increase (see Fig. 1b). Moreover, in this configuration, the SP wave vector depends on the magnetization of the Fe layer and, therefore, the TMOKE signal can be related to the angular derivative of the R_{pp} multiplied by a factor ($\Delta\theta_{\min}$) corresponding to the modification of the SP wave vector. This is clearly seen in Fig. 2, where we show the TMOKE signal and the angular derivative of R_{pp} for different samples multiplied, in each case, by the $\Delta\theta_{\min}$. We also represent the theoretical simulation for each structure. The value of $\Delta\theta_{\min}$ as a function of the thickness of the Au upper layer is shown in Fig. 3 for the two sets of samples and their expected theoretical evolution. As can be observed the modulation factor of the 4.3 nm set samples is greater than that of the 2.7 nm set. Moreover, as we increase the thickness of the Au upper layer $\Delta\theta_{\min}$ decreases. This behaviour is due to the effective amount of magnetization seen by the SP, which is related to the integrated intensity of the electromagnetic field inside the Fe layer.

Finally, we will analyse the use of this structures as improved transducer for biosensor devices. We will study the sensitivity of the TMOKE signal to the changes of the liquid refractive index in a 30nmAu/4.3nmFe/5nmAu/glass sample and we have compared these, with the change of R_{pp} shown in a 48nmAu/2nmCr/glass structure (R_{pp} signal) for the same change of refractive index. The changes of the TMOKE signal are show to be a factor of two greater than the R_{pp} signal, which is due to the derivative character of the TMOKE signal as it was shown above.

Layered bismuth iron garnet films for magneto-optical applications.

M. Kucera¹, R. Gerber²

1. Faculty Math. & Physics, Charles University, Prague, Czech Republic; 2. School of Sciences, Salford University, Salford, United Kingdom

Bismuth substituted iron garnet (BiIG) is an attractive material for variety of magneto-optical (MO) applications due to its high angles of the Faraday rotation and rather low optical absorption in the visible and near infrared spectral range. These garnets can be considered to be used in optical communications (nonreciprocal devices such as optical isolators), MO imaging devices of stray magnetic fields (in superconductors or flaw detection in magnetic steels), or in magnetic photonic crystals (combining Bi garnets and dielectric mirrors).

Here we report on magnetic and MO properties of Bi iron garnet double-layer films produced by the pulsed laser deposition (PLD), in which an antiferromagnetic coupling is observed across the layer boundary. Such exchange coupled magnetic double-layers or multilayers have attracted considerable attention due to their direct overwrite capability and magnetically induced superresolution required in the MO high density recording applications.

The PLD garnet films were deposited onto (111) oriented GGG substrates using a KrF excimer laser. The best quality films were obtained at substrate temperatures between 550 and 600 °C and at oxygen pressure near 20 Pa. The films were characterized by the XRD, atomic force microscopy, magnetic, optical and MO measurements. The films exhibited an epitaxial growth, yielding samples of good crystalline and optical quality with fine granular structure and strong (111) preferred crystallographic orientation. The nominal film composition $\text{Bi}_{2.1}\text{Dy}_{1.0}\text{Fe}_{4.0}\text{Ga}_{0.9}\text{O}_{12}$ was close to that of the target. The typical average grain size was about 200 nm and the average r.m.s. surface roughness was from 3 to 9 nm depending on the deposition conditions. The Faraday and polar Kerr effects were measured in the spectral range from 250 to 900 nm and at temperatures from 20 to 500 K. Huge Faraday rotations up to 60 deg/μm are observed in the near ultraviolet region. The films exhibited square hysteresis loops and a strong perpendicular magnetic anisotropy. All the films had magnetic compensation temperature, which was strongly dependent on the deposition conditions. To study the exchange coupling in such films a double-layer garnet system was prepared in which the individual layers differ in their compensation temperatures. This was achieved by the steep change of the oxygen pressure during the PLD process whilst the substrate temperature was kept constant. The growth process suggests that a layered garnet system comprising two layers of slightly different nominal composition was obtained. Due to different distribution of magnetic cations (Fe^{3+} and Dy^{3+}) over the three available garnet sites, the resulting layers differ significantly in their magnetic compensation temperatures. The Faraday rotation hysteresis loops of samples incorporating such double-layer systems revealed a complicated magnetic reversal process, Fig. 1. This behavior can be understood assuming that the layers couple antiferromagnetically across their boundary. Namely, in the BiDy-iron garnet, the rare earth Dy^{3+} magnetic moment is antiparallel to the resultant moment of the Fe^{3+} sublattices. Consequently in the layer with lower compensation temperature the magnetic moment originating from Fe^{3+} ions dominates, whereas the layer with higher compensation temperature Dy^{3+} moments dominates. Since the Fe^{3+} spin subnetwork in one layer is antiparallel to that in the second layer a domain wall is created between the individual layers and, as a result, a complicated magnetic reversal process is observed.

In summary, such granular garnet double-layer films represent a switching system that demonstrates the existence of a magnetic coupling between two insular layers of almost the same nominal composition, which differ in their compensation temperatures. By tailoring the PLD operational

parameters, the layered systems of required compensation and Curie temperatures may be fabricated in a single fabrication step. Such garnet layered systems could have the potential as an alternative approach for magneto-optical recording media.

This work is a part of the research plan MSM 0021620834 financed by the Ministry of Education of the Czech Republic.

Thermal properties of Spin Torque Oscillators: Singularity in Effective Energy.

P. B. Visscher, S. Wang

Department of Physics and MINT Center, University of Alabama, Tuscaloosa, AL

It is important to understand thermal fluctuations in spin torque systems, in order to predict oscillator linewidths, spin torque switching rates, and spin-torque MRAM stability. It has been found [1,2] that although the spin torque term in the Landau-Lifshitz equation is not conservative in the usual sense, it is possible to define an effective energy $E_{\text{eff}}(E)$ which describes the thermal behavior in the sense that the probability distribution of the magnetization vector \mathbf{M} given by $f(\mathbf{M}) = \exp(-E_{\text{eff}}(E(\mathbf{M}))/k_B T)$ [1,2] is a steady-state solution of the Fokker-Planck equation.

The effective energy is computed from an integral $\eta(E)$ of the spin torque over the orbit at energy E , as $E_{\text{eff}}(E) = \int^E [1 - \eta(E')I/\alpha] dE'$, where I is proportional to the current and α is the Landau-Lifshitz damping coefficient. For the common case of in-plane anisotropy, in the past $\eta(E)$ has been computed numerically and fit to a polynomial [1], but the fit is quite poor. We have found that this is because in general $\eta(E)$ has a logarithmic singularity at the energy barrier. This arises physically from the fact that the energy landscape is very flat near its saddle point (the energy barrier), and the orbit period diverges. When this singularity is taken into account, the fit is extremely good, as shown in the figure, and it is possible to do semi-analytic calculations of the effective energy.

As a function of the magnetization vector \mathbf{M} on the spherical surface $|\mathbf{M}| = M_s$, the effective energy $E(\mathbf{M})$ has a “Mexican hat” shape, with a central maximum (the parallel state) and a line of degenerate minima along the precessional orbit. As one increases the current, one can see the usual easy-axis energy minimum (a single value of M , at which the energy is concave upward) become very flat, and then concave downward (a local maximum) surrounded by a precessional orbit along which the energy is a (highly degenerate) minimum. The size of the precessional orbit increases until the barrier separating this minimum from the antiparallel minimum (which has become very deep) vanishes and switching occurs (at zero temperature). Before switching occurs, the shape of the precessional minimum determines the linewidth of the resulting microwave oscillations.

At nonzero temperature, switching occurs at a lower current. This current can be calculated by setting the experimental time scale equal to the reciprocal of the switching rate — within the transition-state theory, this is $f_0 \exp(-E_b/k_B T)$, where f_0 is the precession rate for small oscillations [3]. However, to compute a numerically accurate rate we have generalized to the case of spin torque switching a “bounce” algorithm [4] in which numerical simulations of slow processes are made possible by restarting the simulation (“bouncing”) when the energy tries to dip below some cutoff value.

In the context of spin-torque switching, we will discuss Sharrock-like fitting of mean-switching-current vs. current-pulse-duration curves [5] — because this is sensitive to the form (the Sharrock exponent) of the dependence of the energy barrier on the current, the proper treatment of the logarithmic singularity is particularly important.

The spin torque integral $\eta(E)$ [6] that determines the switching probability, with a three-parameter polynomial fit (dotted line) and logarithmic fit (solid line) to the numerical data from micromagnetic simulation (filled circles). The logarithmic fit is seen to be much more accurate.

Spin torque induced RF-oscillations of the magnetic end domains in CoFeB/MgO/CoFeB nanopillars under subthreshold currents.

S. Cornelissen^{1,3}, M. van Kampen¹, G. Hrkac², T. Schreffl², L. Lagae¹

1. NEXTNS, IMEC, Heverlee(Leuven), Belgium; 2. Department of Engineering Materials, University of Sheffield, Sheffield, United Kingdom; 3. EHSAT, K.U.Leuven, Leuven, Belgium

The spin torque effect, as predicted independently in 1996 by Slonczewski and Berger, has since been subject of lots of experimental research, which has shown that a spin polarized current can induce an oscillatory motion in a magnetization, yielding RF oscillations at GHz frequencies. These oscillations, which turn out to be very tunable, are very promising for future wireless communication devices. The use of MgO based tunnel junctions, as in this report, is a very promising route towards increasing output power, the bottleneck for integration of spin torque oscillators. Compared to spin valve multilayers (with typical MR ratios of 10%) MgO based tunnel junctions yield MR ratios up to 180% for a Fe/MgO system [1] and up to 500% at room temperature for a CoFeB/MgO system [2]. It was also shown that tunnel junctions can show spin torque oscillations [3] even under high bias voltages which shows the potential of MgO for oscillator applications. Here RF-oscillations are described, measured on a nanopillar fabricated from a magnetic tunnel junction built up as follows (thickness in nm): Ta 3/CuN 40/Ta 5/PtMn 20/CoFe30 2/Ru 0.8/CoFe20B20 2/Mg 1.3/CoFe20B20 3/Ta 4, contacted with a (Au 100) top electrode, yielding an RxA product of $165\Omega\mu m^2$. A typical best measurement of the magnetoresistance measured on a $15 \times 5 \mu m^2$ tunnel junction device shows 300% TMR. The rectangular pillars of $100 \times 200 nm^2$ are created by means of e-beam lithography and dry etching.

Nanopillar RF measurements were performed with currents up to 4.5mA in varying external magnetic fields. RF oscillations were discovered in external magnetic fields close to the pillar's switching fields as shown in the left half of Figure 1. Large single peaks were observed for positive currents in the parallel configuration, and for negative currents in the anti-parallel configuration. Other configurations yield broader peaks of lower amplitude. The oscillations are reminding of earlier spin torque induced results near the switching fields of spin valves [4]. Output powers of these oscillations are very low compared to what can be expected from uniform spin torque induced oscillations.

Micromagnetic simulations have been performed to get further insight. The right half of Figure 1 shows the oscillations calculated from our model based on the Slonczewski spin torque term [5] in a solver that solves for local current densities. This simulator has previously shown quantitative agreement for point contacts [6]. In this case the simulations include the free layer under the influence of the magnetostatic fields from the entire layer stack and the oersted field. Temperature effects are not taken into account but nevertheless frequencies (4-4.5GHz) are calculated in a range very close to the experimentally found frequencies (6-8GHz) for similar currents (4 vs 3.5mA). Also it shows the experimentally observed trend of decreasing frequency for increasing external fields. A snapshot of the micromagnetic free layer magnetization vectors, as shown in the right of Figure 2 indicates that the measured oscillations are due to oscillations of the end domains of the free CoFeB layer. The model therefore suggests that the current destabilizes the end domains that are present because of magnetostatic fields. The spin torque induces oscillatory motions in these end domains only, which accounts for the rather low powers obtained from these oscillations. The left hand side of Figure 2 compares the experimentally found oscillatory modes with the simulated ones, which enforces the statement that spin torque is the driving force for the oscillations. In the two quadrants where the simulator predicts oscillations, large peaks are found in the experiment

accompanied by some broader and less powerful peaks ascribed to thermal spin waves. In the quadrants where no oscillations are predicted (zero temperature model) only broad lower power peaks are observed, purely related to current induced thermal oscillations.

The spin transfer effect was first predicted theoretically in 1996 by L. Berger [1] and J. Slonczewski [2] and then observed experimentally in quasi-static magnetization reversal experiments [3]. At present, with MRAM and oscillator applications in perspective, the interest on spin transfer is focused on time resolved or high frequency measurements, in particular, for self-sustained oscillations [4]. Slavin et al. [5] have demonstrated that such oscillations are related to the magnetic excitations (spin-waves) of the system. In this picture each spin-wave mode is considered to be an independent oscillator and the observed signal corresponds to the spin-wave mode of the lowest damping. Such theory relies on parameters like the spin transfer efficiency σ and non linear damping Q [7] that are hard to obtain from first principles. We present an experimental study of current-driven magnetization oscillations in which good quantitative agreement with spin-wave theory is obtained. In addition, we show how σ and Q vary between different spin-wave modes.

The pillars we studied in experiment are made from magnetoresistive read head stacks with an exchanged biased synthetic antiferromagnet (SAF) and a sense (free) layer [6]. They are patterned to have a rectangular cross-section of various sizes, ranging from $100 \times 200 \text{ nm}^2$ to $50 \times 75 \text{ nm}^2$. To observe spin transfer excitations, a DC current $[-12, 12] \text{ mA}$ is injected in the pillar and a magnetic field $[-1.5, 1.5] \text{ kOe}$ is applied parallel to the easy axis of each device.

We observe high frequency excitations for positive magnetic fields (H), which favor an anti-parallel state, and positive currents, which favor a parallel state. In Fig. 1 we present a color-coded map of the power spectral density as a function of magnetic field for a current of 9 mA . We observe five excitations for which the field dependence of the frequencies qualitatively follows Kittel's law (dashed lines). The data are consistent with standing spin-wave modes propagating along the length of the device with dynamic magnetization being uniform across the width of the samples.

In Fig. 1 we show an example of fits based on spin wave theory. The spin transfer efficiency for this device is $\sigma = 55 \text{ GHz/A}$, and the non linear damping is $Q = 4$ for uniform mode and $Q = 1$ for all other spin-wave modes. The observed excitation between 600 Oe and 900 Oe is the uniform spin-wave mode (continuous lines on Fig.1). Around 900 Oe the high frequency signal stops when the SAF layers undergo a spin-flop transition (see hysteresis loop in the inset). After this transition, we observe two modes: the low frequency branch corresponds to the uniform mode and the higher branch is a nonuniform mode with a wave number of 1.

Using the same value of σ and Q , we are able to adjust the frequency versus current curves. In Fig. 2 we show the color-coded map of power spectral density versus the applied DC current for $H = 789 \text{ Oe}$ (before spin flop) and $H = 1130 \text{ Oe}$ (after spin flop). In both cases we observe the expected red shift associated with in-plane precession. For comparison we have plotted in Fig. 2 the expected frequency when non linear damping is neglected.

This report presents results of a micromagnetic analysis of our experimental data on the current-induced spin-wave excitation in the free layer of a nanopillar spin valve. The measurements are made on a Py(30)/Cu(10)/Py(4) structure (in nm). The thin Py free layer (FL) is defined by electron-beam lithography and ion-milling, using a mask in a form of an ellipse with the axes of 150 nm and 50 nm. The thick Py reference layer (RL) is left unpatterned. The field dependence of the device resistance, for a field applied in the film plane along the FL axis, evidences that at zero field the FL and RL are magnetized antiparallel (AP) to each other. That is possibly due to a small demagnetizing field generated by the reference layer, which could be slightly etched. The measurements were performed at room temperature for static magnetic fields applied perpendicular to the ellipse plane. A coherent microwave signal is observed only when electrons flow from the FL towards the RL. Jumps in the frequency versus current curves indicate switching between different oscillating modes. The low-frequency mode (LFM) ranges from 1 to 3 GHz, the next mode (high-frequency mode, HFM) starts at about 4 GHz. All the modes have approximately the same power.

The simulations are performed using our home-made solver SpinPM by numerical integration of the Landau-Lifshitz equation, which includes an additional spin-transfer torque - $\gamma a_j \mathbf{M} \times [\mathbf{M} \times \mathbf{m}]$ (γ is the gyromagnetic ratio, \mathbf{M} and \mathbf{m} are unit vectors along the magnetization direction of the free and reference layers accordingly, a_j is a spin-transfer parameter proportional to the current). A two-dimensional mesh is used and only the FL is actually taken into account in the simulations. We took $M_s = 700$ emu/cc for the saturation magnetization, $\alpha = 0.018$ for the Gilbert damping parameter (yielded from SQUID and FMR measurements accordingly), $A = 1.3 \times 10^{-6}$ erg/cm for the exchange constant, anisotropy constant $K = 0$. The discretization step was 1.5 nm. The thermal fluctuations and the angular dependence of a_j are neglected.

Using a simple expression for the spin-transfer parameter a_j [1], we get for our device $a_j = 200 \times p \times I$ (in Oe), where I is the current in mA and p is the current polarization. For each field, there is a critical value of a_j for the onset of the oscillations. To define p , we compare the latter to the corresponding experimental critical current [2]. This procedure yields $p = 0.17 \pm 0.02$. This value is consistent with the value $p = 0.14$ for AP configuration, extracted according to the Ref. [3] from the spin accumulation distribution calculated for our device. A very careful derivation of p is important as it defines a balance between the Oersted field and the spin-transfer. Our calculations show indeed that the excited modes may be strongly affected by the spin polarization.

The field dependence of the out-of plane component of the vector \mathbf{m} is calculated for a $1 \mu\text{m} \times 1 \mu\text{m} \times 30$ nm plate. The direction of the in-plane component $\mathbf{m}_{\text{in-plane}}$ of this vector is arbitrary for ideally perpendicular field \mathbf{H} . An unavoidable (and usually undefined) in experiments small misalignment of the field \mathbf{H} from the perpendicular to the plane direction may influence the direction of $\mathbf{m}_{\text{in-plane}}$. The dependence of the spectral peak frequency on the direction of $\mathbf{m}_{\text{in-plane}}$ was thoroughly calculated for several values of H and I . We find that it is a key parameter, which defines the excited oscillating mode.

Our study reveals that the oscillatory state of the system is always a vortex. Three modes may be excited in our system (one LFM and two HFMs). The LFM is an oscillation of the vortex core around the ellipse center. The dependencies of the oscillator frequencies on the current show a quantitative agreement of the calculated LFM with the experimental one. If the simulations are performed assuming that the FL size is equal to the size of the lithography mask, there is a strong disagreement between simulations and experiments when the experimental mode switches to the HFM. The HFMs found in the simulations have frequencies above 10 GHz and very low emitted power (3 to 10 times less than the LFM); they have no correlation with the experimental data. We have studied the dependence of the excited modes on the FL size and aspect ratio, which may possibly deviate from the nominal values due to imperfections of the patterning process. This study shows that under quite realistic assumptions about the latter parameters, a good agreement with the experiments may be found.

Angular dependence of generation linewidth of in-plane-magnetized anisotropic spin-torque oscillator.

V. Tyberkevych, A. Slavin

Department of Physics, Oakland University, Rochester, MI

The analysis of a stochastic dynamics of a spin-torque oscillator (STO) with the amplitude-dependent frequency was performed in [1], yielding the following expression for the generation linewidth $\Delta\omega$:

$$\Delta\omega = \Gamma_0 (kT/E_0) (1 + (N/(Q\Gamma_0 + \sigma I))^2). \quad (1)$$

Here Γ_0 is the ferromagnetic resonance (FMR) linewidth in the STO “free” layer, k is the Boltzmann constant, T is the absolute temperature, E_0 is the average energy of the STO auto-oscillations, N is the nonlinear frequency shift coefficient, $Q \sim 1$ is the dimensionless parameter characterizing the nonlinearity of magnetic damping, I is the bias current traversing the “free” magnetic layer, and σ is the coefficient that depends on the spin-polarization efficiency and geometrical sizes of STO. In this work we analyze the angular dependence of the generation linewidth of STO based on an *in-plane* magnetized *anisotropic* nano-pillar structure. In this case the dependence of the generation linewidth on the in-plane magnetization angle ϕ_0 is provided by the in-plane magnetic anisotropy H_A (see inset in Fig. 1) that can be caused both by the magnetocrystalline anisotropy of the magnetic material and by the shape anisotropy (non-circular shape) of the pillar “free” layer. The in-plane magnetization of an STO is more preferable than the out-of-plane magnetization, because the same oscillation frequency is achieved for a substantially lower bias magnetic field H_0 . At the same time, it is known that even a small anisotropy substantially changes the nonlinear properties of spin waves [2], and, due to the above described nonlinear mechanism, can lead to significant variations of the generation linewidth $\Delta\omega$. Thus, in the practically interesting case of relatively small bias and anisotropy fields, $H_0, H_A \ll 4\pi M_0$, one can obtain simple expressions for N in the limiting cases of easy ($\phi_0 = 0$) and hard ($\phi_0 = \pi/2$) axis magnetization:

$$N(\phi_0 = 0) \approx -(\omega_0/2)(H_0 + 4H_A)/(H_0 + H_A), \quad N(\phi_0 = \pi/2) \approx -(\omega_0/2)(H_0 - 4H_A)/(H_0 - H_A), \quad (2)$$

where ω_0 is the FMR frequency for the given field orientation. It is clear, that the modulus of the nonlinear frequency shift coefficient $|N|$ for the hard-axis magnetization is always smaller than for the easy-axis magnetization. At the same time, linear damping rate Γ_0 and other parameters that determine the linewidth Eq. (1) depend on the magnetization angle ϕ_0 rather weakly. Therefore, the generation linewidth $\Delta\omega$ for the hard-axis magnetization is always smaller than for the easy-axis magnetization, as it is shown in Fig. 1 for the typical parameters of an STO. In the range of bias fields $4H_A > H_0 > H_A$ the sign of N changes as ϕ_0 rotates from easy $\phi_0 = 0$ to hard $\phi_0 = \pi/2$ orientation and, consequently, the nonlinear coefficient N vanishes ($N = 0$) for a certain intermediate magnetization angle. At this angle a clear minimum of the generation linewidth is observed (see curve 1 in Fig. 1). For larger magnetic fields, $H_0 > 4H_A$, the linewidth has minimum at the magnetization angle $\phi_0 = \pi/2$ and increases with the increase of H_0 (see curves 2 and 3 in Fig. 1). Recently, a qualitatively similar behavior of the generation linewidth $\Delta\omega$ has been observed in the experiments reported in [3].

Our results show that the performance of STOs can be significantly improved by using nano-pillar devices magnetized along the hard in-plane axis $\phi_0 = \pi/2$. For this direction of magnetization the generated frequency and threshold current remain almost the same as for the easy-axis magnetization $\phi_0 = 0$, but the generation linewidth is substantially reduced due to the lower value of the nonlinear frequency shift coefficient N (see Eq. (2)).

Dependence of the generation linewidth $\Delta\omega$ of an STO on the in-plane magnetization angle ϕ_0 for several values of the bias magnetic field H_0 : 1 – $H_0 = 2H_A = 0.6$ kOe, 2 – $H_0 = 4H_A = 1.2$ kOe, 3 – $H_0 = 6H_A = 1.8$ kOe. Other parameters of STO: $4\pi M_0 = 8$ kOe, $H_A = 0.3$ kOe, $\alpha_G = 0.01$, $Q = 3$, “free” layer thickness 3 nm, shape of the nano-pillar – circular with the radius of 50 nm, spin-polarization efficiency 0.2, bias current $I = 3$ mA, temperature $T = 300$ K. The inset shows the “free” layer of the STO with the direction of the bias magnetic field and easy and hard magnetization orientations.

Mutual phase-locking of two spin-torque oscillators: Influence of time delay of a coupling signal.

O. Prokopenko¹, V. Tyberkevych², A. Slavin²

1. Faculty of Radiophysics, Kiev National Taras Shevchenko University, Kiev, Ukraine; 2.

Department of Physics, Oakland University, Rochester, MI

Spin-transfer-torque effect [1] opens a possibility for the development of a novel type of nano-scale microwave devices – *spin-torque oscillators* (STO). The practical application of STOs faces two main problems – low output power and large generation linewidth, both of which can be solved using the mutual phase-locking of several STOs [2, 3]. Using numerical simulations it has been demonstrated recently [4, 5] that the finite delay time of the coupling signal can lead to a substantial (~ 100 times) increase in the frequency band of phase-locking.

In this work we develop a theory of phase-locking of two STOs with account of the delay of the coupling signal. We consider the case of 2 nano-contact STOs coupled only by propagating spin waves. Our method and results, however, can be easily generalized to different types of coupling. The dynamics of the two weakly-coupled STO can be described by the system of coupled nonlinear equations for the complex amplitudes $c_j(t)$ of spin wave modes, excited in j -th nano-contact [3]:

$$dc_1/dt + i\omega_1(|c_1|^2)c_1 + \Gamma_{\text{eff},1}(|c_1|^2)c_1 = \Omega_{1,2}\exp(i\beta_{1,2})c_2, \quad (1a)$$

$$dc_2/dt + i\omega_2(|c_2|^2)c_2 + \Gamma_{\text{eff},2}(|c_2|^2)c_2 = \Omega_{2,1}\exp(i\beta_{2,1})c_1, \quad (1b)$$

Here $\omega_j(p_j)$ and $\Gamma_{\text{eff},j}(p_j)$ are the frequency and effective damping rate (that includes contribution from the positive natural damping and current-induced negative damping) of j -th mode, coupling frequencies $\Omega_{j,k}$ are defined by Eq. (6) in [3], and $\beta_{j,k} = \omega_k\tau_{j,k} = \omega_k a/v_k$ is the phase shift of the spin wave (radiated by the k -th nano-contact) acquired during its propagation to the j -th nano-contact ($\tau_{j,k}$ is the propagation time, a is the separation between the nano-contacts and v_k is the velocity of the spin wave). The system (1) without time delay ($\beta_{j,k} = 0$) was derived and analyzed in [3]. The description of the time delay by phases $\beta_{j,k}$ is valid for relatively small delay times $\Omega_{j,k}\tau_{j,k} \ll 1$.

In the absence of coupling ($\Omega_{j,k} = 0$), each of the Eqs. (1) has a free-running solution $c_j(t) = \sqrt{P_j}\exp[-i\omega_j(P_j)t]$, where the power P_j is determined by the condition of the vanishing of total damping $\Gamma_{\text{eff},j}(P_j) = 0$. For the weak coupling ($\Omega_{j,k} \ll \omega_{j,k}$) it is possible to perform a perturbative analysis of Eqs. (1), and obtain criteria of phase-locking in a closed analytical form. Thus, in the case of almost identical oscillators (where all the parameters of two oscillators, except the free-running frequencies $\omega_{j,k}(P_j)$, are identical) the phase-locking occurs when $|\omega_1(P_1) - \omega_2(P_2)| < \Delta\omega$, where the phase-locking band $\Delta\omega$ is given by

$$\Delta\omega = 2\Omega\sqrt{(1+\eta^2)|\cos(\beta - \arctan\eta)|}. \quad (2)$$

Here $\eta = (d\omega/dP) / (d\Gamma_{\text{eff}}/dP)$ is the dimensionless measure of the influence of the nonlinear frequency shift ($d\omega/dP$) compared to the influence of the nonlinear damping ($d\Gamma_{\text{eff}}/dP$), and β is the phase difference between the oscillators caused by the delay of the coupling signal.

The optimum phase shift $\beta_{\text{opt}} = \arctan\eta$ for which $\Delta\omega$ has a maximum value $\Delta\omega_{\text{max}} = 2\Omega\sqrt{(1+\eta^2)}$ changes from 0 for $|\eta| \ll 1$ (conventional oscillators) to $\pi/2$ for $|\eta| \gg 1$ (STOs). The latter fact has been recently observed in numerical experiments [5].

The dependence of the phase-locking interval $\Delta\omega$ Eq. (2) on the distance a between the oscillators for typical STO parameters is shown in Fig. 1 (see curve 1). The overall decrease of the synchronization band (see curve 2 in Fig. 1) is caused by the decrease of the coupling coefficient Ω with the increase of the distance a .

Our results reveal the relation between the frequency nonlinearity of the STO and the optimum delay time (or, equivalently, phase shift) of the coupling signal, and allow one to calculate the

parameters of the oscillator array (such as STO separation a) that are optimum for the STO synchronization.

Dependence of the frequency band of phase-locking $\Delta\omega$ for two STO separated by a distance a : 1 – phase-locking band $\Delta\omega$ with account of time delay and frequency nonlinearity η , 2 – maximum possible band $\Delta\omega_{\text{max}}$, 3 – phase-locking band $\Delta\omega$ for linear oscillators $\eta = 0$ multiplied by 10. Parameters of STOs: normally magnetized (magnetic field 15 kOe) circular nano-contacts of the radius 50 nm, saturation magnetization $4\pi M_0 = 8$ kOe, Gilbert damping constant $\alpha_G = 0.01$, nonlinear damping parameter $Q = 3$, exchange length 5 nm, supercriticality parameter $I/I_{\text{th}} = 1.5$.

Influence of the Demagnetizing Field in Spin Dynamics with A Perpendicular-to-Plane Polarizer.

C. Jui-Hang, C. Ching-Ray

Department of Physics, National Taiwan University, Taipei, Taiwan

It is known that a “perpendicular-to-plane polarizer (PERP)” used in spin-transfer torque device has many interesting results, and with potential application in spin-injected device [1][2]. In the device, the polarization of the

injected spin current is perpendicular to the easy plane of the free layer. As a result, the precessional frequency of a large-cone angle ($|\theta| \approx \pi/2$) steady state of the free layer moment can be tuned by changing the injected current in the absence of the external applied field. The first analytical results of the perpendicular-to-plane polarizer were given in Lee’s paper [3]. In their paper, the critical current density is proportional to the uniaxial anisotropy field H_k . Since they assume the cancelation of the demagnetizing field and fringe field from the pinned layer, the critical spin-torque amplitude for large-cone angle precession motion to start is independent of the damping constant α , demagnetizing field, and fringe field. In the article, we take an extra consideration of the effects of the demagnetizing and stray fields, and derive a rigorous form of the critical current density, which is sensitive to the damping constant, demagnetizing and fringe fields. The Landau-Lifshitz-Gilbert (LLG) equation of motion for the free layer moment including a Slonczewski’s spin-transfer torque is $d\mathbf{M}/dt = -\gamma(\mathbf{M} \times \mathbf{H}_{\text{eff}}) + (\alpha/M_s)\mathbf{M} \times (d\mathbf{M}/dt) + (\gamma a_j(\theta)/M_s)\mathbf{M} \times (\mathbf{M} \times \mathbf{p})$, where \mathbf{p} is the unit vector of spin polarization direction along the z axis, and $\mathbf{H}_{\text{eff}} = H_k(\mathbf{M} \cdot \mathbf{x}/M_s)\mathbf{x} + (H_z - 4\pi M_z)\mathbf{z}$ is the internal effective field, including the in-plane anisotropy field, stray field, and demagnetizing field. In spherical coordinates, the LLG equation can be written as a set of two first-order differential equations, $[(1+\alpha^2)/\gamma]d\theta/dt = h_1 + \alpha h_2$, and $[(1+\alpha^2)/\gamma]\sin\theta(d\phi/dt) = -h_2 + \alpha h_1$, where $h_1 = -H_k \sin\theta \sin\phi - \cos\phi + a_j(\theta)\sin\theta$, and $h_2 = H_k \sin\theta \cos\theta \cos^2\phi - (H_z - 4\pi M_s \cos\theta)\sin\theta$. To find the instability for the spin current at large cone-angle

precession motion, we have to average the rate of energy change, where the potential energy for the free layer magnetization is $U(\theta, \phi) = K(1 - \sin^2\theta \cos^2\phi + h_D \cos^2\theta - 2h_z \cos\theta)$. K is the uniaxial anisotropy constant, $h_D = 4\pi M_s/H_k$, and

$h_z = H_z/H_k$. Taking time average for the energy variation, we obtain the stability threshold for spin-current-driven motion at the large cone-angle limit ($|\theta| \approx \pi/2$), $J_C^{\text{PERP}} = \alpha(4e/\hbar) [M_s \bullet t/g(\theta \approx \pi/2)] [(H_k^2/2 + 2\pi M_s H_k + H_z^2)/(3H_k^2/8 + 2\pi M_s H_k + 2H_z^2)] H_z$, which depends on damping constant α , anisotropy field, demagnetizing field, and stray field. Instead of the linear response of anisotropy field H_k [3], we find that the critical current density for the perpendicular-to-plane polarizer device depends on the anisotropy field nonlinearly as shown in Figure 1; and further, the threshold current density can be reduced.

Investigation of spin-wave radiation and current controlled three-magnon-scattering in spin-torque nanocontact devices.

H. Schultheiss¹, X. Janssens², M. van Kampen², S. Cornelissen², F. Ciubotaru¹, A. Laraoui¹, B. Leven¹, A. N. Slavin³, L. Lagae², B. Hillebrands¹

1. Fachbereich Physik and Forschungsschwerpunkt MINAS, TU Kaiserslautern, Kaiserslautern, Germany; 2. IMEC, Leuven, Belgium; 3. Oakland University, Rochester, MI

The magnetization dynamics of spin torque oscillators are of large interest for the fundamental understanding of the interaction between a spin polarized current and a magnetic thin film. A deeper understanding of the eigenmode spectrum of a nanocontact and the mechanism of spin-wave radiation is advantageous for technical applications.

Here we report on Brillouin light scattering microscopy investigations of the magnetization dynamics in spin-torque nanocontacts under the influence of an applied ac and dc current. The magnetic resonance frequencies of the nanocontacts are determined by Brillouin light scattering microscopy for different externally applied magnetic fields. For the observed resonance frequencies the spin-wave radiation patterns are studied with high spatial resolution. The spin-wave radiation patterns are studied for several applied microwave frequencies. Strong nonlinear effects are observed and discussed within the framework of three-magnon-scattering.

Intriguing is the shift of the power threshold for these nonlinear processes when a dc current is applied. Depending on the dc current direction the threshold and efficiency of the three-magnon-scattering can be strongly enhanced or reduced. This is a clear evidence that the internal damping due to magnon scattering can be tuned by a dc current.

Support by the DFG within the SPP 1133 and by the EC-MRTN SPINSWITCH (MRTN-CT-2006-035327) and EC-Dynamax (IST-033749) is acknowledged. MvK acknowledges the IWT Flanders for financial support.

Spin-wave spectra in the vicinity of the contact area of the spin torque device measured with Brillouin light scattering microscopy for different applied microwave frequencies. The diagonal indicates the directly excited magnetic resonances whereas the signals above and below the diagonal show the intensities of spin waves created by nonlinear processes.

The power threshold for the appearance of spin waves with half the excitation frequency due to three-magnon-scattering can be tuned in a wide range if a dc current offset is applied. Below -2.5 mA the half frequency generation is completely suppressed.

Mutual phase-locking in high frequency microwave nanooscillators as function of field angle.

We perform a qualitative analysis of phase locking in a double point-contact spinvalve system by solving the Landau-Lifshitz-Gilbert-Slonzewski equation using a hybrid-finite-element method. We show that the phase-locking behaviour depends on the applied field angle. Starting from a low field angle, the locking-current difference between the current through contact A and B increases with increasing angle up to a maximum of 14 mA at 30° and it decreases thereafter until it reaches a minimum of 1 mA at 75°. The tunability of the phase-lock frequency with current decreases linearly with increasing out of plane angle from 45 to 21 MHz/mA.

The model simultaneously solves the modified Landau-Lifshitz-Gilbert equation which is expanded with the asymmetric Slonczewski spin torque term and the Maxwell equations with a finite element/boundary element method.

The study was carried out on a spin valve structure consisting of Co90Fe10(20nm)/Cu(5nm)/Ni80Fe20(5nm). The Co90Fe10 layer is considered as the fixed layer meaning that the magnetization is pinned in terms of the spin torque driven magnetization processes due to a larger thickness, d , and higher saturation magnetization, M_s , compared to the Ni80Fe20 free layer. The spin valve system is contacted with two Cu point contacts (40nm in diameter) with a centre to centre distance of 500nm. The overall size of the simulation area was 1000 nm in diameter, with a discretization size of 4.5nm. We apply a fixed current through point contact A ($J_{e,A} = 7.16 \times 10^{12}$ A/m²) and a varying current through point contact B at an external field of 740 mT at 15° out of plane. Starting with the same current density through both contacts two well distinguishable peaks can be observed (see figure 1). Although the current through both currents is the same two different frequencies can be observed (one at 24.5 GHz and the other at 25.108 GHz). This is connected to the variation of the local change in magneto resistance, the direction of the applied field, the asymmetric Slonczewski term and the incoming spin waves from each point contact. Increasing the current density to 1.67×10^{13} A/m² (21 mA) a phase-locking behavior can be observed, see figure 2, which originates from spin waves traveling through the device and synchronizing the individual oscillators at a frequency of 24.505 GHz. By increasing the current density above 1.83×10^{13} A/m² (23 mA) the coherence of the individual oscillators breaks down and two separate oscillation frequencies of 24.5 GHz and 24.475 GHz can be distinguished. By increasing the applied field angle to 30° two things can be observed: a red shift in frequency and a shift of the locking regime to higher currents. The tunability changes to 31 MHz/mA and the locking current difference (difference between current through contact A and B) ΔI_{AB} is increased to 14 mA. For an out of plane field angle of 45° the slope of the curve $f_B(I_B)$ becomes smaller, so that the frequency decreases with increasing current at a rate of 21 MHz/mA; the locking current difference ΔI_{AB} drops to 6 mA. For high out of plane field angles of 75°, the frequency of the magnetization oscillations near contact B first decreases and the one from A increases until they oscillate with the same frequency. The phase locking regime persists until the current in contact B is increased by 1 mA, where after two well distinguished frequency are observed, and show a blue shift in frequency with current. The average increase in frequency with current is 179 MHz/mA. ΔI_{AB} is reduced to 1 mA. We show in this paper that the locking current difference is a function of applied field angle, which has its minimum of 1mA at high angles (75 degree) and reaches a maximum at low

angles 15 degree. This value is similar to the locking-current difference found experimentally for a field angle of 75° [1] and shows that these results are in good agreement with the experiments published by Rippard [1] and Kaka et al [2].

This project is supported by the EU FP project 6 TUNAMOS (IST-16939).

The spin torque due to a spin polarized current in a nanomagnet can induce either magnetization reversal or several different kind of magnetization dynamics (self oscillations)[1,2]. Recent time domain measurements of nanomagnet dynamics in exchange bias nanoscale spin-valves (IrMn/Ni80Fe20(Py)/Cu/Py) of elliptical cross sectional area (130nm x 60nm) show magnetization reversal and persistent dynamics excited in nanosecond scale[3]. Time domain measurements together to frequency domain measurements are able to explain completely the magnetization dynamics [4,5].

The frequency domain analysis gives information about the excited modes during all the measurement time with no information about the range of time where the mode is excited, this range can be determined by means of single shot storage oscilloscope measurements.

For the device employed in [3] those measurements show in the range of 20ns a frequency spectrum with two peaks, the same measurements in the range 0-4ns or 16-20ns show one the two peaks isolated.

Here we study in detail the same devices of ref[3] by means of the micromagnetic simulations and the micromagnetic spectral mapping technique (MSMT)[6]. We numerically solved the Landau-Lifshitz-Gilbert-Slonczewski equation [7] including the thermal field as an additive component to the effective field (we simulate a background temperature of 4.2K). For the spin torque, we use the formulation presented in [8] where shape of the torque has been computed by fitting experimental reversal data[5]. The pinned layer of the device is exchanged bias at 45 degrees with respect to the easy axis of the ellipse, the external field is applied at -45 degrees with respect to the easy axis. Here we report results related to an applied field of 68mT and current density of $0.5 \cdot 10^8 \text{ A/cm}^2$. Fig. 1(a) shows the temporal evolution (60ns) of the x, y and z component of the average magnetization for that process, as can be noted from the spectrum of Fig. 1(b) the magnetization dynamics is mainly characterized by two excited modes (P1 at 6.4GHz and P2 at 7.35GHz, the insets of Fig. 1(b) show the spatial distribution of those modes computed by means of MSMT (power increases from white to black)). Performing the MSMT in different range of time we observe the magnetization dynamics governed by the P1 mode in the range (0-20ns) and a by the P2 mode in the range 40-60ns. Those results (also observed for other currents and fields) show the existence of jump between different dynamical modes in the nanosecond regime in agreement with experimental data. In the paper we will present a complete non-stationary study of the persistent magnetization dynamics and a generalization tool of the MSMT able to characterize the presence of those jumps systematically.

It is well-known that a spin-polarized current can apply a torque on the local magnetization of a ferromagnet [1]. This effect provided a new technique for manipulating nanoscale magnetic systems. Experiments have demonstrated that spin-torque can be successfully used to build microwave oscillators which do not require the usage of external bias magnetic fields [2] as well as to excite steady-state magnetization oscillations in strongly non-uniform magnetic configurations, such as a vortex state [3]. The vortex-state is a three-dimensional spin structure whose magnetic moments are arranged in closed loops and tend to rise up within a small inner region (the vortex-core) to minimize the energy cost. The sense of flux-closure (counterclockwise or clockwise) is referred to as chirality, whereas the out-of-plane component of the vortex-core (positive or negative) determines the so-called polarity. This latter parameter acquires a fundamental role in gyrotropic vortex dynamics (and vortex-core reversal) because it determines the sense of gyration, independently of the chirality [4,5]. The earlier experiments demonstrated that a vortex-core reversal can be induced by applying either a static or a pulse of a relatively strong external magnetic field [5,6]. Later on, an analogous outcome has been obtained by using either an ac or a dc spin-polarized current [3,7,8]. In particular, it was recently demonstrated that a magnetic tri-layer nanocontact system, subjected to a dc spin-polarized current, can sustain a persistent magnetization precession without the usage of any bias field [8]. Moreover, it was predicted a strategy to increase the precession frequency by using a material with magnetocrystalline anisotropy in the thin magnetic “free” layer (FL) of the structure [8]. In that work, it was shown that the resulting oscillations correspond to a periodic gyrotropic motion of the vortex core, whose polarization and sense of gyration switch periodically. While the main goal of the work in Ref.8 was to demonstrate the feasibility of the so-called bias-field-free configuration, a detailed analysis of the properties exhibited by such oscillator as function of the anisotropy field strength was not carried out. With this in mind, in this work we present such a systematic study in order to gain a better understanding of the magnetization dynamics in nanocontact devices at zero-field driven by dc spin-polarized current and subjected to a perpendicular anisotropy field in the FL of variable strength. In detail, the anisotropy field strength is varied by acting on the anisotropy constant value (k_u) in order to perform a full-scale investigation: from the case of no anisotropy ($k_u=0 \text{ J/m}^3$) to the one corresponding to a strong anisotropy ($k_u=1 \times 10^5 \text{ J/m}^3$). The study is carried out by using our 3D full-micromagnetic simulation framework, where the magnetization is assumed uniform in each cell and the Landau-Lifshitz-Gilbert-Slonczewski equation is solved by a fifth-order Runge-Kutta scheme [9]. The effective field carries the contribution of anisotropy, external, exchange, Oersted and magnetostatic fields. We have neglected the stochastic contribution arising from thermal noise. In all the analyzed cases, the output spectra are dense of harmonics, so that the corresponding time-domain signals are not pure sinusoids. Because it is well-known that spin-wave excitation in such devices exhibits a threshold character, our first investigation is devoted to the analysis of the dependence of the excitation threshold current I_{th} on the anisotropy field strength. Results summarized in Fig.1 (dashed line) reveal a linear dependence I_{th} vs k_u , with the threshold current which decreases with the increase of the anisotropy field. The calculation of the frequency generated at that threshold f_{th} allows to derive another intriguing property. In fact, a nonlinear dependence f_{th} vs k_u is found (see Fig.1, solid

line), similar to the one obtained in Ref.8 in presence of a strong bias field. It shows that, at the excitation threshold, the precession frequency decreases with the increase of the anisotropy field strength. If a similar investigation is carried out at the same applied current value, the inclusion of materials with perpendicular anisotropy is always associated to higher generated frequency with respect to the case of no anisotropy. In such situation, the precession frequency exhibits a non-monotonic dependence on the anisotropy field, i.e. there exists a given value of anisotropy which determines a maximum of the output frequency.

Linear and Nonlinear Frequency Modulation of Nanocontact Spin-Transfer Oscillators: A Micromagnetic Study.

G. Consolo¹, V. Puliafito¹, L. Lopez-Diaz², B. Azzerboni¹

1. Dipartimento di Fisica della Materia e Tecnologie Fisiche Avanzate, University of Messina, Messina, Italy; 2. Departamento de Fisica Aplicada, University of Salamanca, Salamanca, Spain

It has been theoretically predicted [1] and experimentally observed [2,3] that a dc current passing through a thin magnetic layer (“free” layer) of a magnetic layered structure can excite microwave magnetization oscillations in this layer. This phenomenon occurs because the bias current becomes spin-polarized in the direction of magnetization of a thicker (“fixed”) magnetic layer, and then can transfer this induced spin angular momentum to the magnetization of the thinner free layer. One of the most efficient setup which has been used to sustain such steady-state precessions is the so-called nanocontact (or point-contact) geometry [1-3]. In these devices, the output frequency is tunable with both a static magnetic field and a dc current [2,3]. In addition, very narrow linewidths have been obtained as consequence of a large effective volume [4]. One of the most promising applications for communication systems was the experimental observation that the addition of an ac current to the dc bias current can be used to generate a frequency modulated (FM) output signal [3]. Moreover, since the excited output frequency in such devices is generally a nonlinear function of the input bias current [2,3], the possibility to build nonlinear spin-transfer modulators was opened [3]. While the experimental results were in agreement with theoretical models of nonlinear modulation [5], the corresponding numerical macro-spin simulations failed to describe the phenomenon accurately [3] and, to the best of our knowledge, a micromagnetic study has not been carried out so far. With this in mind, in this work we propose a full-scale micromagnetic investigation in order to get a better understanding of magnetization dynamics involved in modulation process as well as to get information about the spatial distribution of the excited spin-wave modes. To this aim, by using our micromagnetic framework [6], we take into account a setup very similar to the one proposed in Ref.3, where a nanocontact device is contemporary subjected to the combined action of a dc current, ac current and an out-of-plane bias field. When no ac current is applied, the output frequency vs. dc current dependence is a nonlinear function which can be partitioned into linear sub-intervals. This latter property allows us to carry out a detailed numerical investigation on both linear and nonlinear frequency modulators. To perform such study, we set a bias point $I_{dc}=18$ mA and we vary both magnitude (I_{ac}) and frequency (f_m) of the modulating signal. For $I_{ac}<0.5$ mA, a linear FM signal is derived whereas, for $I_{ac}>0.5$ mA, a nonlinear FM signal is observed. By acting on the modulation index, also, we analyze two cases of frequency modulation: narrow-band and wide-band.

Our results show that the frequency spectrum of a linear FM signal is composed by a central peak (f_c), corresponding to the carrier frequency, and equal-amplitude sidebands ($f_c \pm n f_m$), corresponding to the symmetric shift of the carrier at integer harmonics of the modulating frequency f_m . On the other hand, the spectrum of a nonlinear FM signal is composed by a central peak at a frequency (f'_c), which is shifted from the carrier frequency by an amount proportional to both the frequency sensitivity and the amplitude of the modulating signal, and nonequal-amplitude sidebands ($f'_c \pm n f_m$). An example is shown in the inset of Fig.1. In the case of a narrow-band modulation, a residual of amplitude-modulation (AM) also takes place (as shown in the main panel of Fig.1). We compare our numerical results to both experimental observations [3] and linear and nonlinear theoretical models of frequency modulation [5] deriving a satisfactory agreement.

Finally, by means of micromagnetic spectral mapping techniques [7], we also analyze the spatial distribution of spin-wave modes at each frequency. The latter investigation allows us to establish how an asymmetry in the frequency domain reflects in the spatial domain.

Intrinsic Capacitance Effect on Microwave Power Spectra of Spin-Torque Oscillator with Thermal Noise.

B. Guan¹, Y. Zhou², F. Shin¹, J. Åkerman²

1. Applied Physics, The Hong Kong Polytechnic University, Hong Kong, China; 2. Institute of Microelectronics and Information Technology, Royal Institute of Technology, Stockholm-Kista, Sweden

Theory predicted that a spin-polarized current can exert a torque on a nano-scale magnet[1]. This torque can excite magnetization precessional motion with a steady microwave frequency ranging from 5 to 40 GHz that is tunable by adjusting current and applied magnetic field, and the quality factor as high as 18,000 [2]. The high Q value and the current tunability of these spin-torque oscillators (STOs) suggests their potential use in microwave signal processing applications.

However, there are also a number of discrepancies between the behaviors predicted by macro-spin simulation and the measured behaviors of the precessional dynamics in STOs. Experimentally, even at the temperature $T=100\text{K}$, the excitation has very narrow linewidth, leading to quality factors Q on the order of 10^4 [3]. But the Q determined by both numerical simulation and analytical approach is much smaller [4]. As STOs have now been implemented in different materials and configurations, e.g. magnetic tunnel junctions (MTJs)[5], we believe that the intrinsic capacitance of the STOs structure will influence thermal stability of the system, and keep the Q factor of microwave power spectrum at a high level.

In our STOs model, a typical giant magnetoresistance (GMR) trilayer system has been adopted, with one fixed and one free ferromagnetic layer separated by a nonmagnetic spacer. The dynamics of the free layer magnetization is determined by the Landau-Lifshitz-Gilbert-Slonczewski equation, the details of which have been given by, e.g., Ref. [6].

The equivalent circuit of a spin-torque oscillator model is shown in Fig. 1. Here, an ideal capacitor C is connected in parallel with the STO to represent the intrinsic capacitance of the structure or that of connecting leads [7].

To study the temperature effects on spin valve behavior, we model the thermal fluctuations by adding a Langevin random field to the effective field, which consists the contribution of applied field, demagnetization field and uniaxial anisotropy field. The added thermal field is a fluctuating random field whose statistical properties obeys the Gaussian distribution [8]. In the presence of thermal fluctuations, the microwave power spectrum gets broadened with increasing temperature. The emitted power at a given frequency is derived by Fast Fourier Transform, and the data are fitted to a Lorentzian profile (dashed line), from which the quality factors Q are calculated.

Fig. 2 shows the power spectra at $T = 30$ with and without the added capacitance. The fitted Q values are 4200 and 1550 respectively. Fig.3 shows the same result at 100K where fitted Q values are 2300 and 1100 respectively. The addition of a small capacitance can hence enhance the quality factor about a factor of 2. Increasing the capacitance is also found to increase the quality factor even further.

In summary, the intrinsic capacitance effect does influence the stability of the system, and it can improve the Q factor value of the STO element even in the presence of thermal fluctuation. It is hence possible that some of the underlying reason for the high quality factors observed in experiments may be ascribed to either intrinsic or extrinsic sources of capacitance in parallel with the STO.

Spin torque oscillator phase locking to a noisy alternating current.

E. Iacocca, Y. Zhou, J. Persson, . Johan

Institute of Microelectronics and Information Technology, Royal Institute of Technology, Stockholm-Kista, Sweden

Recently, it has been experimentally demonstrated that a STO can lock to an injected alternating current [1]. In addition, recent numerical work has shown that there exists an unexpected intrinsic phase shift between the STO and the applied ac current. This phase shift can furthermore be utilized to improve the synchronization robustness of serially coupled STOs [2,3]. In this work we study the detrimental effects of current noise in the injected radio frequency current. We find that the STO will still lock to the injected current despite very large amounts of current noise. While the instantaneous phase difference between the STO and the injected current can be quite large, the average phase relation is still well defined.

A typical simulation with added white noise to the drive current is shown in Fig.1. The Stochastic Landau-Lifshitz-Gilbert- Slonczewski (LLG) equation, which is solved by the Ito calculus and a numerical method described by Milshtein [4], is used to determine the free layer motion. Before the ac current is turned on, the STO is allowed to settle into a steady state precession for about 30 ns. We then allow for an additional 10 ns of precession before analyzing the phase relation between the STO and the rf current.

Fig. 2 shows the intrinsic phase shift as a function of drive current for different noise levels. Despite the added noise, a well defined phase relation persists up to very high noise levels. Fig.3 shows the instantaneous phase relation over 10,000 precession periods for 3 different noise levels. While the average phase shift remains the same, the instantaneous values exhibit a Gaussian distribution with a width proportional to the added noise level.

We interpret the insensitivity to injected noise as due to the inertia of the precessing magnetization. The apparent Gaussian distribution originates from the phase noise of the rf current and not from that of the STO. We believe this insensitivity holds great promise to allow for STO synchronization even in the presence of inherent rf noise in existing Si CMOS technology.

Point contact Spin Torque Oscillators at high magnetic fields: Non-monotonic field dependence of oscillation threshold current.

S. Bonetti¹, J. Garcia¹, J. Persson¹, F. B. Mancoff², J. Åkerman¹

1. Microelectronics and Applied Physics, Royal Institute of Technology (KTH), Kista-Stockholm, Sweden; 2. Technology Solutions Organization, Freescale Semiconductor Inc., Chandler, AZ

Spin torque oscillators (STOs) [1–3] are one of the promising applications in spintronics. In these devices, a spin-polarized current can transfer its spin angular momentum to the magnetization of a thin magnetic layer and induce a precession in of the magnetization itself. Due to giant magnetoresistance (GMR) [4,5] or tunnelling magnetoresistance (TMR) [6–8] effects, one can detect an ac voltage with typical frequencies in the GHz range. These devices are compact (~100 nm in lateral size), can be tuned in frequency in an approximately linear way by varying the applied current and magnetic field magnitude, and the tuning range is rather large, on the order of tenth of GHz [9]. In this work we investigate the threshold of the oscillation region (in terms of applied magnetic field, driving dc current and frequency) when large magnetic fields (compared to the films coercive field) are applied normal to the film plane.

Samples are point contact $\text{Co}_{81}\text{Fe}_{19}$ (20 nm)/Cu(6 nm)/ $\text{Ni}_{80}\text{Fe}_{20}$ (4.5 nm) spin valves. The contact shape is elliptical, with minor axis $a = 130$ nm, and aspect ratio 3:1 between major and minor axes. Results are presented in Fig. 1. The dependence of the threshold current on the applied field is plotted in Fig. 1a (symbols and continuous line). A clear minimum can be observed for a field value of approximately 1.25 T. In Fig. 1b, the relation between the magnetic field and the threshold oscillation frequency is shown. In this case the trend is monotonic, with a visible dip centered close to the same field value.

The first observation, the minimum in the threshold current at a certain value of field, can be explained by comparing it with the demagnetization field of a NiFe thin film [10], which is at about 1.1 T. The two values are close, and in the case when the applied magnetic field counteracts the demagnetization field, the energy needed for the magnetization to be pushed out of plane is a minimum. In STOs, the energy is provided by the continuous flow of dc current, and therefore one expects a minimum in the current needed to start oscillations.

The experimental behavior of the threshold current I_{th} can be fitted with the following empirical equation, quadratic in the applied field:

$$I_{th} = I_{min} + \beta(H - H_d)^2$$

where H is the applied field, $I_{min} = 39$ mA, $H_d = 1.25$ T (close to the theoretical value of 1.1 T), and $\beta = 1.2 \times 10^2$ A/T². This expression is plotted as dashed line in Fig. 1a.

The second observation, the monotonic increase of threshold frequency with applied magnetic field, shows that field tunability is the dominant mechanism in determining the threshold frequency value. These devices show fairly linear frequency tunability both in current and field, as can be seen in Fig. 2. If current tunability had a larger effect than field tunability, one would expect the frequency vs field curve to be similar to the current vs field one (Fig. 1a). However, as clearly observed in Fig. 1b, when both current and field vary over a range which is approximately three times their minimum value (from Fig. 1a), the tuning due to the current just slightly influences (with the appearance of a central dip) the tuning due to the field.

With further experimental data available, we are also planning to perform a study on the linewidth and on the output power of the oscillation peak along the threshold

Fig. 1. Threshold current and frequency as a function of the magnetic field, applied close to the normal to the film plane (10° offset). (a) There is a clear minimum of the threshold current at about 1.25 T. (b) The frequency threshold is proportional to the applied field.

Fig. 2. Oscillation frequency as a function of the driving dc current, at different values of the field. Linearity in both quantities is readily noticed (tunability coefficient are 120 MHz/mA and 18.5 GHz/T). In color scale, the integrated output power.

Time-dependent locking between a spin torque oscillator and an ac current.

Y. Zhou, J. Persson, J. Åkerman

Institute of Microelectronics and Information Technology, Royal Institute of Technology, Stockholm, Sweden

Using magnetodynamic simulations based on the Landau-Lifshitz-Ginzburg-Slonczewski equation, we study the detailed dynamics of the preferred intrinsic phase shift Spin Torque Oscillator (STO) and an alternating current. Depending on the details of both the STO and the applied current, this system can be overdamped, critically damped, or underdamped.

Recently, it has been experimentally demonstrated that a STO can lock to an injected alternating current [1]. In addition, recent numerical work has shown that there exists an unexpected intrinsic phase shift between the STO and the applied ac current. This phase shift can furthermore be utilized to improve the synchronization robustness of serially coupled STOs [2,3]. A typical simulation illustrating the existence of an intrinsic phase shift between the STO resistance and the external drive signal I_{ac} is shown in Fig.1. Before the ac current is turned on, the STO is allowed to settle into a steady state precession for about 24 ns. When the ac current Fig. 2 shows the temporal evolution of the relative phase shift $\Delta\phi$. From Fig. 2, we can see that $\Delta\phi$ gradually transits to the same steady state value $\Delta\phi_0$, regardless of the initial values. The underlying driving mechanism behind the preferred phase shift has been semi-analytically derived in a recent work by following the energy conservation law [3]. Depending on the ac current amplitude, the system can be under damped ($I_{acamp} = 228 \mu A$), critically damped ($I_{acamp} = 57 \mu A$), and over damped ($I_{acamp} = 19 \mu A$) as shown in Fig. 3 (I_{acamp} denotes the amplitude of the alternating current). For larger ac driving current, the system undergoes a under damped ringing transition before it finally settles down in the steady state. The ringing behaviour is expected to significantly affect the robustness of locking states of two serially connected STOs.

In summary, we have studied the detailed temporal locking characteristics of the STO under the interaction of an alternating current by using magnetodynamic simulations of the Landau-Lifshitz-Ginzburg-Slonczewski equations. It is found that the STO locks to the alternating current on a well-defined preferred phase shift regardless of the initial phase differences. The intrinsic $\Delta\phi_0$ and its temporal locking characteristics will impact any circuit design based on STO technology and will have direct consequences for phase locking in networks of serially connected STOs.

Estimation method on multiple sources of MEG based on columnar structure of the cerebral cortex.

H. Fukuda¹, M. Odagaki¹, O. Hiwaki¹, A. Kodabashi², T. Fujimoto²

1. Graduate School of Information Sciences, Hiroshima City University, Hiroshima, Japan; 2. Fujimoto Hayasuzu Hospital, Miyakonojo, Japan

1. Introduction

We propose a new method for estimating multiple electrical sources of brain activity by using magnetoencephalography (MEG) data.

The equivalent current dipole (ECD) method, which uses the moving-dipole model [1], has been generally employed for estimating electrical sources of MEG. There are several drawbacks for this method. First, the least squares algorithm does not ensure that the global optimum solution is obtained because the model has much redundancy. Second, operators have to separate multiple pairs of source and sink before the estimation of multiple dipoles. Third, the estimated position and orientation of the ECD do not necessarily reflect the columnar structure which is hypothesized as a minimum functional subunit of the cerebral cortex [2]. The first and third drawbacks are associated with not only this method but also other conventional methods [3].

In the proposed method, multiple dipoles can be estimated without selecting a pair of source and sink beforehand and employing any repeated algorithms in which a solution depends on an initial value. Moreover, the estimated dipoles reflect the columnar structure.

2. Method

Considering the columnar structure, the position and orientation of assumed current dipoles are limited to the surfaces of the cerebral cortex and along directions perpendicular to these surfaces, respectively.

The surfaces of the cerebral cortex are extracted from MR images of the head and represented by some voxels labeled “surface voxels.” The assumed current dipoles are located at the surface voxels. For each surface voxel, unit vectors, which are oriented toward the adjacent voxels not labeled surface voxels, are calculated. Orientation of the surface vector at the surface voxel is defined as the total sum of the unit vectors. This step is similar to that adopted by Hayami et al. [4].

According to the Biot-Savart law, the relationship between the moment of the assumed current dipole located at the j -th voxel q_j and the magnetic field on the scalp surface reflects the activity of the j -th assumed dipole $\mathbf{b}_j = [b_{1j} \ b_{2j} \ \dots \ b_{Mj}]^T$ can be expressed as $\mathbf{b}_j = \mathbf{L}_j q_j$, where M is the number of the MEG sensors, b_{ij} is the magnetic-flux density measured by the i -th sensor and vector $\mathbf{L}_j = [L_{1j} \ L_{2j} \ \dots \ L_{Mj}]^T$ represents the sensitivity of the sensors to the j -th dipole. \mathbf{L}_j is fixed in this step because the position and orientation of the j -th assumed dipole have been calculated in the surface extraction step mentioned above, while this vector must be detected by a repeated algorithm in the conventional methods.

Here, it is assumed that a single pair or spatially separated multiple pairs of source and sink observed in the N20m component of the somatosensory evoked field (SEF) or in the N100m component of the auditory evoked field (AEF) is/are targets to be analyzed. In these cases, the correlation between the measured field data \mathbf{b} and \mathbf{L}_j will be higher if the j -th assumed dipole is a real dipole. Hence, we consider the assumed dipole with spatially maximal correlation in the cortical surface as the real dipole.

3. Experiments

The proposed method was applied to estimate multiple electrical sources of the N20m SEF elicited by bilateral median nerve stimulation and the N100m AEF data elicited by bilateral pure tone stimulation.

From the SEF data, two dipoles were estimated in the postcentral gyri on both the hemispheres (Fig. 1). It was found that the value of each dipole almost agreed with the value estimated when the right/left median nerve was stimulated separately.

From the AEF data, two dipoles were estimated in the superior temporal gyri on both the hemispheres in many cases (Fig. 2). In some cases, the dipoles were estimated in the upper bank of the Sylvian fissure at a distance of 5mm from the superior temporal gyrus.

4. Discussion

The proposed method could estimate multiple dipoles when applied to the SEF or AEF data. These results indicated that our method can be used to estimate multiple dipoles in the cases where two pairs of source and sink are spatially separated. Moreover, our algorithm always leads to a unique solution once the assumed current dipoles are extracted from MR image. It is insisted that our method is used for analyzing brain activity.

Stochastic resonance in phase synchronization of auditory steady state responses in MEG.

K. Tanaka¹, M. Kawakatsu², I. Nemoto^{1,2}

1. Research Center for Advanced Technologies, Tokyo Denki University, Inzai, Japan; 2. School of Information Environment, Tokyo Denki University, Inzai, Japan

1. Introduction

Auditory steady-state responses (ASSRs) to sinusoidal amplitude-modulated (SAM) waves have been studied extensively. The phase behavior of ASSRs has been used for determining hearing thresholds. However, the mechanisms of the generation of ASSRs are not known. We speculated from the result that synchronization of an ongoing 40 Hz component in MEG was at least partly responsible for the ASSR although the contribution of the superposition of evoked response to each cycle of the stimulus could not be excluded [1]. Possible synchronization of an ongoing process to the stimulus strongly suggested the presence of a nonlinear system, which then could give rise to stochastic resonance (SR). SR is often shown by nonlinear systems and refers to the decrease of noise to signal ratio (N/S) in the output obtained through an increase of the noise level in the input. We measured ASSRs to SAM tones which were presented with white noise of various intensities and examined the relationship between the N/S of the stimulus and the power and synchronization of the 40 Hz component of MEG.

2. Methods

The subjects were 5 males. A 1 kHz sinusoidal wave was amplitude modulated with modulation frequency 40-Hz and modulation depth 1.0 to obtain a SAM tone. A burst of the SAM tone lasting for 1.0 s was used as a stimulus for one epoch of MEG recording. The bursts of SAM were superimposed on white noise which lasted for one run consisting of 100 epochs. The intensity of the SAM tone was set at 40 dB above its threshold measured without the noise for each subject. The N/S used were 0, 0.02, 0.04, 0.06, 0.08 and 0.1. Stimuli were generated using a computer driven sound generator and delivered via ER2 transducers to ear inserts and then to the subject's right ear. MEG recordings were made with a 122-channel whole-head MEG system in a magnetically shielded room. For quantifying the degree of synchronization in ASSRs, we used the phase coherence. We estimated the phase coherence for the latter 500 ms period of the 1 s epoch.

3. Results

Fig.1 shows the power of ASSRs for the 6 N/S values in all the 5 subjects. Some subjects seemed to show 'positive' effect of noise.

Fig.2 shows the phase coherence of ASSRs for the 6 N/S values in all the 5 subjects. 4 out of 5 subjects were seen to demonstrate an increase in the phase coherence at some level of N/S compared to the noise-free condition. The position and shape of the peak differed much among the subjects. However, the peak of phase coherence in 4 out of 5 subjects were obtained for the N/S values for which the noise levels were their thresholds of hearing.

4. Discussions

We measured ASSRs to stimuli consisting of SAM and white noise with various N/S values to see if there was any sign of SR. The optimum N/S to obtain strong coherence in ASSR varied among subjects and hence ASSR power nor phase coherence showed significant increase with addition of noise when averaged over the subjects. One may have to devise an appropriate statistical method to detect SR effect which would not be smeared out by the differences among subjects. One method may be to employ the theory of extreme value distributions and treat the data as order statistics to get around the differences in optimum N/S values among subjects. Also, individual subject's data should also be statistically analysed so that any significant increase in power or phase synchrony at

any N/S may be detected for each subject. We have tried some tentative methods and started to have preliminary results which seem encouraging [2]. Our result suggests that SR can be seen in phase synchrony of ASSR. It should be noted that most of the reported SR was seen for subthreshold stimuli. In our experiment three thresholds are relevant. One is for the amplitude of the carrier sound, secondly the modulation depth, and the other is for the noise level. SR was observed for suprathreshold stimuli with respect to the first two thresholds for the modulated sound and at around the threshold level of the noise.

Preparation, Characterization and Testing of Magnetic Carriers for Arsenic Removal from Water.

A. M. Estevez¹, J. M. Rodriguez¹, A. Alvaro¹, P. A. Augusto^{2,1}

1. Department of Chemical Engineering, University of Salamanca, Salamanca, Spain; 2. DEQ, Faculdade de Engenharia da Universidade do Porto, Porto, Portugal

Abstract

To remove arsenic from water we developing a research project that applies magnetic separation methods. In order to increase the removal efficiency we are using magnetic aggregates. These magnetic aggregates are iron-based and were all (except for one) prepared by us. In this paper we report the preparation steps and some of the results of the characterization and absorption tests we have performed in order to conclude about its structure and efficiency in what concerns arsenic removal.

Arsenic Adsorption

Arsenic is found commonly in water under an inorganic form, mainly as arseniate (As V) in superficial waters and as arsenite (As III) in underground waters. As(III), for ordinary biological systems, is more toxic than As (V) [1,2].

In the present study we are aiming on the conjugation of the magnetic stabilized bed technique with adsorption of arsenic by ferromagnetic iron oxides.

Bearing in mind the above-described high adsorption capacity of the hydrated iron oxide FeOOH for the adsorption of As(III) and As(V) in water, as well as its magnetic properties, and the above-detailed problems in its practical application, we performing, in the present study, the conjugation of the magnetic stabilized bed technique [3,4,5,6] with adsorption of arsenic by ferromagnetic iron oxides, by applying some magnetic aggregate structures [7,8]. This will lead to a new process of arsenic elimination from water by its adsorption in a magnetic stabilized bed of hydrated iron oxide (FeOOH) particles, or, in the cases where these compound present less-adequate mechanical properties, in a magnetic stabilized bed of appropriated Fe-Si aggregates.

Preparation of Aggregates

One of the adsorbents used was purchased, but the rest of them was prepared as part of this work. The preparation of FeOOH is basically based on its precipitation from FeCl₃ 1M and NaOH 1N dissolutions. The magnetic aggregates of Fe-Si, were prepared by a co-precipitation from a dissolution of FeCl₃ 1M and also from a dissolution of Na₂SiO₃ plus NaOH 1N. The solid adsorbents were then dried at 105 °C and afterwards pulverized and filtered to make their size uniform. The several aggregates and the ways they were prepared are detailed in Table 1.

Characterization and Adsorption Tests

Several test and analysis were performed concerning the aggregates structure and absorption ability and in Figure 1 we present one of the most important ones (concerning their arsenic adsorption efficiency), as an example.

Synthesis of superparamagnetic nanoparticles by non conventional routes and their feasible application as contrast agents.

R. Costo, A. G. Roca, M. Morales, S. Veintemillas-Verdaguer
Materiales Particulados, Instituto de Ciencia de Materiales de Madrid, Madrid, Spain

Magnetic nanoparticles are of increasing technological and biomedical interest due to their unique properties [1]. A wide range of medical uses have been developed, from magnetic drug-targeting to hyperthermia and magnetic resonant imaging (MRI) [2]. In the last case, stable water dispersions of magnetic, small, rounded, hydrophilic particles at physiologic pH are preferred [2, 4] and not all methods to synthesize magnetic nanoparticles are suitable to prepare contrast agents for MRI with long blood circulating time [3].

Alternative synthesis routes have been developed in the last few years to improve the nanoparticles size distribution and the reaction yield. One of these new methods is the laser pyrolysis, which is a promising and versatile method that allows the continuous synthesis of various nanoparticles, with well defined chemical composition, size and structure [9]. On the other hand, thermal decomposition of organo-compounds in organic media allows the synthesis of superparamagnetic iron oxide nanoparticles with controlled size and shape, narrow size distribution and very good crystallinity [6, 7, 8].

In this work, aqueous suspensions stable at pH 7 have been prepared from nanoparticles synthesized by these two new methods. The as prepared particles were further modified by surface coating with carboxylic compounds to make them water stable. In the case of magnetite nanoparticles synthesized by laser pyrolysis, first they were subjected to a pretreatment with nitric acid and iron nitrate to improve their size distribution and then coated with phosphonoacetic acid (Sample L). In the case of the hydrophobic magnetite nanoparticles synthesized by decomposition, dimercaptosuccinic acid was used to remove the oleic acid making them hydrophilic (Sample O). A control sample consisting of a commercial iron oxide contrast agent was used for comparison.

All samples were stable in water in a wide pH range and, in particular at pH 7, they present a high negative charge which assures its stability [table 1]. Aggregate sizes smaller than 90 nm were measured by dynamic light scattering, which is an essential requirement for in vivo applications. Finally, magnetic and relaxometric characterization of these dispersions were carried out and it was concluded that particles with higher crystallinity, and therefore higher magnetization saturation and susceptibility, lead to relaxivity values that are almost three times higher than those measured for commercial MRI contrast agents with similar aggregate size.

Departamento de Química, Universidade de Trás-os-Montes e Alto Douro and CQ-VR, Vila Real, Portugal

Iron oxyhydroxynitrate is an ordered precursor of 6-line ferrihydrite in the process of hydrolysis of an iron nitrate salt [1]. The iron(III) oxyhydroxynitrate with general formula $\text{FeO}(\text{OH})_{1-x}(\text{NO}_3)_x$ ($0.2 < x < 0.3$) has been previously obtained in the form of a powder consisting of aggregated nanoparticles after freeze drying a Fe(III) nitrate water solution [1,2]. Here we report magnetic studies on iron(III) oxyhydroxynitrate nanoparticles with different average sizes grown in a organic-inorganic hybrid matrix. This allowed to access the magnetic properties of the isolated nanoparticles. These magnetic properties are compared to those of other iron oxides.

The first step of the nanohybrids preparation involves the synthesis of a cross-linked organic-inorganic hybrid precursor, similar to the one used in the synthesis of an undoped matrix, termed diureasil [3]. In the second step, a solution of iron(III) nitrate nonahydrate, water and ethanol was added to the non-hydrolyzed hybrid precursor. The resulting mixture was then stirred in a sealed flask for a few minutes at RT. After this, the solution was cast into a mould and transferred to an oven at ca. 40 °C for a period of 7 days. Samples were obtained after aging for 3 weeks at ca. 80 °C. Samples were labelled Ih(x), where x is the iron mass concentration.

The powder XRD patterns of the two most concentrated samples of Ih nanohybrids (Fig. 1) show that iron(III) oxyhydroxynitrate nanoparticles were efficiently stabilized in the matrix. Differences between patterns of iron(III) oxyhydroxynitrate and ferrihydrite are apparent: in the iron(III) oxyhydroxynitrate nanoparticles XRD patterns the relative intensity of the double peak at 60-65 °C is the opposite of that of ferrihydrite, and the shoulder appearing at 33 °C in the ferrihydrite nanoparticles is not present in the Ih nanohybrids. TEM images of the Ih(3.8) and Ih(6.5) nanohybrids show the presence of globular-shaped nanoparticles, with diameters of the order of 3 nm. The nanoparticles have nonfaceted and fuzzy edges and the nanoparticles/matrix contrast is low. SAXS patterns of Ih nanohybrids can be modelled as spherical isotropic and diluted Ih nanoparticles dispersed in a homogeneous matrix using GNOM [4]. The main conclusion of this analysis is that the particles size increases with the iron content.

The temperature dependence of the dc susceptibility χ shows that the Ih nanoparticles are superparamagnetic (Fig. 1): all zfc curves present a maximum at $T = T_B$ that increases with the iron content (Fig. 1, inset). This increase agrees qualitatively with the observed size increase, since the anisotropy energy E_a and therefore $T = T_B$ depend on size. Below $T \sim T_F$ the $M(H, T)$ curves of the Ih nanocomposites show irreversibility, that depends on the temperature and field history. Above $T \sim T_F$, the $M(H, T)$ curves of the Ih nanohybrids are reversible, and can be described as having linear and partial saturation components, associated to χ_{AF} and μ_{un} , respectively. We have considered a distribution of μ_{un} , with μ_{un} being described by a Langevin law. $\langle \mu \rangle_{un}$ was found to decrease with temperature and corresponds to a mean number of fully uncompensated Fe^{3+} ions of 3, 4, and 9 in samples Ih(1.7), Ih(3.8) and Ih(6.5), respectively.

For $T > T_B$, a paramagnetic-like doublet in the Mössbauer spectra of the Ih nanohybrids is observed, as expected for unblocked superparamagnetic particles. For temperatures below T_B , the Mössbauer spectrum is magnetically split in a sextet. As observed in the susceptibility, T_B identified with Mössbauer increases with the iron content. In sample Ih(6.5), the magnetic hyperfine field B_{hf} at 4.2 K is similar to that previously found for iron(III) oxyhydroxynitrate powders (B_{hf} 450-460 kOe [2]), being lower than that of 6-line ferrihydrite. At the same time, the isome shift QS shows some differences when compared to that usually found in 6-line ferrihydrite (-0.06 mm/s), approaching for that fitted for schwertmannite ($QS = -0.37$ mm/s at 4.2 K).

Biosorption of Cu(II) ions by magnetically labeled yeast.

S. V. Gorobets, V. V. Lizunov, I. V. Dem'yanenko

National Technical University of Ukraine "Kyiv Polytechnic Institute", Kyiv, Ukraine

Last years in connection with the sharp increase in environmental contamination by ions of heavy metals, the interest to working out new and to improvement of existing ways of clearing of liquids has considerably increased. The yeast culture *S. Cerevisiae* 1968 [1] is one of the perspective and inexpensive biosorbents used for clearing of liquids from ions of heavy metals and represents a by-product of many fermentative manufactures. For removal of yeast, which sorbed the ions of heavy metals, in a high-speed mode, the high-gradient magnetic separation (HGMS) is applied [2]. For this purpose the yeast cells obtain the magnetic properties by joining to them of magnetic labels. The aim of the present work was the finding of optimal quantity of magnetic labels (magnetite Fe_3O_4) which are necessary for the most effective removal of yeast *S. Cerevisiae* 1968 from a solution after the sorption by them of ions of heavy metals (for example, Cu^{2+}).

The yeast *S. Cerevisiae* 1968 was grown up on the mineral Reader's medium which contained 1 % of glucose and 0.1 % of yeast autolysate in aerobic conditions at temperature 28 C. The daily culture was centrifuged and washed twice by a sterile physiological solution. The magnetite Fe_3O_4 was obtained by means of a method described in work [3]. To join the magnetic labels to yeast *S. Cerevisiae* 1968, the suspension of nanomagnetite in water was mixed with a yeast solution (concentration of cells was 3×10^6 cells/ml). The initial concentration of copper ions Cu^{2+} was 100 mg/l. The measurements were performed at a room temperature in intervals of time 1, 3, 5, 10, 20 and 30 minutes. The finding of the concentration of copper ions was carried out with the help of spectrophotometer SF-46.

We made the ferromagnetic heads with the controllable characteristic sizes from 10 microns to 100 microns and with brachiate surface of a type similar to that described in the work [4] by the instrumentality of a new rather cheap electrolytic method. In the present work the efficiency of catching of yeast by a modeling ferromagnetic head of a spherical form with a diameter 100 microns was investigated at different relations of quantity of yeast cells with quantity of magnetic labels (from 5:1 to 100:1).

In Fig.1 the time dependences of mass of copper ions Cu^{2+} sorbed by yeast for various concentrations of magnetic labels in a solution are presented. The curve 1 corresponds to the relation of yeast and magnetic labels in proportion 10:1, and the curve 2 corresponds to the relation 100:1. The curve 3 describes the time dependence of mass of copper ions sorbed by yeast without the adding of magnetic labels. It can be seen that the most part of ions Cu^{2+} is sorbed during the first ten minutes from the beginning of the experiment. It is established that the solution in which yeast with magnetic labels is in the proportion 100:1 catches ions Cu^{2+} better than solutions with a large quantity of labels. At the same time the maximum quantity of sorbed copper ions after 10 minutes from the experiment beginning was observed for a solution of yeast cells without joining of magnetic labels to them. However in this case at the further carrying out of experiment the process of desorption and, as a consequence of this, the increasing of concentration of copper ions in a solution were observed. The similar effect was absent when magnetic labels had been added in a yeast solution. The obtained results are in good agreement with known from the literature experimental data [2,5].

Thus, for effective carrying out of process of biosorption of heavy metals ions by the method of magnetic separation the relation between the quantity of yeast and magnetic labels in solution should be equal to 100:1. I.e., as the results of the present work have shown, the increasing of the

quantity of magnetite in the proportion (yeast:magnetite) leads to the reduction of the efficiency of biosorption of copper ions (see Fig.1). The further reduction of quantity of magnetite leads to impossibility of effective extraction of a yeast-magnetite conglomerate by the magnetic filter with a ferromagnetic head of type [4] after the finishing of the process of biosorption of copper ions. We also note that the application for biosorption of copper ions the yeast-magnetite conglomerates even at small quantity of magnetite 100:1 gives an additional advantage in comparison with use of yeast without giving magnetic properties to them. Namely, in case of use of "magnetic" yeast the process of desorption is absent (Fig.1).

COATING of cobalt ferrite nanoparticles with silica for an in-vitro gmr biosensor agent.

S. Tang¹, S. Bae¹, W. Lee²

1. Electrical and Computer Engineering, Biomagnetics Laboratory (BML), National University of Singapore, Singapore 117576, Singapore, Singapore; 2. Dept of Physics, Sookmyung Women's University, Seoul 140-742, Seoul, South Korea

Introduction

Ferrite nanoparticles are now widely noted in the biomedical field, one application being their use as a biosensor agent to detect biological information, such as in a DNA counter (BARC), and other disease diagnostic biosensors. However, the biological entities should be attached on the surface of ferrite nanoparticles via coating material to avoid problems of cytotoxicity and a probing problem with biological entities[1,2]. Accordingly, development of a new coating material, which can provide high biocompatibility and durability under a wide range of physiological conditions, especially with no serious degradation of magnetic properties, are urgently required for the successful use of ferrite nanoparticles as biosensor agents. In particular, research interests on the investigations of the coating effects on the magnetic property changes during the coating process have increased significantly, because there has been no detailed report on the physical mechanism of magnetic property variation in coated magnetic nanoparticles so far.

In this study, effects of silica coating on the magnetic property in Co-ferrite nanoparticles[3] with high magnetic anisotropy were investigated in terms of coating treatment steps and coating thickness for an in-vitro biosensor agent application. In order to study the effects of magnetic anisotropy on the coating-induced magnetic degradation, Mg-ferrite nanoparticles, which have a softer magnetic property, were compared to that of Co-ferrite nanoparticles.

Experimental procedures

Co- and Mg-ferrite nanoparticles with different particle sizes synthesized by a sol-gel method were dispersed in oleic acid(OA) and oleylamine(OL) for separation. The dispersed samples were mixed with a solution of TEOS and ethanol and then left to stand for 1 hr for coating[1]. Coating status was confirmed by scanning electron microscope (SEM) and the magnetic properties for each coating step were measured by using a vibrating sample magnetometer (VSM).

Results and Discussion

Figure 1 and 2 show the M-H loops of 200 nm size Co- and Mg- ferrite nanoparticles treated at the different coating steps. As can be clearly seen in Fig. 1 and 2, the chemically isolated or silica-coated Co- and Mg-ferrite nanoparticles showed a change of coercivity and saturation magnetic moment compared to the original ones. Furthermore, as also confirmed by Figs. 1 and 2, the magnetic properties in the Co-ferrite nanoparticles for each coating step were not seriously changed as compared to that of Mg-ferrite nanoparticles. OA and OL-dispersed Mg-ferrite nanoparticles that were treated with TEOS showed a 50% increase in coercivity, while Co-ferrite nanoparticles, under same conditions, exhibited only 28% increase in coercivity (Tables 1 and 2). The saturation magnetic moment also showed the same trends as the change of coercivity for both Mg- and Co-ferrite nanoparticles under same conditions. There was a 45 % of decrease in saturation magnetic moment for TEOS-treated Mg-ferrite nanoparticles compared with only 4.5 % decrease for the Co-ferrite nanoparticles. The change of magnetic properties after each coating process step is supposed to be due to the reduced magnetic interaction among the nanoparticles (increased the inter-particle distances) caused by the introduction of silica and the chemically-induced isolation. In addition, it strongly implies that the magnetic anisotropy is directly relevant to the magnetic degradation of ferrite nanoparticles during coating process. In conclusion, all the experimental results shown in this

study clearly confirmed that the change of magnetic properties during coating process is entirely evident at the first coating step - chemically-induced particle isolation by OA or OL. In addition, from the above results, ferrimagnetic Co-ferrite nanoparticles coated with silica can be considered to be a good candidate for an in-vitro biosensor agent due to its small magnetic degradation after coating caused by its large magnetic anisotropy.

Effect of Metallic-coating Thickness of Thermosensitive Magnetic Powder for Cancer Therapy.

T. Takura¹, F. Sato¹, H. Matsuki¹, T. Sato²

1. Introduction

Hyperthermia is a therapeutic method that necrotize cancer tumor by heating. Soft heating[1] has been proposed as one method of it. This is where the thermosensitive magnetic materials inserted into the tumor as a heater produces heat in a high-frequency magnetic field. Although the heater needs to be implanted in the tumor tissue, there are various advantages to soft heating, such as easy retreatment, localized heating of the tumor, and a low degree of invasiveness. So, in this work, we developed thermosensitive magnetic powder coated with Ag-paste. This powder composed of the Ni-Cu-Zn ferrite granules and Ag-paste is used as the heater for hyperthermia. We examined the difference of heating in terms of thickness of Ag.

2. Principle of Our Magnetic Powder

Our powder produces a higher heat due to losses of hysteresis and inductive current than magnetic powder alone. Fig.1 shows the characteristic of the powder in a high-frequency magnetic field. T represents the temperature of the powder and T_c the Curie-point in this figure. While $T < T_c$, the magnetic flux is concentrated in the effect of high permeability of ferrite, and the temperature of the powder rises as a result of the generation of short-circuit current in the metal. On the other hand, when $T > T_c$, the temperature rise is limited because the permeability decreases rapidly and the thermosensitive ferrite does not concentrate the magnetic flux. Since the temperature of the powder does not rise higher than that of the Curie-point, temperature control is achieved with the use of a Curie-point as criteria.

3. Experiment

Our magnetic powder has two heat sources. They are hysteresis loss and inductive current loss. We can examine the rate of heating by comparing magnetic powder alone with the powder with Ag-coating. Fig.2 shows the temperature profile of the magnetic powder. The temperature of the powder with Ag-coating rose near the Curie-point, while that of the magnetic powder without coating was below the Curie-point much. The heating by the loss of inductive current in the metal is the most of heating. Therefore, the thickness of Ag has a relationship to the heating of the powder. We examined heating value of magnetic powder of when Ag-thickness changed. In the experiment, the thermosensitive magnetic powder is Ni-Cu-Zn ferrite granules (150-350 μm in diameter) and the Curie-point is 90 Celsius degree. Our powder for cancer therapy is made by baking Ag-paste on the magnetic powder. The amount of the powder we used is 1.0 g. We used some powder changed Ag-thickness variously (5 μm , 10 μm , 15 μm , 20 μm). The powder, which is placed in the insulator, is thermally excited through the use of a solenoidal coil. The exciting condition is set to 200 kHz and 4 mT. Fig.3 shows the characteristic of the powder as a function of Ag-thickness. As a result, the powder of 15 μm showed the top of the temperature rise.

4. Conclusion

Our original powder achieved higher heating value than magnetic powder alone. It is confirmed that we can increase heating value of the powder by selecting optimal metallic thickness. Therefore, we can expect high effect of cancer therapy.

Fe Oxide Nanoparticles produced by laser pyrolysis for biomedical applications.

V. Bouzas¹, R. Costo², M. García¹, M. Morales², S. Veintemillas-Verdaguer²

1. Dpt. Material Science, Universidad Complutense de Madrid, Madrid, Spain; 2. Institute of Materials Science, CSIC, Madrid, Spain

Iron oxide nanoparticles are commonly used in biomedical applications as contrast agent for Magnetic Resonance Imaging [1]. The magnetic properties of the nanoparticles strongly depend on their features and small changes in shape and size can alter significantly the magnetic response of the nanoparticle. Therefore nanoparticle production methods with a narrow size distribution are required for these purposes. Among the different methods that can provide this kind of nanoparticles, laser pyrolysis has the advantage to produce homogeneous material in quantities fairly larger than other chemical methods, that requires a long time to produce few milligrams and results expensive. Here, we report on the preparation and magnetic characterization of Fe oxide nanoparticles by laser pyrolysis and the relationship between the preparation conditions and the magnetic response.

Iron oxide nanoparticles were prepared by pyrolysis laser (CO₂ laser W=79watts, P=400mbar) using the method described previously [2]. Table 1 summarizes the main preparation parameters. XRD and TEM analysis confirmed the existence of Fe oxide nanoparticles (compatible with maghemite and magnetite) with size between 2 and 4 nm, except for BONFEX06 which showed bimodal size distribution with maxima at 3.7nm and 14.9 nm

The magnetization curves measured at 10 K are presented in figure 1

At this temperature, all the samples exhibit ferromagnetic behaviour and no one is saturated at a field of H=7T. Results are quite similar for samples BONFEX02, BONFEX03, BONFEX04 and BONFEX05 (all these prepared using the same flux of C₂H₄). For these particles is also observed that the magnetization under a 7T field increases as the particle size does as expected: it is well known that Fe oxide nanoparticles present a surface shell with a reduced magnetization [3], and the fraction of atoms in this surface shell increases as the particle size decreases.

Sample BONFEX06 has a very different behaviour. For this heterogeneous sample the curve presents an almost linear behaviour but the graph opens, indicating that, this is not paramagnetic. Although it is very tough to reach conclusions about this complex sample the presence of large and likely more crystalline particles could arise a higher anisotropy. Therefore a field of H=7T is far away to saturate the material and larger fields are required to saturate it. This also could explain the low magnetization of the sample.

Sample BONFEX08 present an intermediate behaviour between the others with the larger HC but the lower magnetization at 7T that, as well, can be understood as a large anisotropy (larger than for BONFEX02, BONFEX03, BONFEX04 and BONFEX05, but lower than BONFEX06).

Comparison of the magnetic measurements with the preparation conditions shown in table 1, it is inferred that that the magnetic features of the nanoparticles can be controlled in a wide range of values through the carrier flux during the preparation, while the addition of an air flux or the evaporation temperature of Fe(CO)₅ seems not to alter dramatically the magnetic properties of the nanoparticles. In particular, larger flux leads to smaller values of the magnetization of the samples under a 7T field.

Magnetic properties and potential biomedical applications of CM-CL-SPIONs.

M. Lin¹, J. Gu¹, T. Veres³, J. Dobson¹, H. Lee², M. Muhammed⁴, D. Kim¹

1. Institute of Science and Technology in Medicine, Keele University, Stoke-on-Trent, United Kingdom; 2. Department of Materials Science and Engineering, Myongji University, Kyunggi-do, South Korea; 3. Industrial Materials Institute, National Research Council Canada, Boucherville, QC, Canada; 4. Materials Chemistry Division, Royal Institute of Technology, Stockholm, Sweden

Recently, we developed a novel versatile backbone nanocarriers carboxymethyl activated dextran crosslinked superparamagnetic iron oxide nanoparticles (CM-CL-SPIONs) for biomedical applications.[1] Due to their potent immovability in water and capability of additional conjugation of bioactive molecules, CM-CL-SPIONs are of particular concern on biomedical applications, such as magnetic resonance (MR) contrast agents, magnetic targeted drug delivery system (DDS) and immunomagnetic cell separation etc.[2] In this study, we attempt to modify and optimize the procedure of SPION surface with crosslinked dextran layer for more functionalization with biocompatible molecules. The synthesis of SPION, introduction of carboxymethyl group after preparing the dextran coating on SPION, the magnetic properties of the sample at each stage by SQUID and their biocompatibility by MTT assay with MG 63 cell line are briefly summarized. Especially, the binding capacity is estimated on the basis of magnetic measurements as well as thermal and physiochemical analysis. Light microscopy was used to visualize MG 63 cell morphology. In addition, fluorescent observation of the cell cytoskeleton and intracellular clathrin localization has also been evaluated.

Fig.1 shows the ZFC/FC curves of CL-SPIONs and CM-CL-SPIONs measured in a field of 50Oe on a superconducting quantum interference device (SQUID) magnetometer. The temperature dependence of magnetization of both CL-SPIONs and CM-CL-SPIONs exhibit a sharp cusp around 17K and 30K in the zero-field cooled (ZFC) susceptibility, respectively. The blocking temperature (TB) was determined to be around 100K (CL-SPIONs) and 120K (CM-CL-SPIONs) from the divergence of ZFC and FC data. Above TB, the thermal fluctuation energy is larger than the uniaxial anisotropy energy. Carboxymethylation process increases the blocking temperature of the nanoparticles. As previously described, carboxymethylation of CL-SPIONs was achieved at hydrothermal condition at high pH, during which, some agglomeration of nanoparticles may take place.[1] In CM-CL-SPIONs, the agglomerated particles act as clusters, which increase the blocking temperature.

That magnetic data was also multi-parametrically fitted with a theoretical model. [3] Firstly by considering $d_0 = 9.4$ nm (predetermined by TEM imaging) as imposed parameter, the intrinsic anisotropy constant K_{eff} was determined to be 4200 J/m³ by fitting the measured ZFC curve with the theoretical curve. It was found that CL-SPIONs sample agree well with the model, while CM-CL-SPIONs sample. At high temperature, the magnetic moment of CM-CL-SPIONs seems to be frozen. This blocked state could be consistent with some agglomerations of strongly interacting nanoparticles in ferromagnetic clusters that drastically change the size distribution of the particles. In order to take into account of these effects, d_0 and σ were adjusted to ZFC curves while keep $K_{eff} = 4200$ J/m³ as imposed parameter.

MTT assay is a cell proliferation assay, based on the ability of a mitochondrial dehydrogenase enzyme in viable cells to cleave the tetrazolium rings of the pale yellow MTT and form a dark blue formazan crystal. The number of surviving cells is directly proportional to the level of the formazan product created, which can then be quantified by reading absorbance at 570 nm with a multiwell scanning spectrophotometer (ELISA reader). MG 63 cell line is a human osteosarcoma cell and

selected for particle cytotoxicity test. Cell viability after 24 hours incubation with CM-CL-SPIONs was tested by a standard MTT assay with MG 63 cell line. Incubated with CM-CL-SPIONs for 24 hours, even up to 1000 μ g/mL concentration, MG 63 cells showed good survival rate. (Fig 2) The cell morphologies were also observed under light microscope for up to 4 days. No significant cell morphologies changes were observed during the 4 days incubation.

Controlling vortex chirality in magnetic submicron dots by modulating the magnetic properties in lateral direction.

Z. Zhong, H. Zhang, X. Tang, Y. Jing, L. Jia, L. Zhang

State Key Laboratory of Electronic Thin Films and Integrated Devices, University of Electronic Science and Technology of China, Chengdu, China

Magnetically soft submicron dots have received considerable attention due to their tendency to support a stable vortex magnetization state, which may be applied in data storage and non-volatile magnetic random access memory. The vortex state can be described in terms of two quantities: (i) a core polarity that defines whether the out-of-plane component (vortex core) of the magnetization points up or down, and (ii) a chirality that defines the in-plane curling direction of the spins. However, due to the geometrical symmetry of the submicron dots, the chirality of magnetization rotation was statistically distributed clockwise or counterclockwise, but could not be controlled on purpose by application of magnetic in-plane fields. The application of magnetic vortex as device elements requires the perfect controllability of the chirality of the magnetization circulation at room temperature. For this reason, methods introducing the asymmetrical structure to achieve the required controlling over the chirality in the vortex state in ferromagnetic submicron dots are investigated [1,2].

Here, We try to introduce the lateral modulated magnetic properties in lateral direction in submicron dots to control the vortex chirality. The lateral modulated magnetic properties in submicron dots may be the magnetization, anisotropy, and exchange stiffness. In this work, numerical micromagnetic simulation using the 3-D OOMMF package is used to study the magnetization configuration and the reversal process of the sub-micron ferromagnetic dot shown in Fig.1 (a), where the submicron dot with a diameter of 200 nm and a thickness of 20nm is composed of two parts only with different magnetization orientated symmetrically to the y-axis in order to reduce the complexity of the analysis. The applied magnetic field is along the x axis. Based on the analytical results, a novel structure based on gradient magnetization in lateral direction was proposed to control the chirality.

All the simulated submicron dots with lateral gradient magnetization are vortex magnetization configuration in ground state and show vortex-type magnetization reversal process. Comparing with the submicron dots with lateral uniform magnetization, there are two features for the submicron dots with lateral gradient magnetization. In one feature, the core of vortex of the submicron dots with lateral gradient magnetization is not in the center of the dots, and the off-distance increases with increasing the intensity of gradient magnetization. In the other, the one-step nucleation process changes to the two-stage nucleation process while increasing the intensity of gradient magnetization, although the magnetization reversal of all the dots is via vortex nucleation, displacement, and annihilation. Fig.1 (b-d) show the typical vortex-type hysteresis loops corresponding to various intensity of gradient magnetization. The intensity of gradient magnetization is defined the difference magnetization between the two parts.

After carefully analyzing the spin arrangement in magnetization reversal process, we observe that a twisted "C" metastable state develops in the part with larger magnetization, which has relatively soft magnetic properties. The part with larger magnetization reverses firstly and then the part with lower magnetization does, so a two-stage nucleation process appears when the applied field decreases. If we introduce asymmetrical magnetization distribution in lateral direction, we may control the open direction of "C" metastable state, and then we can control the vortex chirality in remanent state. Based on the analysis of the magnetization reversal process, we propose a new

structure to control the chirality of the vortex. Our proposed structure is composed of dot with a quarter lateral gradient magnetization parts, which locates at the upper or lower quarter part at the right of the dot. When the applied field along the x axis decreases from saturation, the dot with the quarter lateral gradient magnetization in the upper develops a CCW whirling, while for that in lower quarter, it develops a CW whirling. Results of micromagnetic simulation are consistent well with the analytical results. This new structure opens a new way to control the chirality of the vortex, it is important for the devices relating to the vortex's chirality.

The magnetic force microscopy was applied to investigate noncollinear helical states in multilayer nanomagnets consisting of a stack of three single domain ferromagnetic disks separated by insulating nonmagnetic spacers. The possible existence of helical states in tri-layer nanomagnets is based on the universal long-range interaction between layers through magnetostatic stray fields. The interaction between disks leads to frustration in magnetic moments orientation for the first and third disks. When the interaction between these disks is large enough $2E_{13} > E_{12}$ and $2E_{13} > E_{23}$ (where E_{ij} ($i, j = 1, 2, 3$) are the interaction energies between i and j disks) and the magnetic moments are free to rotate in the particle plane, then non-collinear helical state is realized as the ground state in this system. Note that helical state is doubly degenerate i.e. the energies for “left” and “right” helicoids are equal.

The Co/Si multilayer nanomagnets were fabricated by means of electron beam lithography and ion etching of a [Co/Si] \times 3 multilayer thin film structure grown by magnetron sputtering. The details of the lithography process are described in [1]. The electron microscopy and e-beam lithography were performed using a “JEOL – JEM 2000EX II” scanning electron microscope. The coercivity of the ferromagnetic Co films did not exceed 20 Oe. Si layers were used as spacers, effectively hindering any interaction except the magnetostatic interaction. The Co disk dimensions (diameter and thickness) were chosen according to the single domain requirements [2]. In our experiments, we used disks with diameters of 300 nm and thicknesses less than 20 nm.

The MFM investigations of the magnetic states in the multilayer nanomagnets were carried out using a vacuum scanning probe microscope “Solver HV” (manufactured by “NT-MDT” Company). MFM measurements were performed in the oscillatory noncontact (constant height) mode using home made Co-coated cantilevers. The amplitude of cantilever oscillations was about 30 nm and the average scanning height was 50-60 nm. The phase shift of cantilever oscillations caused by the gradient of the magnetic field was registered as the MFM contrast. All measurements were performed in a vacuum of 10^{-5} Torr, which increases the MFM signal due to increasing of the cantilever quality factor.

To register a helical state of magnetization in tri-layer nanomagnets by MFM we considered a structure where the thickness of Co layers increases with increasing distance between a layer and the MFM probe. Thus, the change of magnetic moment of the layers was used for compensation of the effects concerned with different distances between the disks and the tip. Our calculations and computer simulations showed that a stack with Co layers thicknesses of 16, 11, 8 nm and with 3 nm spacers has the helical state with $\theta_{12} = 109^\circ$, $\theta_{13} = 257^\circ$ (where θ_{ij} are the angles between i and j layers) and this structure is quite optimal for the observation of spiral peculiarities in MFM images of the helical state.

Taking into account the result of model calculations, tri-layer nanomagnets with Co layer thicknesses of 16, 11, 8 nm and with 3 nm Si spacers were fabricated and measured. The MFM image of this structure is represented in Fig. 1. (The dashed lines separate the regions with dark and bright contrast to emphasize the spiral symmetry of MFM contrast). As it is clearly seen the MFM image demonstrates “left” and “right” handed spiral contrast distributions corresponding to the helical states with different chirality.

In conclusion, the helical states in artificial multilayer nanomagnets consisting of three single-domain ferromagnetic disks separated by nonmagnetic spacers were investigated by magnetic force microscopy methods. For optimized tri-layer nanomagnets with Co layer thicknesses of 16, 11, 8 nm and with 3 nm Si spacers the spiral MFM contrast with different chirality was observed experimentally. The realization of helical nanomagnets is not only of interest for fundamental investigations but they could also be used in spintronics devices. In an external magnetic field perpendicular to the ferromagnetic layers, the magnetization distribution can be transformed from non-collinear into a non-coplanar cone magnetic spiral. In this case, we expect unusual transport properties along the magnetic field direction [3-5].

Double vortex interaction of micron-sized elliptical Py element studied by real-time Kerr microscopy.

B. Hong¹, J. Bland¹, J. Jeong^{1,2}

1. Cavendish Laboratory, Cambridge University, Cambridge, United Kingdom; 2. Department of Materials Science and Engineering, Chungnam National University, Daejeon, South Korea

Magnetic vortex dynamics in patterned magnetic elements is a fascinating issue from both fundamental and technological points of view [1]. In this work, different magnetization switching behaviors through double vortex interaction exhibited in micron-sized elliptical magnetic particles were investigated by using a full field Kerr microscopy. Both micromagnetic simulation and experimental measurements were carried out to determine the origin of this behavior. It was found that the direction of which the vortex core rotates largely depends on the edge spins which were not saturated by external field. It was also found that the switching field varies significantly depending on the relative direction of which vortices rotate.

The elliptical shaped magnetic thin film elements were defined by 220~240 nm DUV photolithography on PMMA photoresist, and magnetic thin film were grown by molecular beam epitaxy (MBE) in an ultrahigh vacuum (UHV) chamber with base pressure below 2×10^{-10} mTorr. Metal layers consisting 20 nm Py and 5 nm Cu were grown on silicon (100) substrate. The practical measurements were carried out using Kerr microscope with time resolution of 30 msec. Fig. 1 show the magnetic domain image observed by Kerr microscope when the applied field is parallel to the long axis of the elliptical pattern. As shown in Fig. 1 two very distinguishable switching states were observed. Magnetic elements in Fig. 1a shown two vortex cores each rotating positively (clockwise) and negatively (anti-clockwise), while the magnetic elements in Fig. 1b shown two negatively (anti-clockwise) rotating vortex cores. Furthermore, by comparing Fig. 1c and 1d, it is noticeable that magnetic elements with two negatively rotating vortices shown higher magnetization under same field condition of 0.9 mT.

The micromagnetic simulation was carried out using OOMMF simulation package, with standard Py parameters and a cell size of $10 \text{ nm} \times 10 \text{ nm} \times 20 \text{ nm}$. In this simulation, small amount of edge spins were intentionally introduced to reproduce the practical scenario. The simulation results show strong agreement with the practical measurement. Fig. 2a shows the magnetic domain motion of one positive and one negative vortex cores and Fig. 2b shows the motion of two negatively (positively) rotating vortex cores.

Fig. 3 shows the total energy and magnetization versus applied field of two different switching states of (a) magnetization of non-competing vortices, (b) magnetization of competing vortices, (c) total energy of non-competing vortices, (d) total energy of competing vortices. It was observed that although the initial magnetization and total energy were identical for both configurations, the final values were significantly different. At an applied field of 2.25 mT, the relative magnetization of non-competing configuration reached >0.85 while the competing configuration only reached approx. 0.7. Under the same condition, the total energy was $-2 \times 10^{-15} \text{ J}$ and $-1.25 \times 10^{-15} \text{ J}$ respectively for non-competing and competing configurations. The higher total energy and lower magnetization was caused by the formation of a more stable state due to two competing vortex cores. An anti-vortex core was also formed in between two vortex cores in order to achieve 180 degree spin rotation; this vortex core also contributed to the total energy, and therefore increased the stability of this state.

Evolution of mixed states composed of vortex cores and anti-vortex cores in different helicities under external field.

Z. Wei, M. Lai, C. Lee, Z. San, Y. Hsieh, T. Ho
National Tsing Hua University, Hsinchu, Taiwan

Micromagnetic properties of magnetic patterned thin films have drawn a lot of attention because of the rapid development of magnetic sensors, whose dimensions are often in submicron. For submicron-sized thin films, in addition to single-domain state, many other magnetization states [1] compete energetically. In this article we numerically and experimentally investigate the field evolution of mixed states, each of which consist of the same number of vortex cores and anti-vortex cores [2], in a submicron-sized elliptical permalloy thin film.

Numerically, the 3D micromagnetic simulations of submicron-sized elliptical permalloy thin films are performed by the integration of the LLG equation [3], where the exchange field, magnetostatic field, Zeeman field, and anisotropy field are included in our simulation. The material parameters for permalloy thin films are as follows: the saturation magnetization is 800 emu/cm^3 , the exchange constant is $2 \times 10^{-6} \text{ erg/cm}$, and the uniaxial anisotropy constant is 10^3 erg/cm^3 . Each ellipse is divided into many cubic unit cells, and the side length of each unit cell is set to be 7.5 nm, which is smaller than the exchange length of the permalloy to promise the accuracy in our calculation. When the largest magnetization angular variation between any two successive iterations is below 10^{-8} , we assume the system to have reached the equilibrium state.

Experimentally, the permalloy elliptical thin film array with different sizes and aspect ratios are fabricated by electron beam lithography and e-gun evaporation through lift-off process. First, elliptical patterns on the silicon-dioxide coated silicon substrate are exposed in polymethyl methacrylate (PMMA), the electron beam resist, and a commercial scanning electron microscope (SEM) is used for direct writing. The sample is developed followed by the formation of the elliptical trenches in the e-beam resist. After film deposition using e-gun evaporator, and the lift-off process in acetone, all resist is removed and the permalloy ellipse are obtained on the substrate. The magnetic force microscope (MFM) is used to image the magnetic pole density distribution on the film. The same MFM pattern corresponding to the one obtained from the simulation is adopted to research the magnetization process under field.

Figure 1 shows the numerically obtained remanent magnetization states with different combinations of vortex cores and anti-vortex cores in different helicities. There are totally 4 vortex cores and 2 anti-vortex cores in each case. In Fig. 1(a) the rhombic domain, which is composed of two neighboring vortex cores, is located in the center of the ellipse, and each pair of vortex core and anti-vortex core, which form the so-called Bloch line, is located in one the two sides of the rhombic domain. When the magnetic field is applied along the $+x/-x$ direction, the rhombic domain is tilted, and the Bloch line in the left side of the rhombic domain moves down/up while the Bloch line in the right side moves up/down. When the magnetic field is applied along the $+y/-y$ direction, the rhombic domain is contracted/extended, and each pair of the vortex core and anti-vortex core annihilates almost simultaneously, and in each of the two cases it transforms into two-vortex state eventually. In Fig. 1(b) the rhombic domain is located in one end of the ellipse, and the two pairs of vortex core and anti-vortex core are located in the other end of the ellipse in series, which form a long Bloch line. When the magnetic field is applied along the $+x/-x$ direction, the rhombic domain is tilted, and the Bloch line moves up/down. When the magnetic field is applied along the $+y/-y$ direction, the rhombic domain is contracted/extended, and each pair of the vortex core and anti-vortex core annihilates in sequence from right to left as the field is increased, and in each of

the two cases it transforms into two-vortex state eventually. In addition, the mixed states composed of 6 vortex cores and 4 anti-vortex cores in different helicities are also investigated. In our study, the simulation result is in good agreement with the experimental result.

Introduction

Magnetic logic devices composed of magnetic dots or magnetic nanowires have been much of interest because they are one of candidates as a promising operation system in future computers[1-3]. We have newly proposed the magnetic logic gate (MLG) having the fundamental unit formed by four elliptical magnetic dots, and have successfully demonstrated that NAND and NOR operations can be performed in the MLG using the micromagnetics simulation[2]. Recently, Imre et al. have also observed NAND and NOR operations in the similar MLG using magnetic force microscopy (MFM)[3]. In these MLGs, the distance between the adjacent dots is one of the key parameters because the dipole-dipole interaction between the adjacent dots plays the important role in the logic operations. However, from the experimental point of view, the optimal distance still remain unclear. Here, we investigated the effect on the dipole-dipole interaction between the adjacent dots in Ni-Fe elliptical dot arrays with several distances between the adjacent dots, and optimized the distance at which the magnetization between the adjacent dots coupled by the dipole-dipole interaction.

Experimental Procedure

Ni-20at.%Fe(Ni-Fe) elliptical dots were fabricated by e-beam lithography, e-beam evaporator, and a lift-off technique onto thermally oxidized Si (100) substrates. The thickness was 10 nm, the aspect ratio between the length of the major axis (a_1) and that of the minor axis (a_2) was 2 to 1, and a_1 was varied from 200 to 1600 nm. The major axial distance (D) between adjacent dots was varied from 30 to 250 nm, while the minor axial distance (d) was fixed 1000 nm. The shape of the dot arrays was observed by scanning electron microscopy (SEM). The magnetization process of dot arrays was investigated by magneto-optical Kerr effect (MOKE) magnetometry, while the magnetic configuration of dot arrays was observed using MFM. Additionally, the effect on the dipole-dipole interaction between the adjacent dots was measured by our proposed measurement method, namely, magnetic field sweeping (MFS)-MFM[4].

Results and Discussion

Figure 1 shows the coercivity(H_c) in Ni-Fe elliptical dot arrays as a function of the distance (D) between the adjacent dots. The magnetic field is applied in the longitudinal direction of the dot. In each dot size, its coercivity increases as the distance becomes short below 30 nm. The reason for this might be that the magnetization between the adjacent dots couples by the dipole-dipole interaction at the distance below 30 nm.

In order to clarify the magnetic configuration of the Ni-Fe elliptical dot arrays in detail, we observed MFM images of these dot arrays at various magnetic fields [Fig. 2]. At the distance of 20 nm, bright and dark contrasts appear at each dot edge, and simultaneously reverse at the magnetic field of -30 Oe. This means that the magnetic configuration of each dot changes from a single domain (SD) state to an opposite SD state with a coherent rotation due to the dipole-dipole interaction between the adjacent dots. In contrast, at the distance of 110 nm, bright and dark contrasts appear at each dot edge, reverse in either upper or lower part of several dots, and further reverse completely at the magnetic field of -100 Oe. This reveals that the magnetic configuration in each dot changes from a SD state to a opposite SD state via a closure domain state as the magnetic field

is varied, and that the magnetization of each dot randomly rotates. Furthermore, the curve of phase vs. magnetic field at both edges obtained by MFS-MFM changes from a stepped hysteresis loop to a square one with decreasing the distance between the adjacent dots. (They are not shown) These also reveal that the dipole-dipole interaction becomes stronger with decreasing the distance between the adjacent dots.

In summary, it is concluded that the optimal distance at which the magnetization between the adjacent dots couples by the dipole-dipole interaction is below 30 nm.

The effect of dipolar interaction on the magnetization reversal of nano-patterned permalloy dots array.

Y. Tsai, C. Chang, J. Wang, J. Wu, L. Horng

Taiwan SPIN Research Center, National Changhua University of Education, Changhua, Taiwan

Magnetic thin films in the small lateral length scales have provided a wealth of scientific interest and potential applications, such as magnetic field sensor and magnetic memory. For the memory application, ultra-high density and thus larger memory capacity is the main concern. Advanced nanofabrication techniques have enabled the realization of magnetic dots in few tens nanometers. However, the practical application for memory relies on how well one can control every single dot in the array. It is therefore that the influence on the magnetization reversal of each dot from adjacent dots needs to be understood. Namely, the interdot interactions may restrict the memory density in nature. Herein, millions of identical permalloy dots with various diameter and interdot spacing have been fabricated for the study of interdot interactions. A commercial SEM modified for direct writing system with auto-focusing technique was employed for the fabrication. Alternate Gradient Magnetometer (AGM) and Magnetic Force Microscopy (MFM) were used to investigate the magnetization reversal of these dots array.

The samples were fabricated by a standard electron beam lithography and thermal evaporation through a lift-off technique, the fabrication procedure is as follow. A SiN-coated silicon wafer is spun-coated with a bilayer electron resist (PMMA-MAA/PMMA). Millions of permalloy dots array with individual dot diameter of 250, 500, 750nm and the aspect ratio of spacing to diameter ranged from 0.2 to 2 were made, in which the total array size for each sample is around 3mm×3mm. The permalloy film was thermally deposited and the film thickness was controlled to be 30 nm monitored by a quartz crystal. AGM measurements and MFM imaging were used to study the magnetic configurations of these permalloy dots array due to their excellent field sensitivity and high spatial-resolution.

Figure 1 shows the SEM micrograph of two samples, in which the size uniformity in the millions of dot is within few percent of variation. Figure 2 shows the M-H loops for dot arrays with diameter of 500nm and interdot spacing ranging from 100 to 625nm. Notice that single transition only happens in the array with 100nm spacing and two transitions happen in the others but having different nucleation/annihilation fields. Similar behaviors were observed in other dot arrays. Fig.3 summarizes the experimental data for nucleation field and annihilation fields. It is found that the nucleation and annihilation fields decrease with decreasing/increasing spacing/diameter. For the arrays with larger/smaller spacing/diameter, two transitions were occurred. Fig.4 shows a hysteresis loop and the corresponding MFM images taken in-situ in the present of external field applied, in which the vortex evolution is clearly seen. Such MFM images may provide a deep inside of how the magnetization reversal takes place in each dots array. The vortex nucleation/annihilation in densely dot arrays is influenced by the magnetostatic coupling between the dots. Details regarding to the inter-dot interaction in each sample will be presented.

Magnetic bi-layers are becoming increasingly popular especially as a medium for perpendicular patterned media. In order to understand interaction between the layers and the nature of the effect of the spacing layer and of the interaction between adjacent magnetic dots, we measured a sample consisting of a buffer layer of 5 nm of Ta, on a nonmagnetic substrate, that is coated with two magnetically soft layers of 26nm thick FeCoTaZr, that are separated by an 0.8 nm Ru spacer layer, and finally coated with a 4 nm carbon protective layer. A description of the preparation of this type of material is given by S. S. N. Piramanayagam and J. P. Wang. The main idea of this research is to see the effect of the shape anisotropy on the coupling between the two layers of a patterned medium over a range of sizes and shapes of patterned samples. The purpose of this paper is to show that Preisach modeling of the hysteresis loop is an effective tool to analyze this coupling.

A microphotograph of this type of material that we measured is shown in Fig. 1. The perpendicular magnetization was measured using a vibrating sample magnetometer, VSM, and the hysteresis curve shown in Fig. 2, was obtained for the sample. The medium was found to be magnetically soft, that is, it has coercivity of the order of 5 G, and a squareness the order of 0.3. The coupling between the layers is magnetostatic rather than exchange due to the thickness of the separation layer. The observed hysteresis loop is wasp-waist, that is it is narrower near the demagnetized state than it is as saturation is approached. Wasp-waist hysteresis loops can be produced by a variety of effects, usually between two or more magnetic materials. For example, if two soft magnetic films are ferromagnetically coupled, they can be harder to demagnetize than to magnetize, giving rise to a wasp-waist behavior. This is consistent with our picture of this material.

We then modeled this sample with one of the coupled Preisach models that we previously presented [2]. The result is shown in Fig. 3. The model used consists of two cross-coupled Preisach models in order to obtain a net positive feedback to simulate magnetostatic antiferromagnetic coupling. This computes the irreversible component of the hysteresis loop. If the coupling were negative, then we would have antiferromagnetic coupling. To this irreversible component, we have to add a reversible component. In the model, if the product of α and β is positive, this corresponds to ferromagnetic coupling. The fit was obtained using Gaussian Preisach functions for the irreversible component and an arctangent function of the applied field to simulate the reversible component. Due to the soft nature of the material, it was unnecessary to make the reversible component magnetization dependent.

We have concluded that the model accurately describes the material and that the two films are ferromagnetically coupled. Additional measurements show that the material is not isotropic in the plane, but is wasp-waist with little reversible component along the easy axis and conventional with a smaller squareness along the hard in-plane axis, as shown in Fig. 4. Further work will present the effect of different dot spacing and shape.

1. Physics, Polytechnic of Turin, Turin, Italy; 2. Physics, Materials and Microsystems Laboratory (χ -lab)- LATEMAR Unit, Chivasso (TO), Italy; 3. INRIM, Torino, Italy

A pattern of Co anti-dots has been fabricated by optical lithography by means of an arc quartz lamp working in the UV range. Optical lithography has been selected in order to obtain a very good periodicity on the micrometer scale together with an extended total patterned area (1mm square).

The resist was spin-coated on Si(100) substrates. In order to obtain maximum resolution and optimum sharpness of the resulting features, the resist thickness has been reduced to 600 nm after specific dilution and the lithography has been performed in hard contact mode. Subsequent to resist developing, a high purity Co film of 65 nm was deposited by thermal evaporation in high vacuum (base pressure $< 5 \times 10^{-8}$ Torr). The Co anti-dot pattern has been obtained by lift off process. Removing the photoresist with his proper solvent, both complete adhesion of Co on the patterned zone and complete photoresist lift-off in the complementary zone were obtained.

Morphological analysis performed by Atomic Force Microscopy (AFM) indicates a periodic and regular shape Co anti-dots in an hexagonal matrix configuration forming a macroscopic square matrix.

Magnetic Force Microscopy (MFM) was exploited to obtain images of static magnetic structures existing within the Co anti-dot pattern. The samples were demagnetized before each MFM measurement, by applying a reducing alternate magnetic field, both in plane and out-of-plane. MFM images showed complex although well-defined magnetic domain structures related to the presence of the regular array of holes, which induce local stresses. Magnetic information derived from the MFM images was enhanced by means of a numerical procedure [1], which has been shown to compensate possible artefacts like instrumental distortions and to improve the signal to noise ratio.

MFM imaging does not allow for a precise determination of the magnetization orientation, although it is apparent that the magnetization vector lies predominantly in the film plane. In order to possibly clarify the equilibrium magnetic state of the anti-dot array, our results were compared to micromagnetic simulations concerning similar anti-dot systems [2] in the demagnetised state. Such a comparison makes it possible to deduce the presence of three different wedge-shaped like domains around each hole (see Fig. 1a).

Angle-resolved magnetoresistance (MR) measurements were performed at room temperature of the patterned film in order to verify the pinning effect of the hexagonal antipillar lattice on the propagation of domain walls. An evaporated 15 nm-thick copper bridge was optically lithographed in a chevron shape directly above the patterned area, in order to realize a straight probe for electrical measurements, avoiding current density inhomogeneities which have been shown to seriously affect the measured MR [3]. The sample was submitted to the magnetic field of an electromagnet (maximum applied field: up to 3 kOe); the orientation of the current density vector with respect to H vector was varied in the film plane between 0° to 90° at steps of 30° , and was also set perpendicular to it. As an example, the MR curve at 0° is reported in Fig. 1b.

Both high-field MR sloping behavior and an increase in coercivity with respect to the continuous film have been observed, as recently found in similar systems [4]. The magnetoresistance resulted to be strongly angle-dependent; MR curves were characterized either by an apparent low-field resistance dip, or by a resistance maximum; mixed behavior was observed also. In all cases were the measured MR curves hysteretic and asymmetric.

Singlecrystalline Fe thin films usually exhibit soft magnetic properties, with characteristic square loops along their easy axes and low coercivity values, just a few or at most tens of Oersteds. Their magnetization reversal processes are based on the nucleation of one or a few walls that get unpinned from their nucleation regions and easily propagate throughout the sample [1]. The patterning of these films allows the tailoring of their magnetic properties which is obviously important for technological applications but also, from a more fundamental point of view, to understand different reversal mechanisms occurring in systems including local anisotropies of magnetoelastic origin. In the particular case of ordered antidots arrays, the minimization of the otherwise high magnetostatic energy associated to the stray fields leads to substantial changes in the reversal processes with respect to those of continuous films: large changes in their coercivity and magnetoresistance are usually observed linked to new easy axes configurations and novel domain structures [2, 3].

We present in this work a micromagnetic analysis of the reversal processes of antidots arrays lithographed of single crystalline Fe(001) films by means of two different models, trying to cover both the behavior of an infinite array with periodic boundary conditions (model I, Fig. 1a) and that of a finite one partly covering the surface of a continuous film (model II, Fig. 1b). We have compared their main predictions with the experimental results [4] measured -by means of a magneto-optic Kerr effect device at room temperature- in an array with geometrical parameters equal to those employed in the micromagnetic calculations, lithographed on a Fe(001)/GaAs film, with the diagonals of the (square) array along the [100] directions.

For both models we have considered a square array of circular antidots of diameter $D=1\text{ }\mu\text{m}$, separation $\lambda=1\text{ }\mu\text{m}$ (along the line joining their centres), with intrinsic parameters corresponding to Fe and their crystalline easy axes being parallel to the array diagonals, which are also easy axes from the point of view of the magnetostatic energy. The energy minimization was carried out by integrating the Landau-Lifshitz-Gilbert equation with a cubic discretization cell, 4 nm in size (roughly one tenth of the Fe exchange correlation length), and preserving the magnetization in the film plane. The 3D dipolar magnetic potential was evaluated by means of the DADI Method [5].

A common feature of both models is that the magnetization reversal takes place by means of two irreversible jumps when the field is applied out of the diagonal or the side of the (square) array and that they predict coercivities of the order of 100 Oe, which agrees with the experimental values. In the case of model I the reversal is governed by a nucleation-propagation sequence starting from the inhomogeneous magnetic moment structures present at the antidot surfaces and resulting from the magnetostatic energy minimization; Fig. 2a shows the calculated angular dependence of both switching fields according to this model, θ being the angle between the applied field and the array diagonal. In the case of model II the reversal is due to a wall artificially nucleated in a low anisotropy region of the external frame which propagates through the array; its angular dependence of the coercivity is presented in Fig. 2b and exhibits a very good agreement with the experimental results. Our micromagnetic simulations suggest that the reversal processes are determined by a nucleation-propagation process due to the existence of walls propagating from the continuous part

of the film. The existence of walls propagating from the outer region may be a common feature of many experimental situations and will largely determine the character of the magnetisation reversal in lithographed films.

Theoretical and experimental studies have demonstrated that the magnetic properties of magnetic materials in the form of thin films, e.g. magnetoresistance, coercivity, permeability and magnetization reversal, can be controlled by artificially produced arrays of antidots. Most of the reported results correspond to magnetic antidot arrays obtained by different lithographic process. However, in this work we report on the magnetic behaviour of highly ordered arrays of Nickel antidots obtained by depositing Nickel on nanoporous alumina membranes (NAM) used as templates [1].

The NAMs with arrays of porous with a high order hexagonal symmetry were fabricated using the so called two steps anodization process in oxalic acid. After fabrication, the pore diameter can be modified by a heat treatment in phosphoric acid (5 % in volume) [1]. The Nickel antidot arrays have then been obtained by the deposition of nickel thin films on the NAM substrates, so that the film replicates the array of nanoholes of the substrate. The Nickel film was deposited by ion beam sputtering (deposition rate of $\approx 0.02\text{nm/s}$) at room temperature. The substrates were NAMs with a distance between the centres of two adjacent pores of 105 nm and a pore diameter of 75 nm. The diameter of the antidots, keeping constant the antidot density, has been modified by changing the thickness of the Ni thin film grown on top of the NAM template.

The morphology and geometry of the antidot nanostructures have been studied by SEM, while RBS and AES depth profiling have been used for elemental and chemical in-depth characterization. The magnetic behaviour of the Ni antidot arrays has been studied by vibrating sample magnetometry (VSM) at room temperature with a maximum magnetization field of 1 T. Magnetization loops were measured with the applied magnetic field, both parallel and perpendicular to the plane of the array of antidots. In some cases, the magnetic properties were measured in a temperature range between 2 and 300 K by MPMS using a Quantum Design magnetometer.

Figure 1 shows the in-plane hysteresis curves of 54 nm thick continuous film of Ni grown on Si as compared with the same film grown on the NAM and forming an array of antidots. As expected, the coercive field is much higher in the nanostructured array of antidots than in the continuous film (i.e., 19.8 versus 3.1 mT), due to pinning effects. The saturation magnetization for the continuous film $M_S \approx 0.5\text{T}$ is in good agreement with literature values for Ni [2]. On the contrary, the saturation magnetization of the antidots array is clearly enhanced with respect to that measured in the continuous thin film deposited on Si. This effect has been observed previously and is probably due to Ni/Al₂O₃ interface effects.

Figure 2 shows the coercive fields for both applied magnetic fields (i.e. parallel and perpendicular to the surface), as a function of the thickness of the Ni film grown on top of the NAM. The figure shows a clear decrease of the coercive field as the thickness of the Ni film increases, for both the in-plane and out-plane configuration of the applied magnetic field. Assuming that the coercivity is related with the pinning of the domain walls produced by the antidot, the observed decrease of the coercivity could be associated with the reduction of the antidot diameter as the thickness of the grown film increases.

Finally we have also studied the magnetic properties of the antidots array as a function of the temperature and we will show that it is possible to tailor the magnetic behaviour of the Ni antidot nanostructures by controlling its characteristic sizes, i.e. antidot diameter and interantidot distance.

TAILORING magnetization reversal mode and switching field of magnetic nanostructure with perpendicular anisotropy.

M. Rahman, N. N. Shams, Y. Wu, C. Lai

Materials Science and Engineering, National Tsing Hua University, Hsinchu, Taiwan

Introduction

Patterned magnetic nanostructures exhibit very different properties from those of continuous films and recently attracting great attention due to their technological importance in high-density magnetic recording media [1-3] and fundamental studies. However, fabrication of patterned structure with different feature geometry over large area as well as control of their magnetic properties are quite challenging. In the present study, we demonstrate a method to control the feature geometry and their switching characteristics of magnetization.

Experimental procedure

At first, a thin Al film deposited on a Si wafer by sputtering is anodized to get porous alumina with densities $\sim 1 \times 10^{11} \text{ cm}^{-2}$. Two AAO/Si templates with aspect ratio, A (ratio of the hole height to diameter) of 2.3 and 1.1 are prepared by controlling the post treatment time in dilute phosphoric acid. Then $\{\text{Co}(0.5\text{nm})/\text{Pt}(2\text{nm})\}_5$ multilayers (MLs) are deposited onto the AAO/Si templates and bare Si wafer by sputtering at room temperature. The morphological characteristics of this structure are observed by using scanning electron microscope (SEM) and transmission electron microscope (TEM) imaging. Magnetic properties are measured by using a vibrating sample magnetometer (VSM). Magnetization reversal process investigated by first order reversal curve (FORC) technique.

Results and discussion

Cross sectional TEM and plane view SEM observation (Fig.1) reveals that the magnetic material is deposited mainly on the top of the land and around the perimeter of the holes for the aspect ratio, A of 2.3, resulting a network structure or a continuous film with holes. When the A is reduced to about 1.1, significant amount of magnetic materials deposited inside the holes at the bottom but not completely filled. Though few magnetic materials are still deposited on the wall of AAO near the top, but the thickness is significantly thinner than that on the land and at the bottom. As the anisotropy of Co/Pt MLs is related to individual layer thickness and deposition direction, the magnetic materials at the top and bottom may be considered to be near isolated [4].

The films exhibit strong perpendicular anisotropy and squariness ratio, S of almost unity and negative nucleation fields for the samples deposited on Si and AAO/Si with the A of 2.3. The coercivity, H_c of MLs on AAO/Si is about 1550 Oe, more than one order magnitude higher than that on Si (140 Oe). The increase of H_c can be ascribed to the pinning effect imposed by the holes. The H_c and S are reduced to about 1250 Oe and 0.85 respectively, as the aspect ratio is reduced to 1.1. Fig. 2 shows the angular dependence of the switching field, H_s of Co/Pt MLs deposited on Si and AAO/Si as a function of the angle between applied field and easy axis. The magnetization reversal of Co/Pt MLs deposited on Si is dominated by domain-wall motion with negligible pinning, while the reversals of Co/Pt MLs deposited on AAO with A of 2.3 is governed by strong domain-wall pinning. The switching fields, H_s of (Co/Pt)/AAO/Si film is quite insensitive to the angular variation from the easy axis when the A is 2.3. The H_s remains constant for the angular deviation of about 45° from the easy axis. Micromagnetic simulation confirms that this kind of behavior is due to the pinning effect induced by the holes [3]. This unique switching behavior is promising to address the problem of adjacent track erasure in high density magnetic recording. With a decrease of A to about 1, H_s follows Stoner-Wohlfarth (S-W) like angular dependence showing a minimum at 45° that indi-

cates rotation-dominated reversal. The switching behavior well corresponds to the microstructure shown in Fig.1 (b) and good in agreement with the result obtained from first order reversal curve (FORC) measurement.

Conclusion

A simple approach is demonstrated to tune the switching field and magnetization reversal process of magnetic nanostructure by controlling the feature geometry. The fabricated structure can be used for high density magnetic recording. Moreover, the approach may be promising for fabricating magnetic nanostructure for practical applications and understanding of nano-scale magnetic phenomena.

Mesoscopic magnets consisting of networks of interacting ferromagnetic dots have drawn increasing attention due to its potential applications in digital computation[1]. It is well known that the magnetic switching of isolated nanomagnets can be drastically modified when they are in close proximity to each other due to the dipolar interaction field. These field-coupled magnetic elements function as the building blocks for the next generation of logic computation. Anti-dot structures (the reverse of isolated nanostructures), is another class of magnetic nanostructures in which arrays of holes are embedded into contiguous magnetic materials. They can be described as artificially engineered “defects” in an otherwise continuous film. The question of how these defects affect the macroscopic and microscopic magnetic properties of the continuous media is of great interest, and the switching mechanism during the magnetization reversal process is an important issue which is still being studied rigorously. With advance in lithographic and other control fabrication techniques, it is now possible to create regular array anti-dot structures in thin magnetic films. It has been found that the anti-dots can act as pinning centers inhibiting the movement of domain walls during magnetization reversal [2]. In this work we have systematically investigated the magneto-static interactions in square lattice ferromagnetic dots and anti-dot structures. For the dot array the inter-dot spacing (s) was varied from 100nm to 1 μm while the dot diameter was fixed at 600nm. For the anti-dot structures, the hole diameter was 500nm while the inter-hole spacing was varied from 250nm to 1 μm .

The periodic arrays of 25nm thick Ni80Fe20 dots and anti-dots were fabricated on silicon substrate using deep ultra violet lithography at 248nm exposure wavelength, electron beam deposition then followed by the lift-off process. 36 different patterns on a single 5x5mm² sample were fabricated for direct comparison of the magnetic properties. Successful lift-off was determined by the color change of the patterned film and confirmed by examination under a scanning electron microscope (SEM).

Shown in Fig.1(a) is SEM micrograph of the dot array with $s=100\text{nm}$. The corresponding SEM for dot array with $s=1\mu\text{m}$ is shown in Fig.1(b). Shown in Fig.1(c) is the SEM for the anti-dot array with $s=250\text{nm}$ and the corresponding array with $s=1.3\mu\text{m}$ is shown in Fig.1(d).

We systematically investigated the switching behavior of these structures using magneto-optical Kerr effect (MOKE) magnetometry, with magnetic field sweeping frequency of 1Hz and spot size of 20 μm . Shown in Fig 2(a-c) are the representative M-H loops for the dot array with $s=100\text{nm}$, anti-dot array with $s=250\text{nm}$ and the reference film deposited under the same process conditions. We observed marked changes in the magnetic properties due to different reversal mechanism in both the dot and anti-dot arrays compared to the continuous film. The large increase in the coercivity for the anti-dot array can be attributed to the pinning of domain walls in the vicinity of the holes.

A detailed analysis of the variation of the coercivity as a function of s is shown in Fig 2(d). As expected, for closely packed holes ($s=250\text{nm}$), the coercivity is larger compared with hole array of $s=1.3\mu\text{m}$ due to the significant increase in the pinning sites for the domain walls. These results will be supported by magnetic force microscopy and micromagnetic simulations.

We have further investigated the effect of magnetic anisotropy in anti-dot structures by engineering the holes in various lattices. Shown in Fig.3 are the four variations of the anti-dot with neigh-

boring holes positioned in a fixed pattern. The interaction between the holes significantly changes the dynamics of the reversal mechanism for the entire lattice.

Double Ferromagnetic Resonance Absorption Of Non-Saturated States In Arrays of Bi-Stable Magnetic Nanowires.

J. De La Torre Medina¹, J. Olais-Govea², A. Encinas², L. Piraux¹

1. Université Catholique de Louvain, Louvain-la-Neuve, Belgium; 2. Instituto de Física, San Luis Potosí, Mexico

In this work we present ferromagnetic resonance (FMR) measurements performed on arrays of single domain, bi-stable magnetic nanowires (NW). Arrays of CoFe NW have been grown by electrodeposition at a constant potential into the pores of a track-etched polycarbonate (PC) membrane with porosity $P = 4.5\%$ and pores diameter $d = 30$ nm. FMR measurements are carried out in the frequency swept mode by the microstrip transmission line method[1]. The transmission coefficient between 0 and 50 GHz is recorded by applying a constant magnetic field in the direction of the wires axis. These measurements are then repeated at different magnetic field values between ± 10 kOe. An important feature of low diameter high aspect ratio NW is that they present a behaviour close to that of ideal infinite monodomain cylinders with square hysteresis loops. In this way, our nanowires present a bi-stable magnetization along the wires axis, where the two equilibrium states are named here after positive $m(+)$ and negative $m(-)$ with respect to the wires easy axis[2]. However, the whole array of NW obeys a coercive field distribution, which arises from inhomogeneities such as wire length, interwire distance, misalignment of the wires, diameter dispersion, and specific microstructure of each wire[3]. An insight of the coercive field distribution is the successive reversal of the magnetization with the magnetic field of individual wires. This reversal of NW corresponds to intermediate non-saturated magnetic states containing a finite number of $m(+)$ and $m(-)$ NW as represented by the point A over the hysteresis loop of figure 1. In the resonance response of non-saturated states, groups of NW in the $m(+)$ and $m(-)$ states precess in opposite directions, which result in different resonance frequencies for each group of NW. In addition, transmission spectra have a double FMR absorption as long as both the $m(+)$ and $m(-)$ groups of NW are present. This is a consequence that wires with its magnetization oriented in opposite directions satisfy different dispersion relations. In figure 2 it is shown the recorded FMR signal at different points over the hysteresis loop and can be observed that the shape of the transmission spectra changes with the NW magnetic configuration. Indeed, at each point over the hysteresis loop the number of $m(+)$ and $m(-)$ wires depends on the value of the applied field. As can be seen in Fig. 2 the FMR signal does not changes if it is recorded during the (a) descending and (b) the ascending magnetization curves at the same absolute field value. In addition, the apparition of the double peak in the FMR signal takes place once the system goes out from saturation. In figure 2, for negative reverse fields the low frequency peak corresponds to the $m(+)$ NW while the $m(-)$ NW absorb at higher frequencies. Conversely, for positive reverse fields the FMR frequencies for the $m(\pm)$ NW are reversed. The double absorption peak corresponding to non-saturated states changes in intensity as the reverse field is increased. Particularly, since the absorption or imaginary part of the susceptibility χ is proportional to the net magnetization, the intensity of each peak is proportional to the corresponding number of $m(+)$ and $m(-)$ NW[4]. For instance, in the descending part of the cycle, corresponding to a rotation of the magnetization from the positive to the negative direction, the intensity of the $m(+)$ peak decreases while that of the $m(-)$ increases. It is worth noting that the field dependence of each peak is opposite as the reverse field goes in opposite directions. Finally, this double absorption is reproducible and provides an interesting use for novel and more functional microwave devices.

Soft magnetic properties and high frequency characteristics in FeCoSi/native-oxide multi-layer films.

H. Zuo, S. Ge, Z. Wang, Y. Xiao, D. Yao

Key Laboratory for Magnetism and Magnetic Materials of Ministry of Education, Lanzhou University, Lanzhou, China

Soft magnetic thin films used in high frequency range are required to have high electrical resistivity (ρ) to minimize eddy current loss, and a large saturation magnetization ($4\pi M_s$) and in-plane anisotropy field (H_k) to increase ferromagnetic resonance (FMR) frequency. Although metal-insulator granular films have demonstrated soft magnetic properties and high resistivities, it is only at metal volume fractions approaching percolation threshold that soft magnetic properties are obtained [1]. But the effective saturation magnetization decreases in proportion to increasing the oxide fraction. Recently, a newly introduced discontinuous metal/native-oxide multilayer structure [2], which has been exposed in situ to oxygen to form oxide surface layers, can significantly improve the soft magnetic properties and high frequency characteristics.

In this study, magnetic multilayer films $[\text{FeCoSi} (d)/\text{native-oxide}]_{50}$ consisted of magnetic FeCoSi layers and in situ oxide layers were deposited on water-cooled glass substrates by DC magnetron sputtering. The dependences of soft magnetic properties and high frequency characteristics on FeCoSi thickness d and oxidation time t were investigated using a vibrating sample magnetometer (VSM) and a shorted microstrip transmission-line perturbation method [3], respectively.

Fig. 1. shows H_c and H_k dependences on t for the films of $d = 10 \text{ \AA}$. The multilayer film shows a minimum H_c at an oxidation time of $\sim 20 \text{ s}$ where H_k is the largest. The H_c and H_k dependences on d show that H_c is almost constant and H_k increases with d . These results suggest that the appropriate thicknesses of the native-oxide layers and FeCoSi layers are very important in decreasing H_c of the multilayered films, which may be caused by the exchange coupling between the FeCoSi layers. Fig. 2 shows the easy and hard axis loops for the film of $d = 20 \text{ \AA}$. The easy axis loop is very square with $H_c = 8.4 \text{ Oe}$. Importantly, this film exhibits large H_k of 130 Oe , which gives rise to a good high frequency performance. As can be seen in Fig. 3, the FMR frequency reaches a value as high as $\sim 4.1 \text{ GHz}$, which is much higher than those of granular films.

It is concluded that the $[\text{FeCoSi} (d)/\text{native-oxide}]_{50}$ films studied here can be a better candidate for the application in GHz range.

Excellent low loss performance of microwave permeability in high resistive CoFeHfO films by thermal annealing.

K. Dong Young¹, Y. Seok Soo¹, R. B. Parvatheeswara², K. Cheol Gi², T. Migaku³

1. Department of Physics, Andong National University, Andong, South Korea; 2. School of Nano-Science and Engineering, Chungnam National University, Daejeon, South Korea; 3. Electronic Engineering, Tohoku University, Sendai, Japan

The ongoing demands for the microwave devices have stimulated the research on microwave magnetic materials with high real permeability, high ferromagnetic resonance frequency (f_r) and low losses altogether at operating frequencies up to GHz region. Recently, Ha et al. have successfully achieved the optimized composition of CoFeHfO, which possesses a high electrical resistivity ($\rho = 3570 \text{ } \Omega\text{cm}$) along with a large saturation magnetization ($4\pi M_s = 20 \text{ kG}$) and a good induced anisotropy field ($H_k = 84 \text{ Oe}$)[1-2]. However, the microwave permeability performance of the as-prepared CoFeHfO thin films is not really good as it is characterized by their poor imaginary permeability properties in the GHz range.

In this work, we investigate the thermal field annealing effect of microwave permeabilities using the optimum composition of CoFeHfO thin films. The improved high real permeability and low loss properties in the microwave frequency range are explained in terms of the enhanced magnetic properties and the microstructural change after field annealing.

The CoFeHfO thin films with $t = 220 \text{ nm}$ were deposited by reactive rf-sputtering using an $\text{Ar}+\text{O}_2$ atmosphere with a base pressure of less than $2.0 \times 10^{-7} \text{ Torr}$, onto Si(100) substrates at ambient temperature, and in a dc magnetic field of 100 Oe to induce an in-plane uniaxial anisotropy. The film composition was controllably modified by varying the aerial fraction of Hf chip on a $\text{Co}_{30}\text{Fe}_{70}$ target and the partial pressure of oxygen. The CoFeHfO films were annealed at various temperatures T_a for 1 hour under a magnetic field of 3 kOe. The microwave permeability spectra were measured using a one turn coil permeameter in the frequency range from 50 MHz to 9 GHz.

We investigated the annealing temperature dependences of the microwave permeability spectra in the frequency range from 50 MHz to 9 GHz. Figure 1 shows the real and imaginary permeability spectra of $t = 220 \text{ nm}$ sample at different annealing temperatures. The imaginary permeability (losses) shows a merged two peaks behavior in as-prepared and 100 °C annealed samples as shown in Fig.1 (a) and (b), which are located at nearly 1.5 GHz and 3 GHz frequencies, respectively. This result indicates that there are two different magnetic phases in as-prepared sample consisting of the minor and major parts of low and high induced anisotropy. Although the low anisotropy part is minor, imaginary permeability at near the corresponding ferromagnetic resonance frequency can be dominated. The minor part of the low anisotropy can degrade the overall loss behavior in the low frequency range.

However, the imaginary permeability of 150 °C annealed sample, as shown in Fig.1 (c), shows a sharp single peak behavior. The high real permeability of 185 and the negligible low losses are remained up to 2.0 GHz, and then shows a typical ferromagnetic resonance behavior with $f_r = 3.35 \text{ GHz}$. The Gilbert damping constants are obtained by directly fitting the measured permeability spectra using the solution of the LLG equation. The low damping constant ($\alpha < 0.017$) is obtained with film thickness of 220 nm. This result confirms that there is a single magnetic phase and all the magnetization spins are highly aligned to the easy axis direction. The minor part of the low anisotropy is believed to be transformed into the major part of the high anisotropy by structural relaxation during the annealing at $T_a = 150 \text{ } ^\circ\text{C}$. Since the excellent performance of microwave permeability (high real permeability and low loss) is accompanied with improved magnetic properties

for this sample. This material is very beneficial for magnetic devices operating in the microwave range. Further observation of microwave permeability spectra for samples with $T_a > 200 \text{ } ^\circ\text{C}$ results in degraded performance, as shown in Fig.1 (d)-(f), which may be caused by the formation of Co(Fe) precipitations with low induced anisotropy field and random magnetization orientation of nanograins. These results clearly demonstrate that the high resistive optimized CoFeHfO composition annealed at 150 °C exhibits superior magnetic performance apart from low Gilbert damping constant.

In recent years, amorphous thin films of soft ferromagnetic alloys have attracted considerable attention due to their soft magnetic properties and potential for technological applications. One of the most interesting phenomena observed in these materials is the magnetoimpedance (MI) effect which corresponds to the dependence of the impedance of a given magnetic material with an external magnetic field through the skin depth δ_m . In recent years, nanostructured amorphous magnetic were found to exhibit interesting magnetoimpedance properties. In particular we reported very high magnetoimpedance in a F/M/F multilayer, where F is a magnetic multilayered film and M is a non-magnetic metallic film [1]. The theory of MI for these structured samples has been developed by L. V. Panina et. al. [2], which takes into account the dimensionality and magnetic parameter of the system. The Panina's results are mainly based on the problem of the boundary conditions for a try-layer (F/M/F) and the main point of the theory is that the magnetic permeability description is a function of the magnetic field and frequency of the current. However, on the other side, L. Spinu, et. al. [3] has recently reported their results on the transverse magnetic susceptibility calculations by solving of the Landau-Lifshitz equation for a wide range of frequencies. In the present work we report our recent experimental results on the magnetization and magnetoimpedance in structured films produced by magnetron sputtering, together with the simulation data using a mix of the Panina and Spinu recipes. The samples studied were (i) FM/SiO₂/Cu/SiO₂/FM sandwiched layers (SW), where the FM layer is, in fact, a multilayered film [F(10nm) + Cu(1nm)] × 50 and F is the amorphous ferromagnetic alloy Fe_{73.5}Cu₁Nb₃Si_{13.5}B₉ [1] and (ii) a multilayer film (ML) in the form [F(10nm) + Cu(1nm)] × 50. The effect of both, the probe current frequency (in the range 10MHz - 1.8GHz) and the dimensions of the magnetic and non-magnetic layers were investigated.

The results are discussed within the frameworks of the models proposed in ref. 2 and ref. 3. Figure (a) below show the field dependence of Z of SW film at 530 MHz, where the points correspond to the experimental data, while the solid lines are the simulation results. Figure (b) below show the field dependence of Z of ML sample at 1.4 GHz, in the same way the points correspond to the experimental data while the solid lines are the simulation results. MI ratios of 220 % were obtained for this sandwich at 180MHz with a ferromagnetic and Cu layers of 2mm and 1mm, respectively, and sample length of 12mm.
